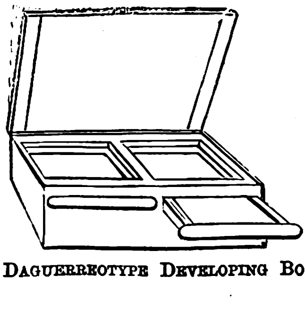
I have the pleasure to-night of introducing to your notice an old worker of the daguerreotype process, Mr. England. He has kindly consented to show the whole manipulation of the process from beginning to end, thinking it might interest what I may call a juvenile audience, for juvenile I suppose most of you are, as regards photography. Mr. England has left me to do the talking, and, therefore, I must do the best I can to explain the operations which will be gone through. We have a little box, divided into two parts, in one of which is placed iodine, and in the other is placed what is called bromide of lime—that is to say, caustic lime impregnated with bromine. You will find that, first of all, having polished it, he will place the plate over one of these apertures—over the iodine; the iodine vapour will be allowed to play upon it a certain time, and then he will shift the plate over to the bromine, and thus he bromises the silver. He will finally give it another touch of iodine vapour, and the plate will be ready for exposure. Mr. England has taken the trouble to polish these plates beforehand, since their polishing is one of the chief difficulties of the daguerreotype process. The fact is, the plates require the most elaborate polish, such as even a silversmith can scarcely give them. One of these plates he will now place over the iodine, and for two minutes allow the iodine vapour to rise and attack the silver. [Mr. England here explained that the first process is to bring the plate to a deep yellow colour, by means of the iodine, and then to place it over the bromine.] In the first place, it is necessary to be able to see the colour, so that a reflector is placed on the one side of the sensitising box, the other being open. By this artifice, the plates may be viewed, and the colour of the daguerreotype plate can be watched, till it has attained a deep yellow colour. It is passed on, to be acted on by the bromine, and that is continued until it attains a rose colour. It is a little difficult, by artificial light, to see the exact colour; this process was seldom worked by artificial light, and, therefore, one may be misled by false colour.

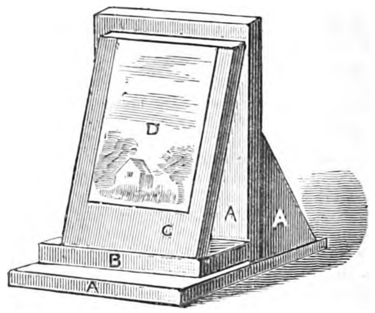


Daguerreotype Developing Box.

We propose, between us, to take a daguerreotype picture. Now, the operation of sensitising is very nearly finished. It has been treated with iodine, and then with bromine, and now it is having a final submission to iodine. The plate Mr. England prepared has now been exposed one minute; Mr. England is rather doubtful about the sensitiveness of the plate; but I am afraid, myself, it is rather over-exposed. Mr. England is now going to develop the picture, and he will do so by the use of mercury. He has here the original mercury box with which he was accustomed to manipulate. He will hang it against the wall, and light a small spirit lamp under a bowl of mercury beneath it. The mercury fumes will rise through an orifice into the box, and so on to a plate; he will watch it from time to time, until it is developed, when we will show it to you. [A copy of an engraving was here taken whilst illuminated by the electric light.]

I should like you to understand exactly what takes place in the daguerreotype plate when it is exposed and developed. On the surface of the plate we have a mixture of silver iodide and bromide, but, for simplicity's sake, I will suppose that there is simply silver iodide on it. When light acts on such a compound, the action is to split up the silver into a salt, which we call silver subiodide, and iodine is liberated, $Ag_2 I_2 = Ag_2 I + I$. The iodine is taken up by the silver plate at the back of the sensitive film. To develop the picture, mercury vapour is caused to condense on the subiodide, and leave the iodide in tact. Amongst some pictures which Mr. England has kindly brought, we have an instantaneous view of New York Harbour, taken about 25 years ago; and I doubt very much whether there are any wet-plate instantaneous picture equal to that; from age it has become a little bit tarnished, but otherwise it is a most perfect picture—the size is about 5in. by 4in. I have a transparency taken from this, and one from a negative, also in the possession of Mr. England. This last is a portrait of Daguerre, taken by himself. This is interesting as showing one of the very earliest daguerreotypes known.

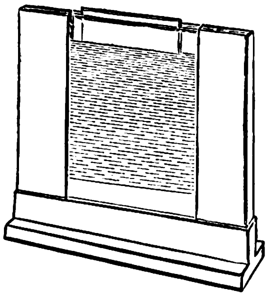
The next process is the Talbotype process. In Talbot's original process, chloride of silver formed the basis, and from that sprung our silver printing process of the present day. But the great improvement he made was by the introduction of iodide of silver. I may mention that he introduced this in January of the same year in which Daguerre introduced the daguerreotype process in France, namely, in 1839. The outline of the talbotype process is as follows:—First of all, he gave a wash of nitrate of silver to plain paper—some papers answered better than others—this he dried, and then washed over it the iodide of potassium, so forming iodide of silver, then dried the paper, and again washed over it the nitrate of silver. Such a paper was found sensitive enough to take camera pictures. But how about the development? Curiously enough, the development of the talbotype picture was discovered in an independent way by the Rev. J. B. Reade. He was practising with the solar microscope, and copying certain objects. One afternoon, having given his paper, which he had washed over with gallic acid, a short exposure, he was obliged to leave it for the night; next morning he found that his image was fully developed. That gave him the idea of the development of what was called the latent image. Talbot introduced this mode of development into the calotype process. This calotype process was the subject of litigation, and the claims of the Rev. J. B: Reade to be the discoverer of the gallic acid development was disputed. I do not wish to enter into the legal question as to who was the discoverer, my own opinion is Mr. Reade should have the credit which belongs to the discovery. From the negative pictures so produced, an unlimited number of portraits would be made by what we call the ordinary silver-printing process. A daguerreotype, on the other hand, could be only reproduced by electrotype, and Mr. England has kindly lent me such a reproduction, which can be examined afterwards. I propose, however, to show you how Talbot was able to make a picture on paper. I intended to have taken a camera picture by the process, with the aid of the electric light, but I find it will take up too much time. I have here a negative with some talbotype paper upon it, prepared as described. I will expose this to the light from a bit of magnesium wire, and then will develop it in the way in which that development was practised in the old time. I have a solution of gallic acid, which I place in a little dish, and with it will mix a solution of nitrate of silver and acetic acid. The acetic acid is meant to retard the action of the gallic acid, to prevent the reduction of the silver before the development takes place. I should say the usual method of using the paper was as follows:—A final wash of gallic acid and silver nitrate was given it, and it was then exposed while damp in the camera. This is what I intended to do, but the minutes steal on us so very rapidly, that I have been obliged to leave out the wash of gallic acid and silver, and to give it a rather longer exposure behind a negative, and thus I shall produce a positive on development. The undeveloped picture is now placed on this piece of glass, and now I proceed to develop it. The glass is placed on a stand, and the light from the lantern, after passing through orange glass, is allowed to illuminate it. The lines begin gradually to appear, and they must now be visible to you all. I continue brushing over the picture the solution of gallic acid and nitrate of silver, with acetic acid, and it becomes still more visible. A paper process is a most fascinating process, because you can dabble about, and do exactly what you like; it is not like the gelatine plates of the present day, which you have to leave to come out mechanically. With paper, if you want to bring it out a little better detail in one place there, you can dab it out; and if you want to keep it back, you can put a little water over the place. There is no process like the paper process to please an artist; not that I profess to be an artist, but, belonging to the Science and Art Department, I have a sort of art instinct, I suppose. I think you can see that the image is very fairly out now. In the old days, I dare say it wonld be considered passable for a beginner—not that I am a beginner, because I practised it in India; but it is a long time ago since I did so. So much, then, for the talbotype process. Now, what is the meaning, I would ask you, of that development? It is a curious thing that a small exposure to light should cause an image to appear. I will ask Mr. Woods to throw on the screen something which perhaps will illustrate how development arises. This morning I was in my laboratory, and I saw lying on the bench a feeble negative which I had badly developed, and which I had fixed with hyposulphite of soda. On taking it up, I found the salt had crystallised over the surface in a most beautiful manner, and I do not think I could point out to you anything which would give you a better idea of what development is than those crystals whose images you see on the screen. When you have silver precipitated from a solution by any means whatever, you have it always in a crystalline form, and as all crystals possess polarity, so crystals of silver possess polarity; and where one silver particle is deposited, there another silver particle will deposit, exactly in the same way as those crystals of hypo-sulphate of soda follow one another in regular course in those beautiful feathers. Thus, then, I look upon it as a physical development; we have a crystalline action going on during development, and nothing else. The iodide of silver is altered into sub-iodide, and this, like the pole of a magnet, attracts the precipitating silver, and from that time, where the silver is deposited, other crystals of silver are deposited. That is what I call physical development.



Stand for Developing Paper Pictures.

Now, there is another kind of development, which some call chemical development; and here I differ from some of my brethren who live on the other side of the water, in Germany, who have chosen to name as chemical development something quite different to what my idea is of chemical development. I say chemical development is only a development which is shown by a change in the colour or material of the substance acted upon, and not by a building-up process, such as we have had before us. Now, I have something which I hope will show you what I mean by this chemical development. I have here a picture, which has been printed on nitrate of uranium; I am going to use simply silver nitrate for a developer. I do not want a reducing agent in the developer in this case, because the uranic salt is reduced to the uranous state by the action of the light, and we shall have a picture formed of silver oxide, because the uranous salt will reduce the nitrate of silver to the state of oxide, and that of itself can be reduced afterwards to the state of metallic silver. This paper was exposed, just before you came to the lecture, to the electric light behind a negative. There is an outline of it now, but when I apply the silver, you will see that it springs out into vividness. It has been rather over-exposed, but this I do not mind, as I merely wish to illustrate a principle. The whole of that picture is formed by silver oxide reduced by the particles of uranium nitrate which have been acted upon by light and by nothing else. The silver oxide reduced is an exact equivalent of the uranium salt which has been altered by light. That is what I call chemical development, and I know no other meaning for the term. It is impossible, except where you have a change in a large amount of the material that is acted upon by light. I hope I have made you understand the difference between this development and the development you saw just now. The gallic acid, in the one case, reduces the silver solution to the state of metallic silver; and, in the other case, the uranous image itself reduces it to the state of silver oxide; but still that silver oxide was only equivalent to the amount that had been acted upon by light, and nothing more. I have here a wet plate prepared. I dare say most of you know what a wet plate is, though some of you may not if you only began photography when the gelatine process came in. To such, I suppose, a wet plate is as much a matter of novelty as a daguerreotype is to many who know what the collodion process is. I will ask you to bear with me, however, while I produce the picture, because I want to show you the use of the electric light. Of all the recent aids to photography, the electric light is one of the most powerful, because with it you can photograph by night or by day. In fact, in some of the advertisements I have seen it stated that they prefer to take portraits by night; I do not know why, but in a country town I saw an advertisement in which they said distinctly they preferred to take photographs by night, as it was more convenient. [An engraving was focussed on the camera screen, and the wet-plate exposed for twenty seconds.] A short exposure will do for this. Now I will try to show you the development on the screen. You see a cell there with water in it. Now I hope you will see the crystalline action taking place before you, and the image will be seen on the screen gradually coming out. A cell containing ferrous sulphate in solution, and a small quantity of glacial acetic acid, is focussed on the screen. The plate of sensitised (and now exposed) collodion is fairly transparent. After placing a piece of yellow glass in front of the lantern, the plate is immersed in the cell, and the image is seen gradually being built up.

There is another mode of development which our friends across the water have chosen to call chemical development, though I cannot agree with them, and that is the method which is called alkaline development. I dare say I could very rapidly demonstrate that to you. The *rationale* of the alkaline development is that when you have a strongly oxidising agent in the presence of an alkali and a silver compound, solid or in solution, then you have the last reduced to the metallic state. Such an oxidising agent we have in the pyrogallic acid, and the alkali generally used is ammonia. Now, this kind of reduction is evidently useless unless it can discriminate between a compound which has been acted upon by light and one which has not. When pyrogallic acid is used in order to make this discrimination, or, in other words, in order that those parts acted less on by light may alone be reduced, something more has to be added, which is usually a solution of a bromide of an alkali. This restrains the reduction inducing the change to take place in the part acted upon by light. It has been usually said that alkaline development is only available for bromide of silver, and until recently I dare say that was the case, or rather it was not the case, but it was thought to be so. I hope on a future occasion to show that iodide of silver is as amenable to alkaline development as bromide of silver, although not so rapidly; and that chloride of silver is very amenable to alkaline development, giving in fact most beautiful pictures. The plate I am going to expose now is a bromo-iodide plate. I have shown you this form of it simply because it is transparent. I have here a negative, and the sensitive plate behind it, ready prepared. Now I expose it to the light from the magnesium wire for a few seconds. I will take a cell, in which I will place some of the alkaline developing solution. The pyrogallic acid and bromide are mixed, and to which the ammonia is ready for adding. I mix a small portion of this latter with the pyrogallic acid and bromide—the bromide, remember, being for restraining purposes. I place the plate in the cell, which is seen in focus on the screen. The picture is one of Mr. England's beautiful statuary studies, and you can see the outline of the bust gradually appearing. That, I say, is another case of physical development.



Cell for Demonstrating Process of Development.

Now, I want to show you why I say it is physical development. I throw on the screen a slide, which is a picture of a young lady, seemingly cut in half, part of her figure being intense, and part not intense. This difference in intensity was produced by exposing a plate behind a negative, and then before development, coating a portion of the plate with bromide of silver. The top layer thus had no exposure whatever, and yet you see where the unexposed film is, there we have the picture very much denser than in the case where there was only the one film. This shows that here we have a case of physical development, for the image is built up from the film itself, being partly fed, as it were, from the film which had received no exposure. There is thus crystalline action taking place in the film, just as much as there was in the silver reduced from the nitrate of silver. I want you to understand why I object to the words chemical development, when we are talking about alkaline development.

There is another mode of development which is now very much in vogue, and that is with ferrous oxalate. In this case we have an organic salt of iron in the ferrous state which is capable of reducing silver bromide, iodide, and chloride, to the metallic state, whilst itself is reduced to the ferric state. That was a development which also required a restrainer. If I had had time there were several more experiments I should have gone through, but I must omit them. There is, however, another kindred developer, which I think is one of the most recent advances in photography, about which I am supposed to be lecturing. I speak of it with great tenderness, because it is my own child. I have now got an iron developer which is capable of being used without any restrainer whatever. I call it ferrous citro-oxalate; it is rather a long name, and some of my audience may not understand it, but I will tell you how it is made. You take a solution of citrate of potash, and then you add ferrous oxalate to it till no more will dissolve, the resulting compound is probably citrate of iron, but in a stronger form than is usually found, and much more energetic than that form which was recently recommended by Dr. Eder, to whom I shall have to refer more at length presently. I propose to use some of that same paper which I used just now. Its use for the purpose I have in view is a novelty. This paper can be developed by the alkaline method, or by the ferrous oxalate method, or by the ferrous citro-oxalate method; it is an excellent paper, and was prepared as I described about two years ago at the Photographic Society, before the gelatine papers came into vogue; it gives a very clear picture, and I dare say that you will also see that it gives very satisfactory negatives. I expose a piece of the paper behind a negative to the light of the magnesium wire again. The negative used in this case was kindly lent me by Mr. William Bedford. It is rather a dense one, and requires longer exposure than I should have given to a thinner negative. The exposure is now given, and on withdrawal from the frame it apparently is a perfectly blank piece of paper. [The paper was wetted and placed on the developing-stand already described, and brushed over with ferrous citro-oxalate without any bromide being added. The lantern was covered with yellow glass, and the light of the disc thrown on the paper.] You see it is beginning to develop; see how beautifully it comes out. This, I say, is a novelty in photography, for here we have an iron developer which needs no restrainer, and a paper which can be developed by an energetic developer. I think I may claim that as an advance over the calotype process.

WHERE THE HOUSE-FLY BREEDS.

As "fly time" approaches every housekeeper wonders where and how the increasing swarms of pests multiply so rapidly. The eggs, mere whitish specks to the unaided eye, are laid in little agglutinated piles in warm manure or in decomposing vegetation, especially that about our stables and barn yards. From 80 to 100 are laid at a time, and, probably, at three to four different intervals by the same fly, though on this point we have no exact data. Within twenty-fours in summer, they hatch into footless maggots, which, after rioting in filth till their tender skins seem ready to burst from repletion, become full-fed in less than a week, and descending into the earth, or sheltering under some old board, contract to brown, shining objects, rounded at both ends, and technically known as puparia. Within the darkness of this hardened skin profound changes rapidly take place, and the insect passes through the pupa to the perfect state, and finally, in about five days, the anterior end of the puparium is pushed off, and the fly quickly crawls out. At first its parts are pale and soft, and its wings are crumpled and useless, but these soon expand, and suddenly, without practice or teaching, the new fledged fly wings its way to your table to mock your displeasure—to share your repast. The length of time required from hatching to maturity varies with the season and temperature, but will not exceed ten days in midsummer, while the life of the perfect fly lasts about three weeks at the same season. As cold weather approaches propagation ceases, and the older flies perish. A few of the more vigorous females, however, retreat, to some nook or cranny, where, in a state of torpor, they survive until the ensuing season—links 'twixt the summer gone by and to come. The insect may also hibernate in the pupa state in the ground. In rooms kept continuously warm, or in more southern latitudes, the fly remains active all winter, and the palace sleeping cars bring them daily to New York from Florida during the coldest months of the year.

Cleaning Dull Gold.—A solution of 80grm. chloride of lime, 80grm. bicarbonate of soda, and 20grm. common salt in three litres distilled water, is prepared and kept in well-closed bottles. The article to be cleaned is allowed to remain some short time in this solution (which is only to be heated in the case of very obstinate dirt), then taken out, washed with spirit, and dried in sawdust.

Sunstroke.—Sunstroke is caused by excessive heat, and especially if the weather is "muggy." It is more apt to occur on the second, third, or fourth of a series of hot days, than on the first. Loss of sleep, worry, excitement, close sleeping-rooms, debility, abuse of stimulants, predispose to it. It is more apt to attack those working in the sun, and especially between the hours of eleven o'clock in the morning and four o'clock in the afternoon. On hot days wear thin clothing. Have as cool sleeping-rooms as possible. Avoid loss of sleep and all unnecessary fatigue. If working indoors and where there is artificial heat (laundries, &c.), see that the room is well ventilated. If working in the sun, wear a light hat (not black, as it absorbs the heat), straw, &c., and put inside of it, on the head, a wet cloth or a large green leaf; frequently lift the hat from the head and see that the cloth is wet. Do not check perspiration; but drink what water you need to keep it up, as perspiration prevents the body from being overheated. Have, whenever possible, an additional shade, as a thin umbrella when walking, a canvas or board cover when working in the sun. If a feeling of fatigue, dizziness, headache, or exhaustion occurs, cease work immediately, lie down in a shady and cool place, apply cold cloths to and pour cold water over head and neck. If anyone is overcome by the heat, send immediately for the nearest good physician. While waiting for the physician, give the person cool drinks of water or cold black tea, or cold coffee, if able to swallow. If the skin is hot and dry, sponge with or pour cold water over the body and limbs, and apply to the head pounded ice wrapped in a towel or other cloth. If there is no ice at hand, keep a cold cloth on the head and pour cold water on it, as well as on the body. If the person is pale, very faint, and pulse feeble, let him inhale ammonia for a few seconds, or give him a teaspoonful of aromatic spirits of ammonia in two tablespoonfuls of water with a little sugar.

SCIENTIFIC NEWS.

◆

THE death is announced of M. Antoine Breguet, at the early age of 32 years. Many visitors to the Electrical Exhibition in Paris will remember him as one of the most energetic of the directors.

The endowment of research is being gradually brought about without the assistance of the Government. In October, the Senatus Academicus of Edinburgh will proceed to elect five graduates of some Scottish University to five fellowships of £100 each, the funds for which have been supplied by an anonymous donor, who promises a repetition of the gift for one or two years at the request of the Senatus. The fellowships are intended for those who, having attained some proficiency in mathematics, physics, chemistry, biology, mental philosophy, history, or the history of literature, are desirous of prosecuting unprofessional study or research into those subjects. The holders of these fellowships must reside in Edinburgh during the winter and summer sessions, and give evidence of their progress in some way approved by the Senatus.

At the request of Mr. Philip Magnus, one of the Commissioners on Technical Instruction, Herr Reuter, director of the Fach-Schule at Iserlohn, has sent to London a collection of specimens of his pupils' work, which is on view at the offices of the City and Guilds of London Institute, Gresham College, E.C. The Fach-Schule at Iserlohn is one of the new German schools of the kind of which a large number exist in Austria, and its special object is to give practical instruction in artistic metalwork. The course lasts three years, and comprises mathematics, physics, chemistry, drawing, style, modelling in wax and clay, wood-carving, engraving, electro-plating, metal chasing, &c. The City and Guilds Institute propose to establish a school of applied art in the City, the first classes being for cabinet-makers and furniture designers.

The Yorkshire College, Leeds, is to be finished as soon as possible. The existing portion of the buildings is that devoted to textile manufactures and dyeing; but the contracts for the other portions having been signed, the works will be pushed on until the College is complete.

At the meeting of the Aëronautical Society of Great Britain last Monday, Mr. Simmons stated that it would be of great advantage if some means could be devised of measuring the pace at a high altitude. The speed of the wind was much greater above than on the earth. When he recently crossed the Channel in a balloon, part of the journey was accomplished at the rate of 130 miles an hour. The reason of the difference he attributed to the resisting power of the uneven surface of the earth. Mr. Craig read a paper which advocated the use of gas engines as a motive power for aërial voyages, to be made by flying machines worked by a screw propeller. Mr. Rogers read a paper upon "How to Sail in the Air by the Use of Wings, as Exemplified by Nature." He dealt generally with the theory of flying, and also advocated light gas-engines as a motive power. A paper was read by Mr. F. W. Brearey upon "The Action of the Pectoral Muscle in the Flight of a Bird," the study of which he commended to all investigators into the mechanical principles of flight. He argued that the power exerted by a bird in its flight had been greatly exaggerated, and that weight became a great accessory to power, an assertion he verified by the use of flying models.

The Manchester Ship Canal scheme is about to take a tangible shape, for at the recent meeting of the provisional committee, the engineers were appointed and instructed to make the necessary survey and furnish the committee with a report and an estimate of the cost.

At a recent meeting of the South Staffordshire Institute of Mining Engineers, Mr. H. Johnson read a paper on "Electricity and the Utilisation of Small Coal," which suggested a very pertinent question. It had, the author said, been stated over and over again that electricians could carry stored electricity without any appreciable loss. If that were so, he saw great advantages to be derived by both electricians and coalmasters by bringing the motors to the coal instead of taking the coal to the motors. The electricians would obtain power cheaply, and the mine-owners would get rid of their slack, which cannot now be sold at a profit. The question is, Why is not something of the kind done?

The Moore Fossils in the Museum of the Bath Literary and Scientific Institution are being classified by Mr. Etheridge, jun., and Mr. Bullen-Newton, of the British Museum, so far as the invertebrate portion is concerned; Mr. Davies has undertaken to arrange the vertebrates.

M. Girard, a young officer in the French Navy, has started for Zanzibar with the intention, if possible, of making a journey across Africa, following in the track of Stanley, and reaching the mouth of the Congo. He pays his own expenses, but is recognised by the French Minister of Public Instruction, who has given him a mission.

We have received a copy of the rules of the Postal Photographical Society, which has been established for the circulation of photographic scrap-books, and for the exchange of prints and notes upon matters connected with the practical operations of the art. Mr. H. H. Cunningham, 7, Fig-Tree-court, Temple, is the hon. sec. The annual subscription is five shillings, and each member is bound to contribute at least six prints to the scrap-books every year.

Oxygenated water, or hydrogen di-oxide (H_2O_2), has been lately attracting attention in various aspects. MM. Bert and Regnard suggested the treatment of wounds with it; and two surgeons at the Saint Louis Hospital, Paris, have thus applied it with considerable success. The substance has advantages over carbolic acid, in the absence of danger of poisoning, and of bad smell. Its action is two-fold: killing microbes (or small organisms), immediately, and furnishing a continuous supply of oxygen to the wound. Ulcers, abscesses, and the like, are advantageously treated with it. In his studies on thermo-chemistry, M. Berthelot has inquired how oxygenated water is decomposed by electric forces. Electromotive force may produce two different phenomena: (1) merely a liberation of oxygen; (2) a liberation of hydrogen and oxygen, giving water by combination. This second phenomenon only occurs if the force reaches that of a Daniell. This accords with theory. A Daniell gives a chemical reaction liberating 24·5 calories; while the decomposition of oxygenated water into H and O_2 requires 23·7 calories.

The following experiment is described in a French contemporary: If drops from a lighted candle be let fall into pure water in a vessel from a height of 6 or 8 inches, these suddenly stiffen in the form of light hemispheres. If a slightly moistened bar of soap be now introduced, the small particles are repelled by it to the sides of the vessel, where they adhere. One may bring these back, and repeat the experiment two or three times; but ere long it fails, because of the dissolved soap. It should be recommenced afresh. The repulsion is attributed to the rapid dissolution of the soap, which at first is at the surface only; when the water already contains a little soap dissolved, the dissolution occurs through the mass of the liquid.

From observations at Vienna with the Campbell-Stokes sunshine-recorder, last year, by Herr Pernter, it appears that the sun shone there 1676·3 hours, out of 4172 hours of possible shining, *i.e.*, only 37 per cent. In the winter half-year, the duration of sunshine kept pace with the height of the sun above the horizon, so that at midday there was the greatest duration; while from morning to noon there was increase of duration, and from noon to evening decrease. Not so in the summer half-year, however. The maximum was not at midday, either on an average, or in separate months; but the duration rose till 11 o'clock (the maximum), fell thereafter, and rose again till 2 o'clock, after which it gradually decreased. Further, in the summer half-year there was more sunshine in the forenoon than in the afternoon; but in the winter half-year the reverse was the case. In the winter half-year the maximum and greatest sum of cloudiness is found in the forenoon; and accordingly the forenoon sunshine has a less duration than the afternoon. The distribution of sunshine over the several months in percentage of the possible sunshine was as follows: Jan., 32·1; Feb., 21·6; March, 27·6; April 25·1; May, 56·2; June, 47·7; July, 60·1; Aug., 57·5; Sept., 39·7; Oct., 10·2; Nov., 20·9: Dec., 21·4.

If an iron or steel bar is brought into a hot solution of common salt, it becomes covered with an irregular layer of salt crystals. According to Mr. Ch. Thompson, an American, who has lately investigated the phenomena, these salt crystals adhere very firmly, and even in wire-drawing they are not stripped off. This property affords industry a welcome means of making hard iron or steel slippery. Mr. Thompson sought to elucidate the action in the process by heating in water a salt-covered wire which, by successive drawing, had been reduced from a diameter of 0·092″ to 0·067″. He found no trace of a soluble iron salt: thus chemical action is excluded, though by oxidation of iron a cement is formed, which helps the adherence of the salt. The cause is rather to be sought (Mr. Thompson thinks) in the powerful pressure in drawing, and consequent high temperature (about 237°), whereby a fusing together of the salt occurs—a kind of regelation. Experiments with other crystalline, easily fusible compounds gave similar results, while infusible or amorphous salts do not show the property of regelation.

A series of experiments have been recently made by Herr Angstrom to determine the changes of volume water undergoes when it absorbs gases of small solubility; and for each of the gases (viz., air, nitrogen, carbonic oxide, oxygen, hydrogen, and carbonic acid) he finds that the increments of volume of water are proportional to the quantities of gas absorbed. Thus, a law formerly established for carbonic acid and ammonia may be considered general. Further, Herr Angstrom constructs a table of *coefficients of dilatation by absorption*, showing for various gases (little and largely soluble) the increase of volume of water in absorbing unit volume of gas. These coefficients differ very little; which seems to prove that the dissolution of gases in liquids is a purely physical phenomena, occurring similarly in the case of so-called permanent gases, and in that of gases easily liquefiable.

A regulator of temperature not requiring the use of gas, is described by Dr. Regnard in a recent number of *La Nature*. He has employed it for some time, and found it to act with great regularity and sensitiveness. In a water bath is inserted a thermometer, having a fine platinum-wire adjustable in its tube above, while another wire enters the mercury of the bulb, being soldered in the glass. These wires are connected with a battery; the circuit being closed when the mercury covers the end of the upper wire. In the circuit is an electromagnet, and armature with long lever attached, which carries at the end a small petroleum lamp. While the current does not pass, this lamp remains under the vessel of water; but immediately the circuit is closed by the mercury the electromagnet acts, so that the lamp is removed from the vessel. Presently, the thermometer cooling, the mercury retires and breaks circuit. Thereupon the magnet loses force, and an antagonist spring pulls the lamp under the vessel again, and so on. This arrangement can be instantly regulated to any temperature one may desire.

A phenomenon repeatedly observed, of late, by Herr Schiaparelli, in the outer ring of Saturn, may (in his opinion) have an important bearing on the physical nature of the ring. The fine, hardly visible line in the ring, seen by Kater and Encke, is not symmetrical on the two sides. In the following loop it divides the outer ring almost exactly into two halves; but in the preceding loop the line (much finer and more difficult to see) is not in the middle, but nearer the outer edge, dividing the breadth as 1 : 2. These observations were made with the Merz refractor, having an 8in. objective, 10ft. focal distance, and magnification of 322 to 417. For greater certainty, Herr Schiaparelli asked Herr Meyer, in Geneva, to look at Saturn with his 10in. refractor; this was done on three separate evenings, and the non-symmetry of Encke's line exactly verified. It will be interesting to test the phenomenon at the next opposition of the planet.

In the French Academy of Medicine, a successful case of treatment of hydrophobia with pilocarpine has been lately reported by M. Dumont, a Caen hospital surgeon. But it would appear that the substance is by no means an infallible remedy; other medical men having injected it in several cases, without apparent good result, while, in still other cases, it has merely abated the violence of crises, and given a little calm—a result obtainable equally by other means.

M. Payart proposes that there should be set up, in the market-places of French provincial towns, a drinking fountain, which should be a means of useful instruction to the peasants and others around. "The Galileo fountain," he names it. The form is that of a pyramid some 13ft. high, resting on a block of stone, which measures exactly one cubic metre (recalling the metric system). One metre is divided on one face of the cube. Four stop-cocks, with plentiful flow of water, are fixed on the faces of the sub-basement. The pyramid has a lightning-rod, and at top, a wind-vane, giving the four cardinal directions. On one of the pyramid-faces is an aneroid-barometer, on the second a thermometer, on the third a clock, and on the fourth, are geographical indications of the commune, or canton; the longitude, latitude, altitude, &c. The remaining space presents the names of the inventors of the various instruments, and the dates of their inventions. (The fountain is represented in *La Nature*, July 8.)

A plentiful supply of vanadium (now largely used for aniline dyes) has been found by MM. Osmond and Witz in the scoriæ of the Creusot works, from dephosphoration of certain cast-iron. These scoriæ contain 2 per cent. of vanadic acid, and have merely to be treated with hydrochloric acid to yield a green liquor, which can be directly utilised in dyeing.

From experiments recently made by MM. Bouley and Gibier, it appears that the trichinæ in meat are killed by being submitted to a temperature of 20°, and even 15°, below zero, Centigrade.

Erratum.—"Scientific News," p. 425. Note on Hildesheim rosebush. The dimensions are given incorrectly, and should be, height about 38ft., width about 34ft. (i.e. "onze mètres," and "dix mètres.")

USEFUL AND SCIENTIFIC NOTES.

◆◆◆

An Artesian Well.—A true overflowing Artesian well, tapping the chalk formation, has just been carried out in the neighbourhood of Woking. The waterworks company, established for the supply of that district, has, for the last six months, been sinking a large shaft at West Clandon, through the London and plastic clays, and, a few days ago, the chalk water-bed was touched by it at a depth of 310ft. below ground, when the water immediately rose in the shaft, finally overflowing the surface at a height of 200ft. over sea-level. It is not often that a well sunk for over 300ft. in dry soil touches a spring strong enough to overflow the surface, and it must be a source of considerable gratification to those interested in the project to know that the anticipations of the engineers have been so completely realised.

Electric Transmission of Power.—J. J. Chrétien states that the first attempt to transmit motive power by electricity was made in 1873, at the Vienna Exposition, by H. Fontaine. In 1876, at Philadelphia, and in 1878, at Paris, the experiment was repeated. Patents were afterward taken out by Chrétien and by Felix for the application of this mode of transmission to cranes and hoisting apparatus. Important experiments upon ploughing by electricity were made at Sermaize, early in 1879, and since that period great progress has been made in pumping, pile-driving, punching, sawing, sewing, embroidering, weaving, printing, etc. He thinks that it is safe to calculate upon the transmission of 50 per cent. of the whole power. Falls and watercourses, when properly regulated, would allow the utilisation of a considerable motive force, at the same time that they favoured irrigation and diminished the probability of disastrous freshets. Tides and windmills, in spite of the intermittence of their labour, may be advantageously used through the help of accumulators. Solar heat, when transformed into electricity, seems to offer a more desirable solution than the direct application to the production of steam. Coal can be more profitably employed under large boilers, which supply powerful and well-perfected motors, at a moderate rate of consumption, than under smaller boilers, which consume from five to thirty times as much fuel per horse-power.

LETTERS TO THE EDITOR.

WELLS' COMET—MATHEMATICAL V. GRAPHICAL.

[20286.]—Cloudy weather prevented me searching for the comet until July 6th, when I at once found a strange body near the place given for that date, but differing very much in appearance from Wells' comet when I last saw it. It much resembled the nucleus of the great comet of last year, or the planet Mars slightly out of focus. I could not detect any coma or tail in the strong twilight with a 3in. o.g. On the next evening I found it had moved about the right distance for Wells' comet, but the direction of motion was slightly towards the ecliptic, instead of, as it should have been, away from it; but on the 8th and 9th it had only moved about half the former distance each day, and bent down still more towards the ecliptic. On Sunday night it was plainly visible to the naked eye when about three degrees above the horizon, since which time clouds have prevented any further observations. I append approximate positions of this body, which I have also sent to the Astronomer Royal:—

		R.A.	N.D.
July 6th	......	10h. 20m.	12° 15′
,, 7th	......	10h. 25m.	11° 25′
,, 8th	......	10h. 27m.	11° 0′
,, 9th	......	10h. 29m.	10° 35

May I be allowed to explain, in reply to your correspondent, "W. C. E." (letter 20214, p. 377), that I did not intend to convey the meaning that a method of finding a comet's orbit by projection could be superior to a mathematical investigation: the projectional method will be true to within certain limits, depending upon the skill and care of the operator, the mathematical will be perfect if the data are correct; but I conceive any errors in the latter will be embodied in the result.

In finding an orbit, three points are assumed, forming a parabolic curve that will pass through the observed places, having the sun for its focus, and the radii vector joining these points with the sun, and the distance between them shall be equal portions of the plane of the orbit. For this purpose accurate observations are necessary. Now, it will be evident that should the path be altered between the times the observations were taken, the effect upon the orbit so found would be the same as though one or more of the observations were in error, and it would be difficult to satisfy the above conditions, an approximation only being possible, and the investigator would be more likely to distrust the observations than suppose anything had gone wrong with the comet, and every after attempt to find an orbit from three observations while one or more of them was taken before the point of disturbance was reached, would result in the predicted places being in error, though every succeeding attempt would be more correct than the last, and it might be a long time before the investigator would suspect the truth. Such, I believe, has been the history of the present comet: we have had many orbits and corrections, till at last the predicted and observed places for the comet have been nearly alike.

Now, I claim for the graphical method that the cause of all this can be more easily seen, every observation when mounted for use in all future investigations, the whole forming a model, every part of which can be seen at a glance. The case stands thus, I believe; by the graphical method I have discovered that the path of the comet has been disturbed about April 23rd, and have indicated that an orbit found from observation from April 27th enwards, the places found on such an orbit before that date will not agree with the observed places of the comet. I cannot do as your correspondent suggests, and demonstrate this mathematically, but it should not be difficult for those used to such investigations to prove or disprove this proposition; but I am willing to show my apparatus as now set up, which shows this matter very clearly, to any one sufficiently interested to take the trouble to inspect it, if they will communicate with me by letter first, to arrange the time.

Since writing this letter I have obtained two more observations of the comet mentioned above:

		R.A.	N.D.
July 15th	....	10h. 42m.	9° 15′
July 16th	....	10h. 46m.	8° 45′

It is getting fainter, and its motion seems to be very irregular. **J. Lane.**

29, Wyvis-street, Bromley, E., July 16th.

ON THE CONSERVATION OF SOLAR ENERGY.

[20287.]—It is not long since Dr. Siemens laid before the scientific world his ingenious theory to account for the conservation of solar energy, which has attracted so much attention both in this country and abroad; and it is worthy of notice that, though the theory has been subjected to a considerable amount of criticism at the hands of qualified judges, it has, as yet, received no refutation. This is saying a good deal when we remember the indifferent success other hypotheses have met with, and the difference of opinion which existed, and continues to exist, among solar physicists on this deeply-interesting subject.

Our readers doubtless remember the hypothesis upon which Dr. Siemens works, and, therefore, there will be no necessity for us to dilate upon it here. Dr. Siemens sums up the fundamental conditions involved in his theory as follows:—

1. That aqueous vapour and carbon compounds are present in stellar or interplanetary space.
2. That these aqueous compounds are capable of being dissociated by radiant solar energy while in a state of extreme attenuation.
3. That these dissociated vapours are capable of being compressed into the solar photosphere by a process of interchange with an equal amount of re-associated vapours, this interchange being effected by the centrifugal action of the sun itself.

The third condition contains the most important point in the argument—the principle of fan action. To understand this most important principle it is necessary to bear in mind that, as the sun completes one revolution on its axis in 25 days, and its diameter being taken at 882,000 miles, it follows that the tangential velocity amounts to 1·25 mile per second, or to 4·41 times that of our earth. An equatorial rise of solar atmosphere is the result of this high rotative velocity, by which the sun acts mechanically upon the floating matter surrounding it in the manner of a fan, drawing it towards itself upon the solar surfaces, and projecting it outwards in a continuous disc-like stream.

It must be remembered that it is not owing to the centrifugal moment overcoming the action of gravity that the outflow takes place, for the outflowing current is entirely dependent upon the former force. As for the products of combustion rendered back into space, Dr. Siemens assumes that they would gradually change the condition of the stellar material, rendering it more and more neutral, and he even ventures to suggest the probability that solar radiation would, under these circumstances, step in to bring back the combined materials to a condition of separation by a process of dissociation carried into effect at the expense of that solar energy which is now supposed to be lost to our planetary system.

Those who have seen photographs of the eclipsed sun in 1867 and 1878 must have been struck with the resemblance between the hypothetical diagram of Dr. Siemens, and the currents in the solar atmosphere as revealed by these eclipses; they seem, in fact, practically to bear out that which Dr. Siemens theoretically assumes. It is quite certain, however, that in the years of greatest solar activity, the coincidence between Dr. Siemens' hypothesis and what is actually observed, vanishes; and on account of this reason, it was, we believe, that during the last eclipse, the analogy above noticed was not observed.

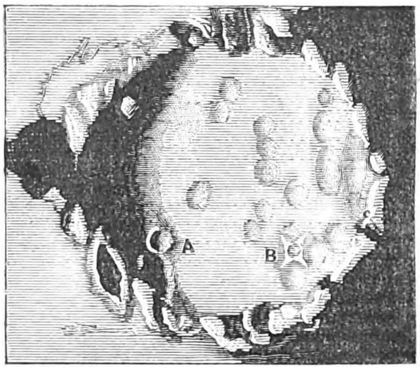
There is another factor which plays not an unimportant part in Dr. Siemens' system of solar economy, and that is shrinkage, or a gradual reduction of the sun's volume, which in some measure counterbalances the expenditure of energy produced at the expense of solar rotation, and helps to give something more than a merely limited signification to the concluding sentence of Dr. Siemens in his paper read before the Royal Society, which is well worth quoting, as it contains sentiments which, even if his highly ingenious hypothesis were rejected to-morrow, would still be re-echoed by all whose delight it is to investigate the mysteries of nature, and to whom our physical relation with the celestial bodies must ever form a lofty subject for contemplation.

"If these conditions could be substantiated," says Dr. Siemens, "we should gain the satisfaction that our solar system would no longer impress us with the idea of prodigious waste through dissipation of energy into space; but rather with that well-ordered self-sustaining action capable of perpetuating solar radiation to the remotest future."

C. H. Romanes.

PTOLEMÆUS.

[20288.]—Referring to Mr. A. S. Stanley's letter on above region (20236, p. 399), the following observations from my note book respecting the depressions on the floor thereof, and the accompanying sketch, made at the time, may be interesting.



FLOOR OF PTOLEMEUS APRIL.22ND 1866

"April 22nd, 1866. I obtained some good views of Ptolemæus, which was on the terminator, and was much struck by the irregularities of its surface. The principal crater, A, was, of course, most conspicuous. There appeared to be a wall, or low ridge, running N. of it, and also a mound to the N.W. The surface of the plain (generally as smooth as water) appeared much diversified with numerous shallow depressions (I can't call them craters), which were generally very large. It was difficult to trace out the smaller crater B, which stood between four of these hollows, appearing to be on the summit of a mound, and having four bright ridges running from it (after the style of Copernicus, but the ridges more rocky and high). I have never seen this appearance of the little crater before, always imagining that it stood on the smooth surface. This shows how careful we should be in not arriving at conclusions from a few observations. The appearance and sketch of the crater was confirmed by my brother William, who observed it some time, and drew my attention more particularly to the small mound N.W. of the principal crater. The small crater B could not be seen with a lower power than 225."

At the moment, I have an impression that this roughened appearance of the floor is by no means frequent, as I have generally seen the surface (even under very oblique light) perfectly smooth and unruffled, and it is only another of those instances which tend to strengthen a lurking idea always present in my mind of an obscuring medium on the lower levels of the moon. But further knowledge may alter these views. In any case, as the region is an interesting one, it should be well watched under different illuminations. I have, unfortunately, lacked opportunity of noting the locality with the superior means now at my disposal.

Herbert Ingall.

Champion Hill, S.E., July 14th.

SMEATON'S BLOCK.

[20289.]—In letter 20260 (p. 426) "F.R.A.S." scarcely does justice to the Smeaton block. According to the plate and description in Dr. Pearson's "Practical Astronomy," it consists of a wooden cylinder divided into two parts by an oblique section, as shown in Fig. 1—in this position it would be an *alt-azimuth*. If, however, the upper part B is turned half-round, as in Fig. 2, it becomes an *equatoreal*. A catch at *c* engages with another at *d*, securely locking them together when in position 2. Of course the angle of the sectional cut has to be so contrived that the upper surface of the combination shall be equal to the co-latitude of the place when at 2.

FIG. 1.

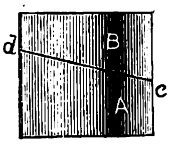


FIG. 2.

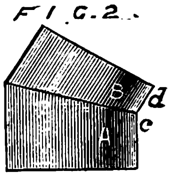


Leicester. **W. S. Franks.**

THE INDIAN CARPENTER.

[20290.]—His tools usually consist of an iron-bodied plane, about a quarter the size of an ordinary jack plane, with a piece of an old file hammered down thin for a blade; one or two chisels, these also usually made out of old files; a saw, like a very bad keyhole saw, but with the teeth made to cut the wrong way—i.e., when drawing the blade towards him: a rough fiddle-drill (this is his most useful tool, being the only one with which he can make a hole); and last, but certainly not least, an adze. Some lucky carpenters possess a screw-driver; but with the ordinary run this seems to be considered rather a luxury.

He has not the slightest respect for any of the tools he uses, and will knock out a plane-iron to make a scraper of it, or use a chisel if he wants a screw-driver, with the greatest complacency.

Once a year, however, his religion teaches him (I am speaking of Hindus) that he must go through a sort of consecration ceremony, piling all the tools in a corner of his house, and propitiating the god that presides over them with cocoa-nut and rice.

His usual position when at work is squatted on the ground, or on one end of a board on the ground, the rest of the board serving for a bench. He has an advantage in this position, as he is thus able to hold work between his toes if small, or with both feet if the piece is too large to clasp with his toe. In this our Aryan brother certainly has an enormous advantage over his English fellow-workman, as he can hold a chalk-line with his left foot and right hand, and strike it with the left hand, and use his feet in a thousand other ways, instead of calling some one to assist him.

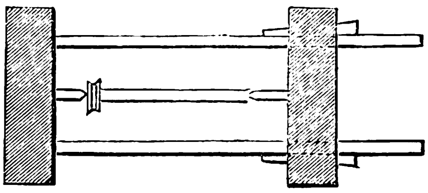
If he is made to work at an ordinary carpenter's bench, he will stand awkwardly at it until his foreman's back is turned, and then sit on it cross-legged as though he was on the floor.

Given English tools, it is usual for him to stick an extra handle to a jack-plane or a hand-saw, so as to get somebody to help him to pull it along. He attains great proficiency with the adze, and can leave work as smooth with it as from an ordinary jack-plane. Moreover, he can split a line with it quite as well as with a chisel. Hammer he has none; the reverse side of the adze doing duty instead.

Considering the tools he works with, it is perfectly marvellous how he can turn out such really good work. He usually combines cabinet-making, and will make furniture, or roof a house, or mend a bullock-cart with charming impartiality.

I am, of course, writing of the ordinary up-country carpenter, not of such as are usually to be found in Presidency towns or large works, where they will compare very favourably with English workmen.

I should like to describe his lathe. It consists of two blocks of wood, with an iron centre in each, connected together, by two pieces, about an inch square by 5ft. long. One block is fast to the connecting-pieces; the other slides on them, so as to be adjustable for different lengths of work. The following is a sort of rough sketch of the general arrangement:—The sliding-block is kept in place by wedges. His only turning-tool consists of a file-tang (I mean the end that goes in the handle) sharpened to a point. Another arrangement of lathe (save the mark!) is necessary if he wants to turn out a box, or any work that requires to be chucked. I had almost forgotten the driving-gear. However, to take an instance. Suppose he wants to make a round ruler. He will first adze the wood something like round, and then fasten it between the centres of his lathe. Having done this, he passes a cotton rope round it, anywhere about the middle, and gets a friend to pull the rope, first by one end and then the other, holding one end in each hand. This imparts a circular motion to it, and when it is moving towards him he will press the file end to it and so turn a groove at one end. Into this groove the rope is put as into a grooved pulley, and then the work is turned. When finished the piece forming the pulley is cut off, either before or after it leaves the centres. For very small work, such as pipe-stems, it is common to find a man turning the work round by means of a bow, the string of which is wrapped once or twice round the work, which bow he holds in his left hand, and the turning tool in the right; but this is only suitable for very small work. The Indian carpenter is a capital hand at copying anything which is given to him. I have recently had some excellent billiard-cues made, the butt being of a different coloured wood joined to the cue proper by what is known as a four point or star splice—not at all an easy thing to work, even with good tools. As a rule, I think, the Hindoo is not gifted with what we call a straight eye. He will deliberately nail a batten on a box, making an angle of 10 or 15 degrees with the side, and look complacently at it, wondering why he is made to pull it off again, and thinking all the time that the sahib is very hard to please.



To sum up my experience, the Hindoo carpenter is essentially lazy. He is not strong enough built to use English tools. He takes no pride in keeping his own tools in good order. For all that, if he is properly taught, he can turn out very good work indeed. As a rule, he is very sharp at picking up an idea, and the only wonder is that carpenter caste being hereditary, like many other Indian castes—once a carpenter always a carpenter—they are not better taught to begin with.

A Melting Mechanic.

THE FOREGROUND IN SKETCHING.

[20291.]—My thanks are due to J. A. Westwood Oliver (202, 275), although the question is still not entirely set at rest. I also procured Green's book, as advised by a previous correspondent, but it leaves out precisely the point at issue. Let the building, &c., be four fields off. I can sketch it thus, and delineate the four fields—i.e., the whole scene—from my feet, and put in at the latter carefully-drawn, detailed leafage; and so far all would be in some sense correct. But, practically, I don't want to draw the four fields, but to take such extent only as the natural sight comprehends when viewing the scene—i.e., what is included within an angle of about 60° in all directions—and this will not embrace the ground near my feet, nor, let us say, any part of the two near fields. I am not sure, but I think such scene *photographed* would be true to nature; but such photo. would give, I imagine, no detail of foreground, but the foreground would, by its composition and structure, have the appearance of being, as it really is, two fields distant from the eye, and the building would also appear at its true distance—viz., *four* fields distant.

The oft-advised rule of art is, I believe, "Draw what you see"; and in a sketch, "Take just what the eye easily embraces," or "Hold up at arm's-length the sketching-block, and include what it covers." But it does not in the case supposed cover the near ground, nor does the eye see it. Ought it to be drawn?

Country Sketcher.

A BLIND MAN'S VISION.

[20292.]—Under the head "Useful and Scientific Notes"—"A Blind Man's Vision," you have published (p. 398, July 7th) a note, the scientific importance of which I do not very well understand, as it gives no explanation of the related phenomena. My chromogerminator and vegetator, which you would not even mention, are, in my opinion, vastly more scientific, and, at the same time, useful. Indeed, the French Académie des Sciences is of my opinion in this respect, and was greatly interested by the presentation made by the *savant* Paul Bert, the late Minister of Public Instruction, of vegetables cultivated in lanterns glazed with coloured glass, which produced most startling phenomena. The learned body was also very much interested by M. Poey's communications of General Pleasanton's experiments in the application of violet-coloured light on the growth of animals.

But since M. Plateau's case has attracted your attention, I venture to write the following lines, probably useless, on the subject, which, in my humble opinion, will present a very scientific and useful interest.

Having read in a French paper a few words about M. Plateau's paper, which did not contain the details, I wrote to this learned gentleman a rather long letter on the subject. It being said that M. Plateau attributed his blindness to his having observed the sun with naked eyes, and that he advised astronomers and amateurs not to imitate him, that he thought that his retina had been paralysed by the action of the sun's rays, &c., &c., I informed the learned *professeur émérite* that I also frequently looked at the sun with unprotected eyes, and that then I could realise its sphericity, see the spots, discern their nucleus, their penumbra, the faculæ, &c.; that I could perceive what Father Secchi called the willow leaves, &c.; that after such observations my eyes were deeply insolated for a long time. That having carefully studied all the physico-physiological phenomena thereby produced, and the conditions of their gradual disappearance, I had sought for and happily found the means to de-insolate the eyes in less than ten minutes, by a process which, ten years ago, I communicated to the Academie des Sciences, where no attention was paid to it. I supposed that, had he been in possession of this means, most probably he would not have lost his sight. I persist in thinking that this discovery has a great value, the more so as it has just led me to another still more important, of which I will say a few words presently.

M. Plateau, still experiencing some effects of light, and precisely those naturally produced on sound eyes by insolation and complementary colours, I am of opinion that his retina is not entirely paralysed (if at all), else he would not feel any light sensation. Very likely his blindness is caused by some matter which prevents the passage of light from the cornea to the retina, it being interposed in the vitreous humour contained in the hyaloid or choroid membrane. I informed M. Plateau of a case of cataract completely cured by electricity. I mentioned my unsuccessful experiment upon the eyes of a French gentleman who, in Mexico, had become blind quite suddenly in an excess of anger, which caused an instantaneous amaurosis. Electricity produced some brightness (*clarté*) in the eyes, sufficient to enable him to distinguish, by their respective and differing *colour*, the positive from the negative poles, but sight could not be revived; which proved that, in this case, the retina was not absolutely paralysed, but that the optic nerve was either paralysed or ruptured. I called his attention to the different sorts of amaurosis, gradual or sudden, partial or total, caused by atrophy or by hypertrophy, in which cases the colours which first become insensible are reversed, &c., and the cause thereof. I advised him to try a peculiar application of electricity, &c. The learned gentleman had the kindness to acknowledge the receipt of my letter, and to send me thanks, but said no more.

Since this, a new fact occurred to me after my observation of the eclipse of the 17th May last. This brought the, to me, great discovery of the real cause of M. Plateau's blindness, and, at the same time, of the powerful action of the magnet upon the circulating fluids and liquids of the human body, which action is most likely to produce the cure of hitherto incurable diseases of the eyes. The action of the magnet on the eyes is wonderful; no doubt, that when known it will become a great therapeutic agent. I am now writing a paper to be sent to the Académie des Sciences on the subject. I might send you a copy of it. I would write it in English if it had any chance of being inserted in the "E. M.," but will not take the trouble if it has none.

Ch. Rabache.

Morchain, Somme, France.

MR. SCOTT-RUSSELL AND THE VIENNA DOME.

[20293.]—The way in which the subject of the expansion or non-expansion of Scott-Russell's structure has been handled by your correspondents, puts me in mind of the story of a certain king asserting that a glass globe full of water weighed the same with or without fish in it; all his courtiers demonstrated how this happened, and proved him to be right—which he wasn't.

I don't hesitate to answer for Scott-Russell that he never by anything he may have said about his dome, or any other iron structure, intended to imply the least particle of doubt of the fact that railway metals expanded on increase of temperature when they were laid as a track; or that they could be linked in, as it is termed, without "expansion," being left between the ends of the rails. Railway engineers have not now to learn the truth of this.

"J. J. A.," another correspondent, will have it that it is easy to understand (?), in the case of a "dome," that the expansion would rather be upwards (!); and Mr. Oliver winds up his views with the belief that "bending" (!!) may possibly account for what is supposed to happen, or rather *not to happen.*

As this latter gentleman defers the discussion of the question to some future opportunity (if ever), it will be well for him, and all who may be drawn into the consideration of this subject, to start with at least one common *fact*, and that is, that the so-called "ring" is *not a continuous length* (one piece) of metal, which, an' it were, would itself have put an end to all opposition and discussion, by expanding in the direction of its length, and consequently in the dimension of its diameter also, on being heated.

The "ring" was built up of plates in sections, in Belgium; and after arriving on the ground, was put together in the form of an endless girder of about 5ft. deep (as near as I can remember), and with heading joints enough, in all conscience, to allow of *local expansion or contraction*, without interfering with the total length of it. This sort of compensated expansion happens in other and straight girders, according to construction, and is *nothing new, after all*, to practical men.

Let me add, for the information of readers who may not be acquainted with the particular construction of the roof in question, that the "ring" is a made-up band of iron plates on edge, acting as a foot to the thrusts of straight iron rafters; or the "ring" may be considered as an endless tie for a series of "principals," the upper ends of whose rafters butt against another much smaller ring at a higher elevation, and upon which an observatory was constructed. The spaces between the rafters are filled in with deeply-indented panel work. The ring was put together on the ground just inside a series of wooden stagings, and *lifted* up as a whole by large long screws made for the purpose at several lifts, and when at the proper height, was held until the iron supports were built under it.

Now that the name of Scott-Russell has come up as it has, Mr. Editor, I am very desirous of "improving the occasion" in another way. I wish to beg that some one of "ours" who may, perhaps, know the story well, will tell us how this giant intelligence — this constructor of colossal ships, and other engineering works of cyclopean dimensions, years ago raised the nearly defunct Society of Arts to healthy life; and, by his own strong will and almost unaided effort, got together that little exhibit of wares in John-street, Adelphi, in 1849, which, undoubtedly, was the parent of the great "Exposition in Hyde-park in 1851," and, consequently, the direct ancestor of all the rest of those other expositions that followed fast and follow faster.

There may happen one of the associates of this great man among "ours," or some one, perhaps, of his immediate assistants of that day, who can tell us what Scott-Russell did in the week before the opening of the "conversazione," as it was modestly called, when, because of the little or no response of "home manufacturers," to the invitation of the "Society" to send in exhibits, absolute failure stared in the face of all concerned in the venture. Can we not learn the precise circumstance of how Scott-Russell, with two helpers—(all honour to them, and their names are world-renowned too), it being too late to work up the country people—started out in London in four-wheel cabs for three whole days, from early morn till late at night, almost *demanding* exhibits; and by personal "entreaty"—(yes! that's the word he used) Scott-Russell and his two friends induced, among others, London *tradesmen who were not even manufacturers* to send, as well as to allow them to fill their cabs many times a day with, goods and exhibitable things from among their wares.

Not only was enough obtained in this way to avoid all appearance of failure, but as much was actually got together as there was space for in the exhibition rooms to exhibit comfortably, and success crowned this first desperate attempt at exhibition.

One more item, Mr. Editor, if you please. Some of your readers may have been visitors at the show I have just referred to, and may probably remember that just before its close a little green baize-covered table, having a roll of paper set out to receive signatures, appeared just where a lecturer would now stand to address an audience. I well remember the paper remaining a whole day with something like a dozen names appended; and *this* was the petition of the Society of Arts and the public to H.R.H. the Prince Consort that he would graciously take the lead in the promotion of a "World's Exhibition," proposed to be held somewhere in London two years after date, or 1851, declaring that such an exhibition was necessary and *rendered possible in consequence of the very flattering way in which exhibitors had come forward,* and the public had met them, at this John-street Exhibition.

"Leviathan" was an appropriate name for the big ship, and the iron roof at Vienna is the largest work of its kind in the world. But, to my mind, the biggest thing Scott-Russell ever did, and that which has had the most influence on mankind at large, was the infusion of new life into the Society of Arts, and afterwards making a success of that little show A.D. 1849, and thereupon moving for the larger one in Hyde Park in 1851.

Now! Who of "ours" can give us details of the above interesting incident in Scott-Russell's life? **J. W. W—s.**

THE JUBILEE OF THE LEICESTER AND SWANNINGTON RAILWAY.

[20294.]—ON Monday last (17th inst.) the town of Leicester enjoyed the advantages of railway communication for a period of fifty years.

Upon the 17th of July, 1832, the Leicester and Swannington Railway (which now forms the oldest part of the Midland system) was opened; and although it does not appear that any festivities will take place upon the fiftieth anniversary, still an event of such interest both to the town and the engineering world should not be allowed to pass without, at least, some mention.

Clement E. Stretton.

Saxe-Coburg-street, Leicester.

RAILWAY SIGNALS—TO H. STOOKE.

[20295.]—WOULD not the signals be safer if the arm were weighted at one end, so that if the rod connecting it with the lever and weight at bottom of post broke, the arm would keep at danger? Also, the coloured specs to be fastened to the arm instead of worked lower down by the rod, as they frequently are? I think the arms, when lowered down to 85° are more likely to work to "danger"—that is, to go to the horizontal position—than when lowered to 45°, as the lower the arm is the more impetus it has to fly up to that position when required. I see on most railways the "home" and "starting" signals are worked clear to 45°, while the "distant" nearly any position between about 25° and 90°. Would it be any practical use to coat the arms with "luminous paint"? **G.**

[20296.]—MR. STOOKE'S gentle comment upon the present state of signals is very true; but it is correspondingly true that the progress of improvement is proportional to the intensity of man's necessity. At last it is found essential that these signals be governed by a more rigid rule than has hitherto been observed, and steps are being taken to bring them to the present state of scientific accuracy. Now it is evident that it is essential for these signal-arms to distinctly indicate danger, clear, and no signal, then why not divide the quadrant into three distinct divisions of 30° each, say, from zero to 30° danger, from 30° to 60° clear, from 60° to 90° no signal. This we venture to think would be a more uniform division than the one before us, which has called forth these remarks. And in all cases we should advise the degree being opposite the centre of the arm. As for the arm being above the horizontal, this should be avoided, and the movement so constructed that it cannot rise above zero. The mechanism which regulates the arm ought to be so arranged that the arm will fall from zero to 15° then from 15° to 45°, and next from 45° to 75°, thus clearly indicating each signal, and avoiding all confusion. **A. Manock.**

[20297.]—IN the ENGLISH MECHANIC, October 21st, 1881 (letter 19338), there is an account of General Hutchinson's report upon the Bow-road accident, of which the principal cause was the negligence of the signalman in not putting on the signals. Now, I had some time previously stated that neglected signals might be avoided, and at the Exhibition of Life-Saving Appliances there are many inventions for railway purposes. I have placed a working model before the public as per advertisement, which appeared in your columns last week. In the adaptation of my apparatus I do not interfere with the locking arrangements in the signal-box or the block-system.

The signalman takes "off" the signal in the usual way, and can place it back to "danger" with his locking lever at any moment; but should he neglect, no ill consequences can ensue, as the train in passing the apparatus has put "on" the signal notwithstanding the "off" position of the signal lever in the locking frame; thus, every train sets its own "danger signal" for any length of time until taken "off" by lever in box. Electric contact apparatus can be connected to give notice to signalmen of an approaching train, or an electric catch could keep the signal in the danger position by preventing the mechanism being actuated *from* the danger position by the signalman himself until the train had passed a certain section of the line.

It is mechanical in construction, and its action could be horizontal, vertical, or segmental, as most convenient; and its release could be caused by an arm, treadle, or other projection being acted upon by an arrangement to the engine or the pressure of the wheel.

The invention is patented in this and other countries, and is approved by practical railway men, to whom it is quite a new idea for signals.

John Harrisson (Inventor),

July 11th. 185, Well-street, Hackney, E.

ON THE ABERRATION OF A PARABOLIC SPECULUM.

[20298.]—MR. WASSELL'S interesting letter sets at rest all doubts respecting the true rule for calculating central error. I see I have mistaken Dr. Hastings' meaning about the difficulty of finding the point C. He is alluding to the focus, whereas I took it as referring to the radiant point. Mr. Wassell says there is great difficulty in finding the focus of the central rays, on account of their small angular intersection. Dr. Hastings evidently refers to the same thing. I am glad, however, that my mistake has caused Mr. Wassell to investigate the effect of a slight variation in the position of the pinhole. He has most conclusively shown that no extreme care is needed in adjusting the place of the lamp.

On referring to my original formula, I find it gives the error due to any position of the radiant point. Neglecting powers of y greater than the square, it is;—

$$\frac{fd}{d-f} + \frac{y^2}{2} \cdot \frac{1}{d-f}.$$

In which d is the distance of the pinhole from the mirror, and f the focus for parallel rays. The first part is the conjugate focal length; and the second, the increase in it, due to aberration from aperture. Now, if $d = 2f$, the aberration is evidently $y^2/2f$; but if $d = 3f$, then it is $y^2/4f$, or the same quantity as Draper gives. The focal length in this case is shortened to $f \times {}^3/_2$.

We may now lay aside theory; and as Mr. Wassell has been furnished with so many excellent specula, he will doubtless have much interesting matter in store for us. I can assure him that it is a pleasure to me to find that my investigations have been of some slight service in the intricate and delicate operation of parabolising a speculum.

Before closing this letter, I will add a few lines containing the opinion of "Prismatique" on this matter. He says:—"With regard to the aberration of a mirror, the difficulty of finding C is equal, to my mind, in the case of both o.g. and mirror: it is certainly a variable point. Thus, if I test an o.g. on luminous point, and a pencil of rays is long in centre of annular out-of-focus disc, I feel sure that when figured to bring all rays to a point, A is not brought to B, or *vice versâ*; but a point between the points A and B is produced. (A and B are the central and marginal foci). Suppose this has caused a zonal error of very slight measure, but sufficient to produce a diffraction ring; when the glass is again figured for this—that a fresh position for C is produced—I am certain.

"As the conditions are exactly the same, to produce good definition in o.g.'s and mirrors, as to ray paths, I think you will agree with me, that even if the zone test proves practically successful—and I feel sure it will—final testing on a star, with all the surface at once, will not—in fact, cannot be, surpassed. If the appearances are understood, sections of the cone of rays in a diagram will certainly help the amateur."

July 10th. **Orderic Vital.**

SMALL DYNAMO-MACHINES—MOTOR FOR TRICYCLE.

[20299.]—I BEG to inform Mr. A. H. Allen, Sheffield, that I make small dynamos as I described on page 354, No. 900, for laboratory use, from the power of one cell upwards. Such a machine as I described is no infringement on any patent. The most I have done with the I armature is to heat to redness 12in. of platinum wire. Of course this is on the "Shunt System," and this is the only kind that is of any use for experimental purposes, as it will work bells, motors, induction coils, and perform every experiment equal to an equivalent number of Bunsen or Grove cells. A machine on the circuit system will not operate on instruments which have an interrupted circuit, such as bells, motors, and induction coils, and to meet the wants I make them on the "Shunt" principle, unless ordered otherwise. We have had some capital notes on dynamo-machines, but it is like throwing pearls to swine. I make this remark on account of over 200 letters which I have received, asking questions concerning my small dynamo—whether it would light 1, 2, 4, 6, 10, and 20 Swan lamps of 10 and 20-candle power, or an arc light of 1,000-candle power. If our valuable correspondent, "E." and others would send sizes, &c., of parts of dynamos instead of these mathematical calculations (which are only understood by one in a thousand) it would be a great boon conferred on us. We have had too many problems. We want something between this and those melancholy replies.

I consider a machine to light one incandescent lamp of 16-candle power is an instrument of torture. I have never recommended them. What possible use can they be to work by hand-power, when one lamp takes about an eighth of a horse-power; and a man has to exert his *full strength* to get a glimmer. The game is not worth the *candle.*

The small dynamo I described is equal to one cell; will do for depositing, charging electro-magnets, &c. The wheel-gearing is for multiplying the speed; although the mitre-wheels are of equal diameters, the flywheel revolves two to one of the handle. The commutator is made of one piece of brass tubing (not of four pieces).

Motor.—Some months since I mentioned I was making one for tricycle; it was made, was very powerful with two Bunsen cells; sure eight cells would do the work when I was constructing it. I knew it would do as a dynamo. Having tried by means of a gut from a foot-lathe flywheel, I heated a foot of wire; so pleased with it, use it as a dynamo; have no time to apply it to a tricycle; am too busy with dynamos. This motor *replaces* several Bunsen cells, and is now my only *source* of obtaining a *quantity* current.

Some person has written to me stating that my description of the small dynamo is an advertisement. But, as I have sent a full description of it, I am exempt, according to "O. S." Perhaps Messrs. Patrick and Son (page 405, last week) will send a full description of their machine; they have stated all it will do. Now, if they will do as I request, their letter will not be a gratis advertisement. **George Tolman.**

[20300.]—I SHOULD be pleased to read a letter from anyone who has fitted up one of the small dynamo machines referred to in letter 20253. I am sorry to have to doubt "Patrick"; but a machine to produce as much current as would require 40 quart Bunsens to be driven by one man is altogether past my belief. I can only repeat what I have said before—that there is at present no machine to be driven by hand capable of really good work. Of course I am open to conviction, and nothing would please me more than to see such a machine, driven by one man, giving a current equal to 40 quart Bunsens. I don't want a statement as to what a machine should do; but I want a statement from someone who has made such a machine, and has been able singly to light and keep lit for half an hour 4 Swan 10-candle lamps.

W. J. Lancaster.

A NEW FORM OF STEAM-ENGINE.

[20301.]—IN reply to George E. Wood (letter 20270), I should be glad to be informed in what manner the 20 per cent. gain is realised, in favour of the "*new form of engine*," seeing that it is admitted to be = to 42 H.P., and the engine against which it has been tested is only 36·5 H.P., both theoretical calculations, showing one to be by 20 per cent. the larger engine, according to his own figures the actual H.P.'s, as tested by the brake, appear to be in the same proportion as the theoretical calculations. *Where, then, is the gain of 20 per cent.?*

The arrangement appears to be so absurd that it is difficult to understand how it could have been entertained, except as a curiosity, seeing that it has double the number of working parts, and the cylinder, weighing 9 cwt., working upon guides, adds a serious amount of friction which does not exist in a stationary cylinder; and the advantage claimed for the cranks being placed at an angle is not realised, as their throw is only one-half of the ordinary type of engine, consequently at the full point only half the power of engine is exerted; therefore, it cannot be credited with the advantages of a double cylinder-engine. Why the foundations should be of less strength is also difficult to see. **H. A.**

THE VIOLIN MUTED.

[20302.]—I CANNOT admit the idea that a light mute placed on the bridge of a violin has a greater effect than a heavy mute, p. 405. It is not the weight, but the pressure, that makes the sound weaker. At first thought, most persons would say the vibration was less or smaller, but the oscillation, or to-and-fro movement, in the middle of the string remains the same either with or without a mute. A wood mute is as effective as brass, so that mere weight (if we could get it without pressure) would not mute the violin. It is known that the slightest pressure on the belly, away from the soundpost, reduces the tone. Yet the bass bar (a strip of wood under the left leg of bridge) is put there to increase the resonant qualities of the soundboard, and is a remarkable instance of adding weight without pressure. Adam was not more surprised at the first sunrise than I when I heard a muted violin. It seems easy to conclude that if the violin is muted by pressure on the bridge that, *per contra*, making the pressure less must increase the sound. Here a great problem stares us in the face, how to produce this pressure without weight, or weight without pressure, for tension represents both weight and pressure; that is, it is dependent on them either in the present application of them, as in a strained drum, or in the natural condition of a piece of wood, which wood possesses tension without the addition of extra weight. It seems easy to suppose that if we fine down the wood we shall ease the pressure. True, but we lose the normal weight which produces the tension. I presume that the Berliner violin is constructed to remove the pressure of the downbearing of the strings without lessening the inherent tension of the body. How do we know what tension or capacity for producing sound there is in a piece of wood? A long piece of wood has more weight and less tension than a short piece, and a thick piece than a thin piece; size has to be considered. And to produce the best result the soundboard should be short and thick enough in the treble, or long and thin enough in the bass, to return the vibration of the strings. We fine down the wood to make it return the motion or pulsations of the string, and add weight to the sides and back to make up for the lost tension; but I think that the sides should be free (this is partly remedied by the *f* holes in the violin), and the lost tension applied to the soundboard itself (this is partly represented by adding the back to belly by sound-post). Now, if Mr. Berliner can reduce the pressure and yet simulate tension (this cannot be done with a chin-rest) in various parts of soundboard to suit the different strings, it will be a grand thing. Now, will he do me a favour, and try, instead of putting off the weight of metal resonator through the breast at the treble end under the finger-board, will he use the *f* holes as means of communication between back and resonator, leaving the breast free and untouched? Less weight would be required with greater power of control, and, I think, an additional tension. **Fiddler.**

THE BERLINER VIOLIN.

[20303.]—Mr. Schucht, page 405, says of the Berliner improver that he believes it to lower the value of any violin it is put on. This is so sweeping a conclusion, that I think it ought not to pass unchallenged.

I described in a former number of the "E. M." a simple way in which anybody might try the effect of this adaptation on his violin; and I then and now maintain that whilst it does not benefit the tone of a really good instrument, it vastly improves the tone of a cheap violin. E. E. Fennessy.

LANTERN-SLIDE OUTLINES.

[20304.]—An easy method: Coat a glass with negative photo. varnish, the glass to be cold; it will dry quickly. When set, lay on the glass a bit of carbon-paper the size of the glass; then lay on the carbon-paper, your print, drawing, or copy, and go over the outlines with a smooth, fine-pointed, bone tracer; be particular not to bear on too hard, or the varnish will leave the plate. Outlines may be traced on the clear glass in this manner. Carbon-paper must be of the fatty kind. I have tried both methods and succeeded.

W. H. Gardner.

FORECAST AND PERIODICITY OF STORMS.

[20305.]—The solar system obeys the law of periodicity. The earth obeys the law in its annual and diurnal revolution. The motions of the moon are periodical. The ocean tides are periodical. Is the ocean tide gathered up at new moon? Then the more mobile and vapour-laden air is proportionately displaced; and it may be that an atmospheric tide exists governed by similar laws. When the moon is at quadrature, or ninety degrees from the sun, both of these bodies are exerting their forces at that angle, neap tides ensue, and where the water flows out the atmosphere flows in, thus the atmosphere is subject to periodical disturbance. The Polar current is influenced by the same causes in some degree. Similarly, the Gulf Stream is at times retarded, and at other times its flow is accelerated. The Gulf Stream leaves our coasts and imparts its warmth to us. The Polar current engages with it, and they modify each other. The air current most prevalent with us coincides with the direction of the Gulf Stream. This air current obeys the combined forces of sun, moon, and tide.

Depressions float over us in this air current, sometimes exerting little force, at other times the depressions are in rapid motion. As the storm period approaches us small depressions are borne up from the Atlantic ocean, and oftentimes they pass to the North West of us, but gradually the current of air in which they travel is deflected, so that the largest depressions pass over these islands. The weather in the British islands oscillates about a certain average standard; hence the old saying, "be it dry or be it wet, the weather will always pay its debt." Here, too, the natural law of compensation, or balancing, comes into play; thus a series of rainy years is balanced by brighter years. Here let me call attention to article, "Saltness of the Sea," p. 395, English Mechanic, No. 902. "The tables show that the neighbourhood of the American coast gave waters very fresh and icy, which are suddenly replaced by hot and very salt waters when the Gulf Stream is entered; then as the route of steam-packets goes along the great bank of Newfoundland, one passes from the current to find anew the fresh and cold waters; these being succeeded by the average water in which navigation continues to European seas. Again, M. Bouquet de la Grye says—"We find under the tropic of Cancer a depression of two metres, and near the United States a considerable surelevation in some cases exceeding four metres. Thus, we have a difference of level of six metres between two points of the same ocean." Now, if we grant the above statements to be true, and I know not how to controvert them, it is evident that a vast salt water-trough, as it may be called, passes from the northern tropic to the frigid zone. This warm salt stream subject to a glowing sun heat during our summer solstice, may evolve large quantities of electricity to be carried by the cloud currents in an eastward direction. And may not the moon, by her power of attraction, deflect both Gulf Stream and air current at the periods of new and full moon? And as cause precedes effect, may not the attraction of the moon retard the flow of air current as well as cause spring tides? In such a case, would not the air-current rush onwards again as the cause of retardation was removed, which would be as the moon neared quadrature? The severe gale of the 14th of October, 1881, when pressure of 53lb. on the square inch was registered (vide English Mechanic, No. 902, p. 413) came seven days after full moon. The gale on the 26th and 27th November, following at an interval of 43 days, or what I term a double period, came five days after new moon. The depression which reached its minimum, April 13th, 1882, came five days before new moon. The depression, April 29th, sweeping along with a velocity of 50 miles per hour, and a pressure of 49½lb. per square foot, came four days before full moon. The depression, May 25th, came when the moon was at quadrature and apogee. The depression of the 9th ult., came within one day of moon's quadrature. The depression of 7th inst. came one day before quadrature. A series of depressions, bringing wind and rain, will begin to move after new moon on the 15th inst., and arrive as the moon nears the quarter. Other depressions will come to us attended by rain a few days before new moon on 10th proximo, and again a few days previous to full moon, 28th proximo; but probably August will be a better harvest month than August, 1881.

I beg to thank my kind advisers, who practically say "Don't say anything about the weather, for you don't know." W. H. Gardner.

GAS-ENGINES—EXPLOSIVES.

[20306.]—Referring to letter 20274, where Mr. "Ll.B.A." makes some calculations showing the power of gas-engines and of chloride of nitrogen, he considers this subject of great interest; and truly it is so, not only in respect of the calculations connected therewith, but also with respect to the anomaly which I shall show appears to exist in the behaviour of the said chloride. I said, in letter 20221, that I thought it likely that some form of nitrogen would become "the power of the future." In this anomaly (I consider) the germ of that power exists, and I now proceed more fully to explain.

Now, as a source of power, heat is universally considered, either directly or indirectly, as the agent, arising from the chemical combination of two or more elementary bodies; but in the case of power arising from the explosion of chloride of nitrogen, instead of combination—decomposition, resulting in the reproduction of the elements N and Cl takes place; whereas, in the ordinary way, if it is desired to produce an elementary body (or unburn a compound), it is found necessary that a chemical equivalent of some other element should be burned; or otherwise, this regeneration is largely effected in nature by the action of the sun.

Now, this property, which seems to belong to nitrogen exclusively (or perhaps to chlorine in some degree), namely, regeneration, holds out the prospect of a perpetual power, without expenditure of fuel, seeing that combination and decomposition both take place *so far as appears* without that expenditure. Imagine that by applying a match to some water, that it immediately expanded into its component gases—hydrogen and oxygen, this would be a similar case of regeneration, inexpensively. Not but that the affinity of hydrogen and oxygen is greater than NCl_3, but yet the affinity of this chloride must be very considerable, seeing that a pressure of 200 atmospheres is required for the liquefaction of nitrogen, and that also chlorine requires great pressure for its liquefaction.

There are two causes which give rise to explosions, and gunpowder may be taken as a type of the joint action of these causes. When a highly-combustible element is intimately mixed with the element required to complete the combustion, a certain degree of quick burning or explosion ensues; but when nitrogen enters into the composition, the explosion is very much intensified, and thus there results a combination and a decomposition explosion united.

It may be observed that nitrogen enters very generally into the composition of explosives. Witness gunpowder, gun-cotton, and allied vegetable bodies acted on by nitric acid; and also the metallic fulminates; and nitro-glycerine includes animal substances.

But let us look a little closer into the behaviour of the chloride of nitrogen. In the process of its formation, where has the latent heat of the absorbed gas gone to? Then, again, in exploding, where has the latent heat of the two gases been obtained from so suddenly? Surely, not from the containing vessel. If we can imagine electricity to be only another form of heat, and "the ether" another form, and suppose that nature really does abhor a vacuum, and that "ether" penetrates all bodies as does the magnetic fluid, then we may possibly account for the great additional space occupied by the original body.

I will now leave this theory to be taken for what it is worth, believing that the exposition I have made of the anomaly referred to will furnish materials for the speculations and investigations of many other correspondents, and designs for the practical application as a motive power.

With respect to the power developed by the explosion of chloride of nitrogen, and calculating only on the ½-volume of nitrogen at 200 atmospheres, this equals 200 × 15 × 144, or an initial pressure on the square foot of 432,000lb., or that number of foot-pounds for 153 grammes of NCl_3, and giving the chlorine gas credit for nothing. This is enough to show that the proper average pressure would be something very considerable, and would answer to a result such as might be expected.

Barry-road, S.E. J. H. Huxley.

COLOUR—PHILOSOPHER'S WHITE, &c.

[20307.]—Having myself been "put down" in the "E. M." (No. 886, p. 79), for venturing to doubt the correctness of the modern blue-and-yellow-making-white theory—and doubting still—I am very pleased to see Mr. Calton reopening the subject, and am anxious to see what the critics have to reply to his arguments. I hope they will be replied to in a more temperate tone than last year, when one infallible presumed to dispose of the whole matter by saying that the whole question had been "thrashed out."

They may be sure that I, and Mr. Calton, too, have but one object in view—the truth; so I will supplement his remarks by a few of my own.

Tyndall's experiments in proof of the modern theory are described in his "Lectures on Light," delivered in America. I will therefore take him as the exponent of the theory, and Longman's edition (1873) of the lectures as a text-book. His popular lecture experiment, of taking two tanks of coloured liquids, one blue and the other yellow, with the different results obtained according as light was passed through these from one or from two separate lanterns, has been so recently publicly repeated, that I will take it for granted that the theory remains exactly as laid down by him in 1873.

I gather that the pigments or colours employed by him are (lecture I., p. 37) ammonia-sulphate of copper for blue, and picric acid for yellow. Whatever they may be, the experiment is a striking and apparently successful one; superposed in one lantern, a green disc is thrown on the screen, passed through the prism (p. 37), "the green band of the spectrum alone remains on the screen." When, however, the two tanks are placed in separate lanterns, and the two coloured discs made to overlap, the commingling of the blue and yellow rays is found to be white instead of green, as one would have expected. I will not even quibble about philosopher's white, but allow, for the sake of argument, that it is to ordinary eyes a good honest white. More, that it is white; that no spectroscopic test I know of will detect anything else. Still, to my mind, it *proves* nothing, for I read (still p. 37), "no natural colour is *pure*. . . . A blue liquid permits not only the blue to pass through it, but a portion of the adjacent green, &c." So we have two acknowledged *impure* colours producing white.

It is an experiment I have performed myself repeatedly with the greatest success; not in public, because I know the fallacy of it. It is so self-evident, because almost any blue and any yellow give satisfactory results if one is satisfied beforehand that blue and yellow make white. The recomposition of white light by the spectrum colours is another lantern experiment which cannot fail. Take any sort of coloured gelatines, anything near the colours, and arrange them on a disc so that they can be revolved rapidly in the lantern; all colour disappears, and a white disc is obtained. I have such a disc, and have often shown it: the colours are absurdly false, scientifically speaking; but I could have sold it over and over again if I would have lent myself to what I *know* to be an imposture.

Our critics, however, will say it has been done with the solar spectrum. That is exactly what I want to know: how, when, and where? I turn back to the same lecture, pp. 30-31, and find an experiment described in which, by a system of lenses and prisms the spectrum is separated into two coloured rectangles, and that "by judicious management one of these colours is rendered *yellow*, and the other *blue*. I withdraw the thin prism; yellow and blue immediately commingle, and we have *white* as the result of their union." This, then, is the proof of the fallacy just exposed by Helmholtz, "that the mixture of blue and yellow lights produces green."

By Tyndall's own showing, what he here *calls* blue and yellow, contain between them all the colours of the spectrum.

I feel most deeply the enormity of the heresy which allows me to call in question Tyndall's usually clear and cogent logic, and am quite ready to be convinced of my error, if error it is; but will first put on record my own explanation. The eye cannot distinguish between yellow and orange. What we call yellow is red and yellow—that is, examined by the spectroscope, it allows the red rays, or some of them, as well as the yellow to pass. *Exp.*—Take a deep ruby gelatine film, one which, spectroscopically, would be passed as safe for gelatine dry-plate work, superpose it with a tolerably deep yellow film (which should cut off any blue rays which *might* pass through); look at the clouds, or any diffused light, and a deep red will be the prevailing impression on the retina; then look at the sun—every *trace* of red will disappear—the impression will be *yellow*.

In the two Tyndall's experiments in question, all the elements of white light are present; in the latter one confessedly, in the former so probably as to amount to certainty.

The question arises, What are the elements of white light? The Brewsterian reply is: Red, yellow, and blue. The modern reply: An infinite number of rays of different refrangibility. Common sense is, generally, so safe a guide that it cannot be ignored, and, therefore, I must incline towards the Brewsterian theory, the more so as, to my mind, it explains the results of the experiments under consideration. Without, therefore, absolutely committing myself to it—for I confess there are points still far from clear—let us see how far it goes towards clearing up No. 1 experiment.

If, then, red, yellow, and blue are the three primary colours, and the yellow allows ever so little red to pass, supposing the blue to be *perfectly pure*, when the two discs are made to overlap we shall have a certain amount of the three primary colours combined on the screen, and in that due proportion we shall have their equivalent of white light. Now take the other side, and suppose that pure blue and pure yellow are complementary colours, and that their commingling produces *white* light, no matter how impure the colours or pigments may be, as far as their *equivalents* are present, an *equivalent* of white light must be produced. By all accounts, then, some white light would be produced. What becomes of the remainder? *Exp.*—Take a coloured disc which can be made to revolve rapidly in the lantern; half-way between the centre and circumference remove the colour from a small portion of the disc (a coloured gelatine film or glass is an easy way of trying the experiment), what happens? We have a uniformly tinted disc, over which light is passing. Supposing the space from which the colour is removed is 36° (i.e., one-tenth white light and nine-tenths colour), the one-tenth of white light will be quite sufficient to destroy all trace of colour to the eye. The impression formed will be that of a white ring on a coloured ground.

Now, in Tyndall's experiment, may we not suppose that, from the acknowledged impurity of natural pigments, the complementary spectrum colours may by accident be present in their respective equivalents to the extent of 10 per cent. If this is so, this in itself would be quite sufficient to account for the apparent purity of the whiteness of the overlapping portions of the discs. There is, however, another element of error. For a film to stand the spectroscope, it must be pretty deep in colour: otherwise the spectrum will be, more or less faintly, visible throughout. But a film in the lantern would not produce, on the screen, such a brilliantly-coloured disc as would be desirable for an audience. The argument may be used against me; but nevertheless I uphold that, up to a certain point, a mixture of white and coloured light seems to be necessary for brilliancy of colour. Is it not, then, probable that each coloured medium, in addition to its contribution to the equivalent of complementary colours, may allow a *trifle* of unabsorbed white light to pass? Each then *may* allow a little white light to reach the screen. Add to these two increments of white light the equivalent of the complementary colours present, and it is no longer astonishing that an apparently brilliantly white disc should be the result.

George Smith.

USEFUL AND SCIENTIFIC NOTES.

Recent Progress in Telephony.—Some important telephone results have been lately obtained by M. van Rysselberghe, the Belgian meteorologist, whose very ingenious meteorograph was shown at the Paris Exhibition last year. He has succeeded in eliminating from telephonic communication through a wire the inductive action of a neighbouring telegraph wire (which gives a crackling kind of noise in the telephone). Moreover, he can employ the same wire at the same time for both telephonic and telegraphic work. Thus, in a recent experiment, a message was sent from Brussels by the Morse telegraph to the directing engineer of telegraphs in Paris, and an oral message sent by telephone was distinctly heard, while the Morse rereiver was in action. Paris is 344 kilomètres wire-length from Brussels. Among other recent telephonic connections we note Venice and Milan (284 kilomètres), Berlin and Hamburg (288 kilomètres), Paris and Dijon (314 kilomètres), Paris and Nancy (353 kilomètres). At the forthcoming exhibition in Munich, telephony is to be tried between that town and Dresden, a distance of 550 kilomètres (or about 343 miles). American accounts report experiments in progress as to what may and what may not be done in telephony on underground wires; a cable for the purpose having been laid by the American Bell Telephone Company along the Boston and Providence railroad. There are 21 rubber-covered copper wires within a lead pipe, ten of these being also covered with tinfoil to carry off extraneous induction currents, while ten are twisted together; the 21st wire is covered with cotton and paraffined. A French naval committee has lately reported on the use of the telephone in diving operations. The transmitter approved as best is a small flat circular telephone, having interiorly two spiral magnets superposed. The Gaiffe telephone as receiver gives good effects. Microphone (doth the ordinary microphone and the Ader) are pronounced less advantageous. A comparison was also made with the ordinary speaking-trumpet, which proves inferior to the telephone, expecially as the depth increases (owing to effects of pressure on the membrane in the case of the trumpet).

Poisoning Insects in Herbarium Specimens.—Baron Thuemen highly recommends the following method:—Have a box made of rather stout tinned iron, which is a trifle wider and longer than the size of genus-cover used in the herbarium. About 1in. from the bottom, a ledge is attached all around the inside; and a tin gutter runs all around the upper edge on the outside. The depth may be adjusted to the requirements of the herbarium; under ordinary circumstances, it need not exceed 24in. to 28in. The box is provided with a cover fitting into the gutter, around the upper edge. When the box is used, a flat vessel (plate, &c.) is placed in the bottom and filled with bisulphide of carbon; a diaphragm of wood or other material is placed upon the ledge, and the specimens of plants, either freshly collected or taken from the herbarium, in their paper covers, laid on top of the diaphragm. The whole box may be thus filled, and it is not necessary to take the plants out of their covers. Finally, the cover is put on, and the gutter filled with water, so as to form a water-joint to prevent the evaporation of the bisulphide of carbon as much as possible. The liquid soon volatilises in the box, and thoroughly penetrates every specimen. Being highly poisonous to the lower animals, it destroys any that may be present, and after a few days, when the cover is taken off, and the plants taken out, they are most effectively "poisoned." The bad odour arising from the fumes of the bisulphide is soon lost by evaporation.

Anti-Fat Dietary.—To those who wish to get some of their superfluous flesh off, perhaps the following anti-fat dietary given by Dr. George Johnson, in *The Practitioner*, may prove of service:—"*May eat*—Lean mutton and beef, veal and lamb, soups not thickened, beef-tea and broth, poultry, game, fish and eggs, bread in moderation, greens, cresses, lettuce, &c., green peas, cabbage, cauliflower, onions, fresh fruit without sugar. *May not eat*—Fat meat, bacon or ham, butter, cream, sugar, potatoes, carrots, parsnips, rice, sago, tapioca, macaroni, custards, pastry and puddings, sweet cakes. *May drink*—Tea, coffee, cocoa from nibs, with milk, but no sugar; dry wines in moderation, brandy, whisky, and gin in moderation, without sugar; light bitter beer, soda and seltzer water. *May not drink*—Milk, except sparingly; porter and stout, sweet ales, sweet wines."

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46791.]—**Sahara.**—I believe the Cunard Co. altered the above ship's name to the "Servia." Sorry that I cannot give you dimensions, etc.—Nemo.

[46940.] — **Soap-making.**—Bayley gives instructions for preparing standard sulphuric acid, in p. 289 of his book. "Svenska" would probably be able to obtain the solution from any analytical chemist. There are several works on volumetric analysis, of which Sutton's (Churchhill, 16s.) is the best. "Methyl orange" should be used as indicator in titrating caustic leys.—Pygmalion Phibbs.

[46980.]—**Brakes (U. Q.)** — The brakes being tried upon the Highland Railway are the Westinghouse Automatic, and Smith's Automatic Vacuum. The Lynn and Fakenham Railway Company has adopted the Westinghouse brake for the whole of its passenger rolling-stock. I presume that the trials to which "A Driver" refers, were the following:—"The East Lancashire Company reported that a train was run for twelve months, ending September, 1854, between Salford and Colne, with a van and two carriages fitted with Newall's brake; this train ran 47,604 miles, and made 25,332 stoppages before the tires required to be turned up."—In reply to the concluding question. The Lancashire and Yorkshire Railway Company has fitted a very large number of vehicles with the Fay and Newall brakes; when it was decided to try the pneumatic brakes, it was desired that some carriages should be fitted with the Fay and Newall brake-blocks and gear, applied by both air and vacuum systems, in order to prove that in the event of a new brake being adopted the old gear could be utilised. A train of six vehicles was fitted with the Westinghouse brake, combined with Fay's gear. Another train of six vehicles, with Smith's vacuum combined with Fay's. Six vehicles have the Sanders and Bolitho automatic vacuum brake; and ten others have the Eames automatic vacuum brake, in each case working in combination with the Fay and Newall brake-gear. From these details it will be seen that the Fay, Newall, and Eames combined brake is *not* a new or separate system, but simply the Eames brake fitted to nine carriages, and a van in combination with the Fay and Newall gearing.—Clement E. Stretton, July 17th.

[47029.]—**Difficulty with Coil.**—To Mr. Lancaster.—Many thanks for your reply on p. 359. I have done as you said, and have taken off the wire up to the place where it gave ½in. spark before, and it does so again. I rather hesitate to soak the coil in melted paraffin, as I fear that the hot paraffin will injure the intermediate layers of guttapercha tissue. Also, will you please tell me whether I am, in thickening the wire at the middle as you said, to wind the wire farther in each time, or to make the insulation thicker in the middle? If you will answer me as to these two points, I shall be very much obliged.—B. B.

[47045.]—**Wire Harness for Weaving.**—I do not know of but two machines for making wire healds. The one H. Macmillan mentions cuts the wire in lengths, brings the two ends together, then twists up one end, thus forming one of the three loops, and, I believe, is used by only one firm, who hold the patent. The other machine takes the wire off two reels, twisting both wires together and cutting off afterwards; is not patented, but worked under lock and key. Both machines are complicated and expensive. Shall be happy to give H. Macmillan more information, if he will refer to my address in the sale column, which would otherwise be an advertisement.—Counter Tenor.

[47050.]—**Hot-air and Vapour Bath.**—In consequence of my offer to Isabelle Stuart ("E. M.," 901), I have received from England, Scotland, and Wales, numerous letters from private inquirers who want to make personal application of my principle. This proves the usefulness of the query. Astonishing to remark, Isabelle Stuart did not write. One of the letters received contained a stamp to prepay the answer. This is a very delicate, but, unfortunately, useless attention, as English stamps have no more value in France than French ones in England. My offer was made to one person, as I could not undertake to write numerous copies of my patent specification; besides, it was in a general point of view. Now, I cannot choose among the inquirers; still, I should like to be serviceable to them all if possible. I will, therefore, with your kind permission, give here a very simple process—not the patent one—by means of which, such baths can be obtained without extra expense. Take a common gas or water-pipe, bend it in U-shape—a coil would be better—and place the curve over your kitchen fire; it will soon get hot; take your bellows and blow in one end of the pipe. It is obvious that the air so pressed, passing into the heated part of the pipe, will issue out at its temperature. Now, if the pipe is at a nascent red heat, it will be at 525° Cent.; if cherry red, 800°; if white, 1,000°. . . It is easy to obtain any desired temperature, either direct from the pipe or by mixing heated with non-heated air, or simply in modifying the blowing. If vapour is wanted, let the outlet of pipe plunge into some water, and directly, vapour will rise. If scented or medicated effluvia are required, proper substances are placed in the vessel. This is simple enough, efficacious, and costless. Now for the bathing apparatus. Take a common iron or wooden hoop; have it suspended horizontally at a suitable height; round this hoop wrap a sheet or blanket, leaving in the centre at top, room to pass the head; place a seat underneath, and, when seated blow in the pipe, the outlet of which should be under the seat. If a modified, aromatised, or medicated air or vapour be needed, it can be obtained, either in steeping the sheet or blanket in proper liquid, or in plunging the outlet in a solution under the seat. A cool-air bath can be obtained in full sun, in having the apparatus wetted or watered; the evaporation causes a very refreshing and most agreeable temperature. These, I repeat, are not my patent processes, but they are sufficient to lead any intelligent reader to many other useful and inexpensive applications of the system, which, of course, does not interfere with "Gereb Admi's."—Ch. Rabache.

[47054 and 47368.]—**Incandescent Lamps.**—In answer to 47054, I should say that six or eight Leclanché cells would light such a lamp, but it would only maintain it for a few minutes. It would not be worth while to try it with these cells: try Bunsens or the bichromate battery. I have not tried Leclanché for such a purpose, so I cannot be positive; but I have Bunsens and bichromate. To 47368, I would say that there is now in the market a small incandescent lamp of 5-candle power, lighted by two quart Bunsens, the price of which is 2s. I believe it has a carbon filament; it is offered by a firm whom I think can be relied on for selling a good article. If "W. L." will advertise his address, I will give the name of the firm and all particulars. He must remember that the Lane-Fox, Maxim, and Swan lamps give a much greater candle-power than these small ones, therefore a greater battery power is required.—W. R. Hicks.

[47059.]—**Iron Chimney Rusting.**—Many thanks to "G. T." for his answer; but I have tried Brunswick black, and it burns off the first time the fire is lighted. I thought, as so many vertical boilers with wrought-iron chimneys are now used, and as I have not noticed all other chimneys rusting like mine, that perhaps there was some composition that would resist the heat and the weather, and so preserve the chimney. If "G. T." or any other reader can tell me of something that will answer this purpose I shall be greatly obliged.—F. R.

[47107.]—**Bleaching Oats.**—No doubt it can be done by means of peroxide of hydrogen; but probably the sulphur method is still the cheaper.—J. R. T.

[47108.]—**Spring Blind.**—Surely it is very simple. The blind-roller is so attached to the spring that, when the blind is pulled down, the spring is coiled up. A toothed wheel on end of roller is held by a pawl, and when the latter is released by a pull on the string, up goes the blind.—T. P.

[47116.]—**The Livadia.**—The last I remember reading about this vessel was, that she was to be broken up; but I imagine that has not been done, or something would have been heard of it, after all the statements made pro and con. soon after her first voyage.—T. P.

[47120.]—**Enamelled Bowls.**—These, like other enamelled hardware, are covered with a frit and put into a suitable furnace. A full description would occupy a lot of space, and it is not quite clear what is meant by bowls.—Nun. Dor.

[47124.]—**Medical.**—This query cannot well be answered without inquiry into the history of the case, and examination of the patient. The fact that the swelling always occurs in one place points to some local special cause, though the principal is, no doubt, bad state of blood.—M.D., F.R.C.S.

[47128.]—**Chinese Cement.**—This cement is known by the name of Schio-liao, and is said to be composed of three parts freshly-beaten (whipped) blood, to which are added four parts of slaked lime and a little alum. The Chinese use it as a paint. It is said to be thoroughly waterproof.—Nun. Dor.

[47129.]—**Pedals to Piano.**—Mr. Davies and others have replied to this query—the former on p. 44, Vol. XXIX., and p. 343, Vol. XXX. On pp. 99 and 152, Vol. XXIV., there are illustrations of two methods of attaching pedals to pianos.—S. Mayer.

[47150.]—**Steam Engine.**—I should advise him to adopt the compound system, that system having proved the best with steamers; there is less coal consumed for cargo carried, consequently more space for cargo, although the consumption of fuel per indicated horse-power by the indicator card is about the same in both systems; with regard to land engines, we have nothing but the indicator to guide us. If simple engines are used, they must cut off early to give a good result; with the compound engine, the high-pressure cylinder can be cut off at 7-10 of stroke, or later. In the simple early cut-off engines, when the cranks are at half-stroke and greatest piston speed, and greatest leverage, giving off the most useful effect, the pressure on the piston is less instead of greater; and when the cranks are at the commencement of the stroke and less piston speed, and least leverage, and least useful effect, the pressure on the piston is greatest. In the compound engines this is not the case, unless a high grade of expansion is on the high-pressure piston. The high-pressure piston gives out its greatest amount of useful effect at half-stroke of crank, when the speed is greatest and leverage of crank greatest. For instance, an engine with 66lb. effective pressure on piston, area of piston 100 square inches, and speed 400ft. per minute, we obtain the following indicated horse-power for the 1-10 at commencement, and the 1-10 at half-stroke, thus—

$$\frac{66\text{lb.} \times 10\text{ft. per minute per 1-10} \times 100\text{ sq. in.}}{33{,}000} =$$

2 indicated horse-power for 1-10 of stroke (at commencement);

$$\frac{66\text{lb.} \times 30\text{ft. per minute per 1-10} \times 100\text{ sq. in.}}{33{,}000} =$$

6 indicated horse-power for 1-10 of stroke at half-stroke. Although the consumption of steam is the same for either 1-10 of stroke (leaving out the ports and clearance spaces for the first tenth of stroke), this discrepancy occurs on account of the crank speed being constant, and the piston speed intermittent. Again, at the commencement of the stroke (or first tenth) the line of piston force is almost at the angle of 90° to the line of motion of the crank, especially on the instroke of piston.—C. J. Little.

[47196.]—**Electricity v. Gas.**—"Fiddler," in answer, seems to have got his ideas on the above subject what I should call slightly "mixed." He evidently looks upon electricity as a specific substance, which can be handled, and, to use his own words, analysed. He also confuses Lewis's incandescent gas lamp with those in which the incandescence is caused by the electric current, having evidently some idea that electricity is used in combination with gas in the former. What does he mean, too, by the following? "We have two ways of making an incandescent light with almost the same materials—the gas lamp with one jar, the electric lamp with many jars." Perhaps he will kindly throw a little more light on the above very obscure sentence. Referring also to his idea, that "hydrogen gas is a large component of electricity," I should recommend him to study an elementary textbook on electrical science, which would, perhaps, disabuse him of his, to say the least, peculiar views. Now, I think that if people, in answering queries, would confine themselves to those subjects which they know—at any rate—a smattering of—it would be much better for everyone, as those who send queries would not be misled by persons who know nothing of the subject on which they write, and we should none of us have the pain of seeing such nonsense printed in our very excellent paper.—W. J. Williams.

[47239.]—**Deafness.**—I should have said force the air into the ear, not through it. I understood there was no absence of the "membrana tympani." Before seeing Mr. Dalby I tried some false drums without effect. Can Dr. Edmunds give a good cure for biliousness? It is a daily and hourly plague to me, affecting my eyesight, consequently writing, spelling, &c. I am a vegetarian and teetotaler. I am sure we owe great thanks to Dr. Edmunds for the prompt and kind manner in which he answers the numerous queries respecting our numerous woes and infirmities.—John Alex. Ollard, F.R.M.S., Enfield.

[47274.]—**Illuminating Clock.**—A coating of Balmain's luminous paint on the face of the clock would perhaps answer "Light's" purpose. The necessary precautions would have to be taken, before applying the paint to iron.—Pygmalion Phibbs.

[47276.]—**Electrical Indicator.**—Figs. 1 and 2, transmitting instrument. Plan S S, framework placed over the most suitable part of reservoir; A A, shaft running in bearings in the usual way; B, a pulley grooved for chain, say 3ft. in circumference—at one end of chain is the float, at the other a counter-weight; C, a boss with two strips of brass, E and F, insulated from each other; D, a projection having two springs, G and H, insulated—B, C, and D are fast on the shaft, E is electrically connected with G, and F with H; J is a collar working loose on shaft A, cut away as shown, having on it four contact-plates, M M and N N; K, a wheel with 12 contact-making pins on it; L, a boss with brass strip on it—J, K, and L are fast together, M and M are connected to pins on K, and N and N to strip L; O, P, Q, and R, brass contact-springs with binding-screws, rubbing respectively E, F, K, and L. Fig. 2 is a section through D.

FIG. 1.

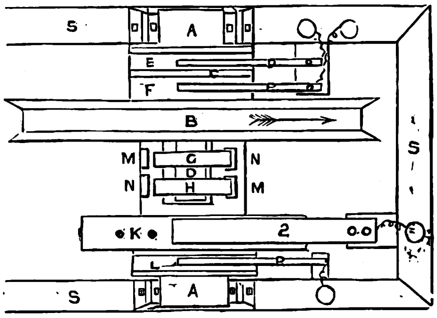


FIG. 2.

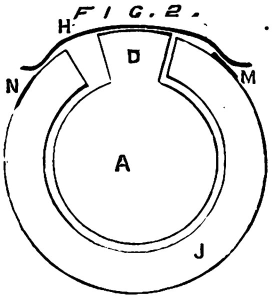

Fig. 3, a polarised relay. Figs. 4 and 5, front and side views of receiving instrument. A, a shaft projecting through front of instrument, having on it the indicator H and a pin, J; a tube works loose on shaft A, on which are fixed two ratchet-wheels, B and C, of 36 teeth each, with their teeth working reverse ways—on B are two pins, between which is J; D and E, two electro-magnets; F and G, their armatures, &c., pivoted at K and L, each having a catch at its upper extremity, G, working on the teeth of B and F of C. *Connections.*—O is connected to one terminal of main battery, P to the other, Q to line, R to earth, F and G (Fig. 3) to line and earth. A (Fig. 3) to copper of local battery. D and E to D and E of Fig. 4, Z to local line. The relay, of course, is at the receiving end of line. *Working.*—Suppose the water to be rising as the float rises, the counterweight pulls B round in direction of arrow, and with it D. D pushes against one side of J, as shown, G making contact with V, and, consequently, L and R; and H with pins on K. Every 3in. the water rises a pin presses Q, and a current passes in this course, P F H M K Q line to relay G C B F earth back to R L N G E O. C (Fig. 3) attracts A, which makes contact with E and sends a local current through magnet E. This attracts

FIG. 3.

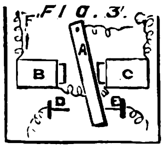

FIG. 4.

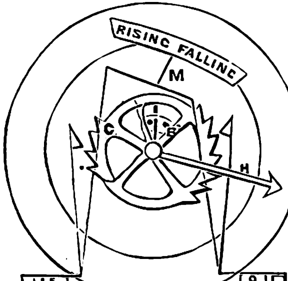

FIG. 5.

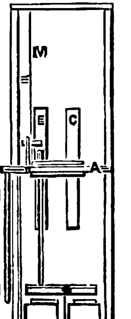


armature G, which, engaging in a tooth of B, pulls pin J, and with it shaft A and pointer H round, indicating 3in. on dial. As G is falling it pulls over M, on which are written "Rising" and "Falling," which brings "Rising" in front of a hole in the clock-face. Suppose, now, the water having risen, say, two inches, begins to fall. Float pulls B round contrary way; D leaves present side of J and pushes against the other; G now makes contact with M, and H with N; consequently, when K again makes contact at Q, a current is sent through the reverse way, and B (Fig. 3) attracts A, which, touching D, sends a current through D (Fig. 4) which attracts F, and F draws M over the other way, showing "falling," at same time F draws C round one tooth, and brings the other pin on B against J, but does not move the indicator until another 3in. of water have fallen. If it did move it now, it would indicate 3in. too little, as "Troubled" will at once perceive. It would be better to have wheels B and C, Fig. 4, of more than thirty-six teeth. I hope, with aid of this description and rough drawing, that "Troubled" will manage; but if not, and he will advertise his address, I will do my best to help him.—DEH.

[47279.]—**Spoilt Glass Shelves.**—Thanks for replies, but we have not yet got at the cause. No acids were near as suggested by H. Stooke. The cellar where the shelves were placed is one in an arch under the road facing the sea at Brighton. There may be salt in the plaster of the wall against which they rested, but I know of nothing stronger. One correspondent says, Clean them with hydrochloric acid. I tried that and every cleaning substance I could think of—such as ammonia, rouge, whiting, &c.; I will try the putty powder for polishing when I return home. Business will keep me away for the next three months. My object in inquiring was to know whether it was something which had got on to the glass and had to be removed, or whether anything had eaten away the polish of the glass; but this none of the correspondents seem to able to determine.—J. E. A.

[47281.]—**Tricycles.**—The double-driving tricycle is the mount of the future. It turns corners, covers rough ground faster and easier than the single. The only good single-driver is the Coventry Rotary, which has the one-sided driving counteracted by both side-wheels steering. The best lever machine is the Omnicycle, which mounts hills far better than any rotary machine made; but it is at a disadvantage on the level by not being able to pedal so fast. The question of rear and front steerers has never been settled, and is a matter of opinion. The former—if you have a brake as strong as it should be—is given to lifting the rear wheel if brake is put on suddenly when riding down a stiff descent. If a single-driver it is positively dangerous to travel more than 10 miles an hour. The front steerer is much more safe down-hill, but requires practice to keep the front wheel on ground when ascending an incline. In answer to 47281, Mr. Lancaster asserts that he can ride 12 miles an hour, and keep it up all day. This statement should be taken with a grain of salt, as it is a very good performance for an ordinary man to average two-thirds of that pace, i.e., 8 miles an hour for 12 hours. If what Mr. L. says about his pace is true, he is far and away the best tricyclist that we have; and if he would compete in the forthcoming championship we might see what a tricycle is capable of with other than a racing man mounted. If it is not true, I think it only right that such a wild statement should be corrected, as it might mislead people who fondly imagine that they have only to buy a tricycle to travel about at 12 miles an hour, and who, after a ride or two, throw the whole thing up in disgust, and lay the whole blame on the makers, much to the detriment of tricycling.—CHEROPHUS.

[47301.]—**Errata.—Vacuum Tubes and Coil.**—For *zinc*, p. 411, read *wire*.—GEORGE TOLMAN.

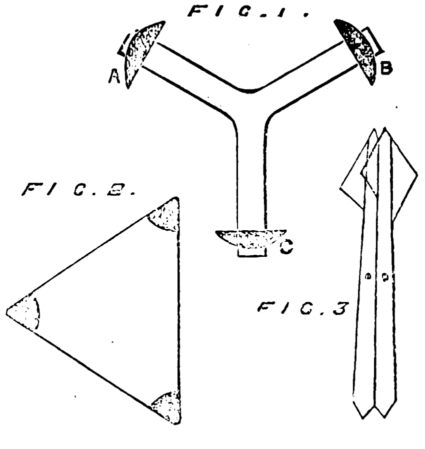
[47307.]—**Mildew on Vine.**—Keep the house as dry as possible as soon as the grapes begin to colour; in fact, no other plants ought to be in the house then. On signs of mildew sprinkle or fumigate with sulphur.—NEMO.

[47307.]—**Mildew on Vine.**—For the past two years I, like "Amateur Gardener" (p. 383), have lost all my grapes through mildew. This year I am more fortunate, as there is no appearance of the pest up to the present time. The treatment I adopted is as follows:—In the autumn I put on the border a thick dressing of manure. In January I pruned off all the lateral shoots, and about a month after I stripped the stems of all fibrous bark. I then made up a compound of soft soap, sulphur, and paraffin-oil (a strong decoction of tobacco is also recommended) to the consistency of treacle; with this I painted over all the branches. When the leaves began to form I covered eight or nine slabs of glass with flowers of sulphur, and placed them as close to the glass roof of the house as possible; I have also, for greater security, placed sulphur in a flour-dredger, and dusted the leaves in certain parts. This treatment with proper ventilation will prevent the pest; but having got it, the only thing I can recommend is to cut the fruit off, throw it away, and ripen the wood ready for the above treatment. My house is a cold one, and filled with various kinds of plants and flowers, as well as the vine, now flourishing.—W. B. L.

[47309.]—**Clarionet.**—As I am about to try my hand at making a B flat clarionet, I should be very glad if "Hampstead" or Mr. Edwin Morgan would kindly give the correct position for the holes; also any other bit of useful information on the subject.—BASSOON.

[47318.]—**Ink-Stains on Carpet.**—Have you tried oxalic acid? If it does no good, I don't think it could do any harm. Milk is efficacious if applied directly after the ink is spilt.—HEMISUS.

[47324.]—**Sketching Stool.**—I send rough sketches, which I think will answer your purpose. Fig. 1 is the shape of iron pins; A, B, C are brass caps which fit the pins; they are put on over the legs, and the pins then riveted, allowing plenty of room in the joints for the seat to fold up. The seat is made of canvas, with strong leather caps at the corners. Fig. 2 is the seat. Fig. 3 is the stool folded up. If querist needs any further information I shall be pleased to give it him if he will advertise his address.—H. B. C., Lambeth.



[47328.]—**Siemens' Armature.**—You can use 16 wire, but make more coils—say one layer of nine rows. Do not have any divisions between wire; no necessity for drilling holes. The new commutator; of course the old form is only for one coil.—GEORGE TOLMAN.

[47331.]—**Brakes on the Midland Railway.**—To "METEOR."—The Midland Railway Company is now in favour of the Clayton modification of the Sanders and Bolitho automatic vacuum brake (generally known as the "two-minute" brake). On the other hand, the Glasgow and South Western and North British Companies have finally adopted and fitted their trains with the Westinghouse automatic brake, for the simple reason that they have proved it to be the best, and they have declined to exchange the Westinghouse brake for any "inferior system." The "M. S. J. S." vehicles, which are the joint property of the three companies, are fitted with both the Westinghouse and vacuum brakes, but all the Scotch traffic is generally worked with the former. As far as the credit and reputation of the Westinghouse brake is concerned, it would be advantageous if its use were discontinued over the Midland line between London and Carlisle, unless the apparatus be maintained by the railway company in fair working order. An article relating to the Board of Trade returns and continuous brakes appeared in the *Engineer* on the 26th May last, in which special attention is directed to the following

COMPARISON OF THE WESTINGHOUSE BRAKE ON THE MIDLAND AND NORTH EASTERN RAILWAYS.

	Total Brakes in use on Engines and Carriages.	Number of Reports.	Proportion of Reports to Brakes.	Miles run.	Proportion of Reports to Miles run.	Reports each should have, supposing the other to be correct, taken from:—	
						Stock fitted.	Miles run.
Midland	332	115	1 for 2·9	430,931	1 in 3,747	11·3	10·7
North Eastern	1984	68	1 for 29	2,734,307	1 in 40,210	686	729

"Here we see," remarks the *Engineer*, "that the failures of the brake on the Midland are apparently ten times as numerous as they are on the North Eastern. Can this really be the truth? If so, why so?" The Midland Company, for the half-year ending December 31st, 1881, return only 5 per cent. of the total miles run with the Westinghouse brake, but make no less than 21 per cent. of the reports against it. These few facts will conclusively prove that, for purposes of comparison, the returns of failures have been rendered practically useless, and that the reputation of a good brake may be unjustly injured by a company who persistently neglect to perform the necessary duty of maintaining it in proper repair.—CLEMENT E. STRETTON, July 15th.

[47333.]—**Drowsiness.**—Some years ago a friend of mine was cured of this complaint, which appeared in a more marked form, by the following treatment:—He moved into a large cool bedroom, where there was a good current of air passing through all night; he undertook to go to bed two or three hours earlier than previously; in this way he obtained ten or twelve hours of very refreshing sleep, which nourished his brain, and armed him for the work of each day. If "P. S." is engaged in writing for twelve hours a day seven days in a week, he can hardly expect to have good health, and his employer must expect him to break down. If, in addition to this, he sleeps all night in a foul or an exhausted atmosphere, the case is much worse, for his lungs are also starved.—H. BARNABY.

[47334.]—**Small Dynamo Machines.**—What can you expect from this small model when the armature does not hold above an ounce of wire?—GEGRGE TOLMAN.

[47337.]—**G.E.R. Engines.**—In answer to "H. S. P.," Sinclair's 8-wheeled tanks are still running. The first ten, Nos. 1400 to 1490, are about to be broken up, having been replaced by Hawthorn's engines. The 580 class of tanks have cylinders, 16 by 22, and coupled leading and driving 4ft. 10in. diameter; 50 of these engines have been built at Stratford since 1878, and 10 more are being built. Nos. 305 and 306 have cylinders 17 by 24, and 6ft. 6in. coupled drivers, with a leading bogie. These are the two finest passenger engines the G.E. have at present. The 245 and 600 class have cylinders 18 by 26, and single drivers 7ft. 6in. in diameter. These engines are very heavy on fuel and repairs, and give very little satisfaction. I may mention that Mr. Worsdell is having some fine 4-coupled express engines built at Stratford, of his own design. The cylinders are 18 by 24 inside, 7ft. drivers, and single bogie wheels 4ft. diameter. They will be fitted with Joy's valve-gear, steel frames, and boilers. The cylinders are a solid casting, the valves working on top in the bed of the smoke-box. These engines, when finished, will supply a long-felt want on the G.E., as most of the trains require coupled engines to work them efficiently.—ETNA.

[47338.]—**Leclanche Battery.**—Use porous cells; well wash the carbon before putting in; will require good zinc rods; four cells would ring two bells.—GEORGE TOLMAN.

[47338.]—**Leclanche Battery.**—Put new porous pots and zincs, charge pots with broken carbon and peroxide of manganese, exciting liquid sal-ammoniac. One cell is sufficient for a small bell. Are these cells worth the trouble?—REYNALDA.

[47341.]—**Electric Locomotive Engine.**—Make the motor exactly like the small dynamo I described, page 354, June 23, but without the fly-wheel and gearing; it is a good motor.—GEORGE TOLMAN.

[47349.]—**Dry-plate Queries.**—To MR. W. ROBINSON, JUN.—Best thanks for your replies, but the first (*a*) does not convey what I wished to elicit. I have long since learned how to temper my developing ingredients to suit circumstances. Please assume that I expose, under identical conditions of subject, light, lens and exposure, two or more plates by as many different makers. One uniform developer may not be best for all. This I know; but I do not know why one of the plates will give as good a negative with ½gr. of pyro. as another with 3gr., and one will bear with impunity as much ammonia as would ruin another. I have tried this over and over, and I wish to learn the reason why different makes of plates require such different treatment. I have not got any book on emulsions to which to refer.—W. H. S. W.

[47351.]—**Mathematical.**—Will you kindly permit me to point out that the assumption made by "An Engineer's Son," on page 434, is entirely illegitimate, for $(1 - x)^{-n}$ is not a constant, but a function of x. Therefore, if we take the coefficients of 7 in $(1 - 7)^n$ and multiply each by $(1 - x)^{-n}$, each product will be a function of x, and not by any means one of the coefficients of x in $(1 - 7)^n (1 - x)^{-n}$.—J. H. M. JACOBY.

[47351.]—**Mathematical.**—I know of no other way to do this except by induction, as given by J. H. M. Jacoby. "An Engineer's Son's" assumption is clearly illegal, as $(1 - x)^{-n}$ is not independent of x. We might say in a similar manner that the coefficients in $(1 - x)^3 (1 - 2x)^{-3}$ equidistant from the beginning and end were equal, because those in $(1 - x)^3$ are, and each coefficient is multiplied by $(1 - 2x)^{-3}$. But this is untrue. —HEMISUS.

[47358.]—**Shocking Coil.**—This size was described within the last eight weeks.—GEORGE TOLMAN.

[47360.]—**Battery for Electric Clock.**—I find the gravity Daniell cells answer well for clockwork. I wrap all zincs in calico. The Silvertown Company wrap all zincs in their medical batteries (Leclanché) in calico.—REYNALDA.

[47360.]—**Battery for Electric Clock.**—The gravity cells are the best you can have. There are, of course, a variety of them, both in size and construction. The zinc does eventually become coated with copper, and if you can devise a method of keeping the copper away from the zinc, you will have the best possible cell for the purpose you wish to use it. The deposit of copper is a difficulty that I am afraid you will be some time getting over.—W. J. LANCASTER.

[47363.]—**Watch Cylinder.**—"A Fellow-Workman's" reply to "Hall" in last week's "E. M." is so wide of the mark, I can't refrain from writing to say that if "Hall," or any other of our amateur horological readers, follow such a course (as described by "A Fellow-Workman") in putting in a cylinder-plug, they could only produce a job as bad as the way of doing it—if, indeed, it could be done at all. In putting in a cylinder-plug, I do not use a file in any part of the job; but, according to "A. F. W.'s" way, it is all done by a file. There are some capital articles in back numbers of the "E. M." by our late correspondent, "Seconds' Practical," on "Turning," which I would recommend "Hall" to read. If, however, he has not the Nos. referred to, I will be pleased to put him in the right way of doing the job if he writes to me. A description here would not be of sufficient general interest to call for the space it would occupy, as the *modus operandi* has appeared so many times in "ours." If "A. F. W.'s" promised instructions, with drawings, on putting in a cylinder-plug are based on his principle of filing them in, they will not be worth anything. An engineer would as soon think of trying to file up a piece to act as a piston-rod for an engine, as a practical watchmaker would think of putting in a plug in the manner "A. F. W." describes.—G. K., Stockton.

[47364.]—**Silver Filagree Brooches.**—Washing with soap-and-water will do very little good. Better follow out "Alfojoe's" directions, only instead of a long immersion in cold vitriol and water, a short boiling in the same preparation will be more effectual. You can boil them in a copper or brass pan. When rinsed out and dried, burnish the edges and points of the work, and you will get the right effect. Don't scratch-brush, as the object is to get a dead white surface in contrast with burnished edges.—J. E. A.

[47368.]—**Incandescent Lamp.**—The filament is platinum. Two Bunsens will do it—cost about 2s. 9d.—GEORGE TOLMAN.

[47368.]—**Incandescent Lamp.**—I think "W. L." would find he could work one of Swan's small incandescent lamps with two good-sized Bunsen cells. I have worked one of Swan's 5-candle lamps with three 1-pint cells.—SPELTER.

[47368.]—**Incandescent Lamp.**—Like "W. L.," I am anxious to hear of the smallest number of cells that will give a fair light. I at present use eight Bunsens, and get only very meagre results. I believe a few lines from some of "Ours" on the subject would be very interesting to many readers of the "E. M."—REYNALDA.

[47368.]—**Incandescent Lamp.**—There is a so-called incandescent lamp, with two coils of platinum wire, that a couple of quart Bunsens will make it give about half a rushlight. This is an imitation of a lamp I brought out last year, and am making now, with about 10 coils of iridium-platinum wire; this lamp requires 5 Bunsens to light it. Then there is the Swan (carbon filament) 2½-candle lamp, which will require about 8 Bunsens to illuminate it. The 20-candle lamps will require 25 Bunsens. You can make an incandescent lamp for even 6d.—W. J. LANCASTER.

[47372.]—**Lens.**—"Focus" does not give sufficient particulars to enable anyone to tell him what curves he requires. He should have said what is the refraction of the glass or glasses he intends using, and the radii of the convex lens. The concave must have a negative focus of 2 1-7in. Now, if his lens be equi-convex, its radii will probably be very nearly 1·5; and if the same sort of glass be used for the concave, the inner curve may be 1·5, and the outer 3·75. This is as near an approximation as can be given, without more definite particulars.—O. V.

[47373.]—**Cracked Varnish on Globes.**—I should advise "J. C. L." to apply a little alcohol or spirits of wine with a sponge to his globes; if it is a shellac varnish, it will be dissolved.—SPELTER.

[47373.]—**Old Cracked Varnish on Globes.**—Use methylated spirit warmed, and apply it with either a sponge or a tuft of cotton-wool; the latter is much the better way. Take your time over it, and you will be successful.—W. J. LANCASTER.

[47375.]—**Lightning Conductors.**—To MR. LANCASTER.—By all means carry the wire straight into the earth, and as far away from the bottom of the chimney as possible. Then let the ends of the copper rope be opened, and either soldered or riveted to a large iron plate imbedded in moist earth if possible. If there is no moist earth, then put the plate in a deep hole—say ten to fifteen feet deep, and the plate to be well bedded in gas coke. I much prefer the plate to be a long one, and let down well in the earth with coke all round it.—W. J. LANCASTER.

[47376.]—**Bone Calcination.**—These are subjected to destructive distillation, the same as wood for pyroligneous acid and naphtha. If required for animal charcoal, in a retort. An iron one is generally used for this purpose, with a coil descending into a tank of water, at the end of which is a well for the end of coil to dip into, to collect the dipple oil or by-products.—JACK OF ALL TRADES.

[47377.]—**Casting Small Articles in White Metal.**—Your moulds must be made of gun-metal, cast iron, or steel, highly polished, and your metal just hot enough to run, to do them to perfection.—JACK OF ALL TRADES.

[47378.]—**Legal.**—A wife who assaults her husband or breaks his furniture can, of course, be summoned to the police-court, and convicted of that assault or the malicious damage. Or, if a wife gets constantly drunk and causes a disturbance, she might be turned out of the house by her husband and taken into custody by the police. But, then, "M. B." does not wish any exposure, and there is the difficulty. The only way I can suggest is for husband and wife to separate—by allowing her so much a week or month, under a deed so drawn that the money shall be paid to trustees, and shall cease if she returns to annoy him. If "M. B." does not even want a separation, then, I fear, his question is quite outside the province of a lawyer.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall.

[47380.]—**Clark's Process for Softening Water.**—The process known by this name is very much of a chemical paradox; for, to remove lime from water, more lime is added. Water is hard—as a rule—because it holds in solution carbonate of lime, and it is enabled to do that only when an excess of carbonic acid is present. By boiling or heating to such a temperature as will expel the excess of carbonic acid, the lime is thrown down in the form of carbonate, commonly spoken of as chalk, though chalk is a distinct natural product. By adding a paste or a mixture of lime and water to water holding carbonate of lime in solution, the lime seizes on the excess of carbonic acid, and nearly all the lime in the water is deposited in the form of carbonate. Where the water is hard from the presence of sulphates, sodic carbonate (washing-soda) is added. To soften Thames water, take 1oz. of freshly-burnt quicklime to every 30 gallons, slake the lime and mix it to about the consistency of cream; then either pour it into the water or run the water on to it, rousing it thoroughly. The white precipitate of carbonate of lime will form at once, and in a few hours will be perfectly settled.—NUN. DOR.

[47382.]—**Engine Query.**—Put ⅛in. lead on your valve. The cut-off of course depends to a certain degree on the amount of work you require to do; but ¾ or ⅝ stroke is about the usual in ordinary condensing engines, but in compound engines the cut off is much earlier. A good sensitive governor, with ordinary throttle-valve, would prevent racing when load is taken off.—G. J. C. E.

[47382.]—**Engine Query.**—1-16in. is sufficient lead for the engines you mention. Your second question cannot be satisfactorily answered without an indicator diagram. If you can obtain one I shall be happy to give you every information respecting the cut-off, and general arrangement of the slide-valve.—FRED. WALKER.

[47383.]—**Hardening.**—I have generally seen a very good job made with prussiate of potash. Heat the part to be hardened to a bright red heat in a clear fire, then dust over with potash, and without putting in the fire again plunge it end downwards into water with the chill off. You will find it come out a mottled grey colour, which is easily polished with emery-cloth. Perhaps you heat it too much. —G. J. C. E.

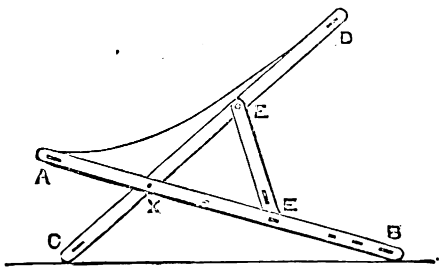
[47383.]—**Hardening.**—You must take one part prussiate potash, two parts of salt, and pour sufficient hot water on them to dissolve. With this wet up some fine wood charcoal dust; place your axle in a tube with about ½in. clearance all round, and ram this in well and stop with clay, and subject it to a dull red heat for one or two hours; you will make a job of it. There is no necessity for slaking it, for it will be very hard without. Bone-dust will answer the same purpose; the longer the process the deeper. By this method they will not become distorted, which they are very apt to be when slaked. They are certainly harder when slaked. A bright cherry red heat is hot enough.—JACK OF ALL TRADES.

[47384.]—**Coil.**—There is very likely a fault in the contact-breaker. I have recently improved mine—not because it did not work well, but because the copper began to get out of shape. I cut out a piece of brass sheet so as to extend ¾in. beyond the coil, and thus lengthened the contact-breaker by that length, and made it of thin clock-spring. This part of the coil requires careful adjustment at any time. It should not, when at rest, be far from the core. See also that there is perfect metallic contact at each joint, and each connection is clean. Do not solder with muriatic acid when connecting. Did you thoroughly soften your wire core? I left my solid one in the forge all night, after blowing it a bright red. Are you also certain that you made your connections according to my description? My coil continues to give satisfaction, and I shall be very glad if I can assist you so that yours may do the same.—FRED. WALKER.

[47385.]—**Spectacles.**—Your correspondent requires a pair of concave glasses; I should think those having a negative focus of about 8in. or 9in. would suit him. He may have some little difficulty in procuring them; but Mr. Lancaster will be able to advise him as to this matter.—O. V.

[47385.]—**Spectacles.**—To MR. LANCASTER.—I should prefer to see you before I could definitely recommend a particular focus concave; but assuming that you have nothing but ordinary myopia, I should give you a pair of 9in. concaves; these should enable you to see well at 20in. to 24in. away. A pair of 8in. would enable you to see the music at 3ft. away; but I am afraid you would not be able to read the music at that distance. You must, of course, remember that the numbers I have given are in each case the focus of the lenses, and not any numbers as usually given in the trade, No. 1, 2, 3, and so on. You might perhaps send another query, stating whether both eyes are of one focus, or whether one eye is in any way better than the other.—W. J. LANCASTER.

[47391.]—**Portable Lounge Chair.**—"An Amateur M." will get out four pieces of scantling, each 4ft. long by 1½in. by ⅞in. This section will vary according to the strength of the wood he uses. I used ash. Joint them two and two as in sketch,



joint × being 14in. from one end of each. Join the two pairs by cross slat mortised in at A, B, C, and D, about 20in. apart, or as wide as he likes. The stay at E, and, of course, a corresponding one on the other side, to be jointed on at 15in. from ×, and to be 15in. long. The two stays to be united by a slat mortised through each, near their lower ends. Said lower ends drop into notches or mortises along A, B, at such places as will give comfortable angles to taste. I have marked the four in my own chair, which I have found comfortable. The webbing is to be nailed to the cross slat at A and D, and to be just long enough to allow of the chair collapsing flat. Be sure that A, B, and its corresponding frame come outside C, D, and E, F, or the chair will not fold up flat. I have found this chair most convenient and comfortable to use, either as an upright chair, a reclining lounge, or a short bed, or hammock, and very firm in all positions.—Treadle.

[47392.] — **Perfumed Pastilles.**—Take gum benzoin in powder; add to it a small quantity of ground cinnamon, pounded frankincense, cascarilla bark, and camphor. Mix these together with a little thin gum-water, roll into shape you require, and dry. To be set fire to. (From Cassell's "Amusing Experiments.")—Nihil.

[47392.]—**Perfumed Pastilles.**—"An Amateur M." will find the following make excellent pastilles.—Gum storax, 6 parts; gum benzoin, 6 parts: gum copal, 6 parts; cascarilla bark, 3 parts; charcoal, 48 parts; gunpowder, 1 part. All these must be in the very finest powder, and moisten with starch mucilage; shape into little cones and dry.—Erin-go-bragh.

[47394.]—**Combustion of Coal.**—Since one cubic foot of air weighs ·0807lb., all you have to do in order to change weight into volume is to divide the given weight by ·0807. Referring to query 47094, 237·4cwt. = 112 × 237·4lb. = 26588·8lb. = 26588·8 / ·0807 cub. ft. = 329477 cub. ft. of dry air at 0°, and pressure of 15lb. (not 2,942 cubic feet, as given in my answer to query 47094, p. 360).—R. Kanthack.

[47395.]—**Large Tank.** — The tank should be put together in position, and the bolts all put in, though not screwed up tight. If there be fillets cast all round the pieces to give parting room for the joints, the bolts may be just hand-tight; if not, some pieces of wood must be cut so as to preserve the shape of the tank, and the bolts tightened just so as to hold wood in position. The rust-joint is made with one part of powdered sal-ammoniac, two parts of flowers of sulphur, 95 parts of iron borings, pulverised as much as possible, and mixed with water, so as to form a paste, and caulked in with caulking chisel. This cement sets quickly, but if time allows, 200 parts iron borings, one flowers of sulphur, and two sal-ammoniac makes the strongest joint, though slow setting. The bolts may all be tightened after cement has set. —Fred. Walker.

[47397.]—**Engraving Machine.**—The tracing point at one end of the brass rod of the machine is passed by hand over the figures, which are held in the curved back, and as nearly in contact with them as may be; the other end of the rod to which the drill is fixed being supported in gimbals is, of course, free to move in every direction. Your querist will probably at once see that the reduction of the copy depends upon the distance of the drill from the point of suspension in the gimbals. The driving-wheel is, of course, turned by an assistant. A very full description of the valuable engraving machine of Messrs. Cooke, of York, will be found in, I think, the November number of *Engineer*, 1870.—N. S. Heineken.

[47400.]—**Electric Light for Workshop.**—The electric light will cost you more than twice as much as gas. You have about 500 candle-power illumination now, and to get a similar amount of light from incandescent lamps you would require 25 of them, and to light them a 30-light dynamo and a good 10-horse engine. You can readily calculate the first cost, and, with interest and working expenses, you will find that twice the cost of gas will be much below the cost of electric lighting by incandescence. On the arc principle you can use a smaller dynamo, and a 4 horse-power engine, and get 3,000 candle-power. If you have plenty of driving power to spare, then, with a little extra attention required in the use of a dynamo, the cost would be about the same as the gas.—W. J. Lancaster.

[47403.] — **Lawn-Tennis Court.** — I should think that it would be best to make the court of cinders, thus:—Level and ram the surface; put a 3in. layer of broken stones or bricks, small enough to pass through a 1½in. ring; cover with about 1½in. of dry breeze or ashes. Well roll and keep rolled. If good binding gravel is obtainable, it may be used instead of the ashes, and makes a very good court. If desired to be asphalte, level and ram as before. Put 6in. of concrete, composed of clean, fine gravel (shingle) and lias lime, one of lime to five of gravel. Cover with gas-tar asphalte (made with gas-tar, a little lias lime and dry clean sand boiled), and spread and level while hot. Real asphalte may be used; but, of course, it is much more expensive. The surface may be formed of the best Portland cement and washed sand, one to three. But this also is expensive, and not so likely to stand out of doors. Altogether, I think the cinder or gravel court would be the cheapest.—Hemisus.

[47403.]—**Lawn-Tennis Court.**—To make any hard court, you must excavate four or six inches of soil and fill in with concrete or rough stones, mixed with blue lias lime, and brought to a level. On the top of this you can put cement; first a layer of 1½in. or 2in. mixed with half sand, and then on the top another layer of pure cement. Or you can put asphalte, i.e., gravel boiled up with gas-tar. If this mixture is not boiled, it is useless. Of this, too, there should be two layers, the top one being the finest; but I would not put this on for three or four months after the first, which may be played on, so that the soft places will be discovered. The asphalte must be well rolled, and over the last coat must be sprinkled a little very fine and clean gravel. Or you can make a fair court of cinders, putting them on coarse below and finer above, beating and rolling them well in; or, if you have good gravel in the neighbourhood that can be used, and, if it is of a binding nature, it will be preferable to cinders. Remember that any court must be made either convex or inclined towards one side, to let the water run off; and that without a margin beyond the bare 26 yards by 12 yards, which at the ends should not be less than two or three yards, it will be very inconvenient, as 25 per cent. of the strokes require the players to run outside the actual boundary of the court. An asphalte court will cost about £50, and a cement one nearly double; if made of cinder or gravel, the cost should not exceed £15 or £20, though in all cases the expense will much depend on the material used for the foundation.—Devoniensis.

[47404.]—**Carriage Lamps.**—One reason why the oil flows over is this:—The reservoir being above the wick the oil flows down and out at top of wick. This occurs always when the lamp is out, and sometimes when lit, on account of the wick not being able to burn all the oil as fast as it comes. I dare say the motion of the train also increases the evil. The remedy would be to have the reservoir below the wick. If you look through the back numbers of "E. M." you will find a similar question fully answered.—G.

[47405.]—**Locomotive.**—One would be better able to form an opinion upon seeing the corrosion, but I have no doubt there has been a galvanic action quite sufficient to account for the wasting of the plates.—W. J. Lancaster.

[47406.]—**Dew-Cap.**—You can make a very good dew-cap out of cardboard. First, put a thin strip of note-paper around the end of telescope containing lens, then begin to paste long strips of thin cardboard round and round until about ⅛in. to 3-16in. thick; then make a cardboard tube, 9in. long, to be glued true on the outside of the cardboard ring you have already made. Paint the inside of tube dead black, and the outside with two or three coats of bright black.—W. J. Lancaster.

[47407.]—**Concave Lenses.**—You can do the grooving with a small wheel; similar to those used by glass-cutters, running in the lathe. You will be unable to make a good job of one: there must be experience before there is success. Still, you can but try, and if you will, you can in time succeed.—W. J. Lancaster.

[47412.] — **Coulomb's Law of Electro-Statics.**—You must read, "inversely proportional to the *square* of the distance between them." This is the correct law.—W. J. Lancaster.

[47412.] — **Coulomb's Law of Electro-Statics.**—The formula $f = 9 \times 9^1 / d^2$ is correct; see also what is said in art. 16, p. 16, which treats on the law of inverse squares.—R. Kanthack.

[47412.]—**Coulomb's Law of Electro-Statics.**—The formula is correct. The former statement must have been an oversight on the part of Prof. Thompson. If "H. E. A." refers to Art. 16 of Thompson's book, he will find the Law of Inverse Squares stated correctly.—Vis Viva.

[47412.] — **Coulomb's Law of Electro-Statics.**—I have not Thompson's book at hand, and, therefore, do not know what may be the case to which he is referring; but, certainly, the force exerted between two small charged spheres is inversely proportional to the square of the distance. This does not necessarily apply to every case.—Ll.B.A.

[47413.]—**Marble.**—Take two parts of carbonate of soda, one part of powdered pumice-stone, and one part of finely-powdered chalk; sift it through a fine sieve, and mix it with water; then rub it well all over the marble, and the stains will be removed; then wash it over with soap and water, and it will be as clean as it was at first.—F. S. Harrison, Alresford, Hants.

[47420.]—**Steinheil's Eyepieces.**—These eyepieces are constructed on what is known as the "solid stick" principle. There are two methods of achromatising a sphere: either by placing a double concave stick of flint-glass between two double convex-lenses of crown-glass, as in the Coddington lens, the whole forming, essentially, a cylinder with spherical ends; or by placing a concavo-convex lens of flint-glass at each end of a double convex-stick of crown-glass. Steinheil's e.p.'s are made on the latter plan; whether they are patented or not I cannot say.—O. V.

[47421.]—**Transparent Gum.**—Have you tried a little alum-water? I have only just thrown some away that I made up five years ago, to mix with plaster of Paris, for putting the brasses of paraffin-oil lamps on, to prevent the capillary action of the plaster. It was as bright as the clearest water to look at.—Jack of All Trades.

[47422.]—**Stamping Note-Paper.**—All whites, for whatever purpose, distemper or oil, require a little black or blue mixed with them, to neutralise the yellow tint thrown up by the medium with which they are mixed. Ivory-black preferred; blue cannot be depended upon. Many colours lose their bloom when mixed, mix them with what they will; but an artist that knows what he is about can remedy this to a great extent. Whites, greens, lakes, and vermilion are very delicate in this way, and the purest medium is required for them, or they get foxey: some blues are the same.—Jack of All Trades.

[47424.]—**Crystallising Vessels for Epsom and Glauber's Salts.**—Why not use stoneware cisterns? Nothing cleaner.—Jack of All Trades.

[47425.] — **Electrical Measurement.** — As current = E.M.F. / R, the law of deflection does not apply to the "electromotive force" and "resistance," for both E.M.F. and R. might be simultaneously decreased, while "current" remained constant.—R. Kanthack.

[47425.]—**Electrical Measurements.**—I am afraid "Student" has rather vague ideas about electromotive force and resistance, but I will try to be as clear as possible. 1st. A galvanometer can only measure one thing directly, namely, current; but we are able to measure E.M.F. and resistance indirectly. Supposing the same current to go through a galvanometer, it is obvious that if the galvanometer be in the same magnetic field, there will be the same deflection. Now by Ohm's law $E / R = C$. We may therefore measure the same current in two different cases, and yet E be different because R is different; if we know E to be the same then R will be the same—not otherwise; or if we know R to be the same, E must be the same. We may thus compare the E.M.F. of two batteries by first getting a deflection with a known resistance—this will be the resistance of battery and coils of galvanometer and any other inserted resistance; now replace the first battery by the second, and add or subtract resistance till we get the same deflection, then the two electromotive forces will be to one another directly as the two resistances. By making the known resistance very large we may neglect resistance of battery and coils of galvanometer. I do not at this moment think of any method of measuring resistance by equal deflections. Any further help I shall be glad to give.—Ll. B. A.

[47427.]—**Calculating Strains in Boiler.**—It is difficult to explain this without the aid of algebra, but the process is so simple that I will proceed as follows. To simplify the matter we wil first suppose that the seams or joints of the boiler are as strong as the plates themselves. Now to get the strains on the circumferential seams, or on the cross section of the boiler, it is evident that if we find the area in square inches of one end of the boiler and multiply by the pressure on each square inch of this surface, we shall find the total strain on the cross section of the boiler, and if we divide this total strain by the number of square inches of iron in the cross section of the boiler, we shall find the strain on each square inch of iron in the section of the boiler. Call the radius of the boiler r, the pressure of steam per square inch P, and the strain per square inch of iron in the section of the boiler S. the area of the circular end will be πr^2, the pressure will therefore be $\pi r^2 \times p$. The number of square inches in the section of the iron will be $2 \pi r \times t$; t being the thickness of metal; divide one by the other and we get $S = \pi r^2 p / 2 \pi r t$, or $S = r p / 2 t$. Now for the longitudinal seams or section. Suppose the boiler to be made up of a series of rings, 1in. wide; the strain tending to force the two halves of each ring apart will be $2 r \times p$; the area of the two ends, or the area of the metal so strained will be 2 (1in. × t), or simply $2 t$; divide as before, and we get $S = 2 r p / 2 t = r p / t$, which is evidently double of the first value of S, obtained for the cross section of the boiler. There appears to be some mistake in the figures given in the query—*feet* have been multiplied by *inches* apparently. The diameter of the boiler is 6ft., so $r = 36$in. p is 50lb., and $t = \frac{3}{8}$in. The first value of S will therefore be 2,400lb., and the second value of S will be double that, or 4,800lb., or something over two tons per square inch strain on the plates of the boiler. The ultimate strain of best plates is 25 tons per square inch, but this should be multiplied by ·7 to get the strength of double-riveted joints, or by ·56 for single-riveted. In calculating the area of the end of the boiler, we must take it as if it were flat, and not curved, as it usually is. I have referred to the query on p. 387, but I never heard of the end of a boiler, 5ft. diam., being made flat and without stays. It would be difficult to find a formula for calculating its thickness.—M.I.C.E.

[47428.]—**Etching.**—To "R. B."—The decimals you give of proportions of etching mordant are quite right; but if you take 15½ grains troy weight to equal 1 gramme, it will be exact enough; I am afraid there is no simpler way of finding proportions, but any druggist would make up the mixture for you. I put 2 drachms of beeswax to 4oz. of turpentine for ground; but I think 3 drachms of wax to same amount of turpentine would be better, as two coats of my ground are not enough to protect the plate properly; you have probably put too much wax in yours; I think Japan varnish is very much the same as Japan black. I used Brunswick black instead. If you pour a portion of the ground on to the plate, moving it about so that it goes all over the surface, and then let it run off at one corner back into the bottle, a sufficient quantity will remain on the plate for a first coat, and a second coat applied in the same way, when the first one is dry, will be enough to protect the plate, and will be easily penetrated by the heavy steel needle with an etching point at each end; it is well to keep a cork on the end not in use when you are etching, as you may injure your eye with the point. The chief advantage of smoking the ground is that it prevents the polished copper dazzling the eye, and also that you can see more readily what progress you are making, the bright lines where you have etched showing through the black surface. If you put the plate in etching fluid before grounding it (page 39, "Handbook") the surface will get dark and will do away with dazzling effect, and the point of the needle will scrape away the dark shade when you etch, and the bright lines will show on the dark surface. The brightness of the copper is deceptive, however, and makes one imagine that there is more work done than there really is. If you wish to smoke plate you might try camphor. I always set fire to my ground when I use ordinary tapers to smoke it; I haven't tried camphor. I have not much experience in etching, but I shall be very glad if I can save you unnecessary failures. You might advertise your address, and I could correspond with you direct, and save your having to wait so long for a reply.—R. B.

[47429.]—**Electro-Gilding.**.—Give the articles a coating of copper in a sulphate of copper bath. The copper will cover the solder. Then try your gold.—Nihil.

[47429.]—**Electro-Gilding.**—Scratch-brush the soldered part dry. Then use a more intense current to drive the deposit on to the part. Don't have too poor a solution.—J. E. A.

[47429]—**Electro-Gilding.** — "An Amateur" who says he cannot make the gold touch the soldered parts of the article he wants to gild, will find that if he takes a few pieces of iron wire and ties them together so as to form a small brush, and dips them in a solution of blue copperas, and then draws them over the soldered parts so as to form a thin coat of copper, he will then be able to manage to make the gold take to it.—Possum.

[47431.]—**Speed.**—The time required is that at which the sum of the lengths would be covered at the sum of the speeds; the question, therefore, becomes, How long will a train take to run 66 yards at 90 miles an hour? 66 yards is 3-80 of a mile; the time required is thus, 3-7200 of an hour, or 1½ second.—Fellow of the Institute of Actuaries.

[47431.]—**Speed.**—Your query is the same as "How long does it take two bodies [brake-vans in this case], the one running at 50 miles per hour, the other at 40, (30 + 36) yards apart, to meet? This is equal to "How long does it take a body, running at 90 miles an hour, to travel 66 yards?" The answer to which is 1½ second, 90 miles: 66 yards :: 1 hour: 1½ second.—Camera.

[47431.]—**Speed.**—As I understand this query, its solution appears to be as follows:—Since the trains are moving in opposite directions at 50 and 40 miles an hour respectively, the two engines are separating at the rate of 90 miles an hour. Now the total length of the trains is 66 yards; how long will a train moving at 90 miles an hour be in travelling this distance? It moves 44 yards in a second, so that the time required is 1½ second. —O. V.

[47431.]—**Speed.**—50 miles per hour = 24 4-9th yards per second, 40 miles per hour = 19 5-9th yards per second. It is, therefore, evident that in one second of time both trains have travelled through (24 4-9th + 19 5-9th) = 44 yards of space. Then, since the first train is 30 yards, and the second 56 yards long, when the brake-vans are clear, both trains extend 66 yards. It is, therefore, required to find in what time both trains will have run 66 yards. Let x = required time in seconds.

$$x\left(24\frac{4}{9} + 19\frac{5}{9}\right) = 66;\ \text{or } x = \frac{66}{44} = 1\tfrac{1}{2},$$

or 1½ sec. = time required.—C. W. B.

[47431.]—**Speed.**—As we have to find when the ends of the two trains are together, it is evidently the same as to find what time it would take two bodies to meet, 66 yards apart, one going at a rate of 50 miles an hour, and the other at 40 miles an hour. This is easily done. Let a = distance in yards first body has to go before meeting, then $66 - x$ is the distance the second body has to go. The first body takes one hour to do 50 miles or 3/4400 minutes to do one yard, and $\therefore 3x/4400$ minutes to do x yards. Similarly the second body takes $(366 - x)/3520$ minutes to do $(66 - x)$ yards. But these times must be equal. $\therefore 3x/4400 = 3(66 - x)/3570$ which gives $x = 110/3$ yards. And the time taken by the first body to do 110/3 yards = 110/3 × 3/4400 minutes, or 1/40 of a minute, which is required time. Or, arithmetically—it is clear that the point at which they meet divides the 66 yards in the ratio of the speeds. And the ratio of the speeds = 5-4. ∴ first body goes 5-9 of 66 yards or 110/3 yards, and time is 1-40 of a minute, as before. —Hemisus.

[47431.]—**Speed.**—Let A = the train 30 yards long travelling at the rate of 50 miles per hour; let B = the train 36 yards long travelling at the rate of 40 miles per hour. If A were at rest, B's brake-van would have to travel 36 + 30 = 66 yards to clear A's van, and *vice versâ*. Therefore, by proportion, if A does 50 miles in 1 hour, how long will it take to do 66 yards? As 88,000 yards : 66 yards :: 3,600sec. to answer = 2·7sec. Again, if B does 40 miles in 1 hour, how long will it take to do 66 yards? As 70,400 yards : 66 yards :: 3,600sec. to answer = 3·375sec. Now take the average time they would do 66 yards in.

3·375
2·7
2)6·075sec.
3·0375 = average time.

As the two trains are running in opposite directions, it would only take half the above time for the vans to clear.

2)3·0375
1·51875sec. answer;

or, roughly speaking, 1½sec.—Solus.

[47433.]—**Portland Cement Floors in India.**—Possibly the Portland cement cracks:—(*a*) because the coat (¼in.) is not thick enough; (*b*) because the previous coat of plaster is allowed to get too dry before the cement is put on, or is too smooth to allow the cement to "grow" to it. The plaster surface should be roughened first, and then the cement put on, at least ½in. thick.—Hemisus.

[47433.] — **Portland Cement Floors.** — The experience I have of Portland cement as a finish to concrete floors is that ¼in. is not sufficiently thick. The soundest floor is that in which no difference is made between the finishing coat and that immediately beneath—in fact, there should be no finishing coat; but the whole floor, for 1½ to 2in. thick, should be homogeneous; and this, as it sets under the trowel or float, will be fined by the coarser sand settling to the bottom; 1 to 3 will be found a better proportion than 1 to 1, which is too *fat*. One cause of a thin skin separating, is the neglect of putting a fillet of wood along one side and one end of the apartment, to be removed as soon as the cement begins to set, for on this taking place, the whole mass expands in every direction; consequently, the centre of least resistance is heaved up, only to be speedily destroyed by traffic over it. The water-flooding is an excellent expedient if it is not used too soon.—C. I. B. F.

[47433.]—**Portland Cement Floors in India.**—In Calcutta, where I had a great deal to do with cement floors, we used to proceed thus:—The substratum having been laid, with bricks on edge set in mortar, or with concrete, we then spread a layer of about 4in. of a composition which is made of pounded bricks and freshly-slaked lime. The bricks are to be pounded into pieces about the size of a pea or a little larger; or what is called "soorkee siftings" may be used, which is simply the larger portions of the pounded bricks which will not pass through the sifting screen. A mortar is then made of one part by measure of lime to about two parts of the siftings, with a small proportion of finely-powdered bricks. This mixture is well mixed with water, and laid over the substratum to a depth of 4in.; a row of women and boys is then set to work, who beat it with little wooden mallets; this beating must go on for some days, until the layer is thoroughly consolidated, and by that time the layer will have become reduced in thickness to about 3in. It is better to allow it to set for some days before laying on the cement. The floor in this stage will have a somewhat rough appearance, which is all the better, as the cement will stick to it better than if it were smooth. The sand used for mixing with the cement was a coarse, sharp sand, dug from pits (not river-sand). About one and a half to two parts of sand are to be mixed with one of cement, and not too much water. This should be spread over the floor to a thickness of not less than ⅜in., and well levelled. A little dry cement is then to be powdered over the surface, and rubbed in with a mason's trowel; by this means a hard skin is produced when set. There is no use in flooding with water. The natives of India are very expert in making a hard shiny surface to these floors, by rubbing with the trowel slightly moistened. In England, where pounded bricks would be costly, probably gravel and sand would do as well.—M.I.C.E.

[47433.] — **Portland Cement Floors.** — "A Melting Mechanic" never will succeed in the way he proceeds. Bricks set on edge give no bite to the cement, and he has practically only a ¼in. flag on his floor, which cannot possibly stand any weight without cracking. Let him break up his bricks, stones, or sharp clinkers into small pieces, the largest no bigger than walnuts. Keep these free from mould or dirt—clean sand will not hurt: mix these in the proportion of one bucket of best Portland cement to seven or eight buckets of his hard material; put these on a board stage about 6ft. square; mix well together whilst dry. When mixed, get one man to pour water very clean out of a fine-rosed water-can on to a part, whilst another turns the same portion over on to a free portion of the wooden stage. This goes on until all is turned over. It must be then turned back again, more water being added, if necessary; but it is better to add enough the first time. If not mixed sufficiently it may be turned over a third time. It is then ready to be placed in a barrow, and taken to the spot where it is to be laid. A third man should lay it while the first two are making a fresh lot. A layer of 2½in. to 3in. is thick enough for garden walks or inside houses. As it is laid it should be well rammed, and the surface made as level as possible with the slope or fall it is intended to have permanently. When finished the surface will present a honey-combed look, with plenty of little holes to bind the next coat. Allow it to stand a week or a fortnight before finishing, watering the surface from time to time, and, if obliged to walk on it, place boards across it. It is now ready to finish in this manner: Pure cement and water are mixed together of the thickness of cream, and well worked on to the surface with a plasterer's trowel, putting on as thin a coat as possible, and working the cement into all the holes and crevices, and leaving a smooth surface. This should not be walked on for at least a week, and should be often watered whilst setting. A layer of sawdust renders this easier, as it retains the water longer; but sawdust must not be put on the first coat, as it would fill the little holes which give the bite or key to the final coat. If this be well done, a floor will be made which will practically last for ever. New cement is not good for forming concrete. It should be at least a month old, and kept in a dry place, being turned over occasionally, so as to expose the whole to the air. If fresh cement is used it is apt to crack. It is also important to have everything clean — bricks and stones clean and free from vegetable matter, the water quite pure.—E. H. Roe.

USEFUL AND SCIENTIFIC NOTES.

◆

A Jointed Axle for Tramcars.—A tramcar axle has been recently patented by a Dane, the object of which is to allow the wheels to pass round sharp curves without grinding. For this purpose the axle is divided in the centre, the end of one half having a hollow, and that of the other a corresponding projection, somewhat similar to a ball-and-socket joint, the necessary stiffness being given to the axle by a tube which surrounds the axle and extends between the naves of the wheel, against which it bears by gun-metal collars. At the centre, between the tube and the axle, is a gun-metal bearing, in which the axle can revolve. The wheels act in such a manner that in running along a straight line the wheels and axle turn together, as in an ordinary pair of wheels, but on passing round a curve the axle slips round in its joint, so that the wheel on the inner radius of the curve is retarded and the outer wheel accelerated in proportion to the sharpness of the curve, great smoothness being obtained in the vehicle, and less wear and tear of the tire and rail.

A New Use for Old Tin Cans and Scrap Tin.—According to the *Berg-und-Huettenmannische Zeitung*, a better method for utilising old tin cans than simply to melt off the solder has been devised. E. Rousset first heats the tin, old or new, in an oxidising flame, which burns up all the pure tin and that combined with iron. When this is stopped the scraps of iron are seen to be covered with a brown and brittle crust, the upper layer consisting of oxide of tin, the lower of magnetic oxide of iron. It is passed through rollers and then forms a powder that contains both oxides. The iron that remains after sifting out the powder makes good wrought iron or cast iron, but is particularly fitted for precipitating copper. The oxide of tin, although mixed with oxide of iron, can be easily worked into tin, and the metal obtained from it is free from sulphur and arsenic. But will it not contain traces of lead?

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[47434.]—**Lathe.**—Will Mr. J. H. Evans, or any other kind reader of "E. M.," inform me how to Babbitt the mandrel bars, rest, &c., of lathe illustrated in No. 876? What am I to put on mandrel, &c., so that they will not be fast when Babbitted? How am I to chamber the holes in standards? How is Babbitt metal made? Would white metal answer as well?—MINER.

[47435.]—**Magic-lantern Mechanical Slides.**—Would anyone who is in possession of the choreutoscope or the chromodrome, give a drawing of each part separate with sections? He would, I think, be conferring a favour on many amateurs. There are a number of magic-lantern manuals published which appear to be merely commercial puffs brought ought by shopkeepers to recommend their own apparatus. Can anyone say if Mr. Samuel Highley is still alive? I made his acquaintance in 1866, and got a good deal of information from him on magic-lantern matters. Nothing published on the subject, so far as I am aware, equals his papers on Lantern Optics, published in Cassell's "Technical Educator." He gives full constructive details for lantern-fronts—useful alike to the shopkeeper who employs journeymen brass-fitters to make up apparatus, and to the amateur who essays to construct his own.—GEREB ADMI.

[47436.]—**Pain in the Bowels.**—Will Dr. Edmunds kindly advise in my case?—I have been subject for quite ten years to sudden attacks of violent pain in the bowels, which nothing will relieve until my bowels are moved; the pain lasts about four or six hours, leaving afterwards great soreness, especially on the right side of the stomach, so much so that I can scarce walk upright for several days. I am a printer by trade, 28 years old, and a moderate liver. I have sometimes thought it was lead-poisoning, caused by my trade; but the symptoms do not agree with what I have read on the subject.—W. B.

[47437.]—**Steam-Pipe.**—Would anyone kindly tell me the standard "pitch" of threads used for steam-piping, from, say, 1in. up to 3in.?—NEW QUERIST.

[47438.]—**Astronomical.**—"F.R.A.S.," in letter 20150, p. 326, states that one of the necessary conditions for dividing Delta Cygni with a four-inch glass is twilight. Does the remark apply only to this particular object? If not, the inference is that twilight is the best time for certain delicate observations. The point is of interest to observers. Will "F.R.A.S." kindly explain?—RIGEL.

[47439.]—**Cement.**—Can any correspondent furnish me with a recipe to make the above to resist 300° of temperature that will not crack, and be durable and inexpensive?—W. R. H. R.

[47440.]—**Converting Peat into Charcoal.**—Will some reader give particulars of the process of converting peat into charcoal?—JAS. SMITH.

[47441.]—**Minute Photography.**—With what kind of lenses were the French despatches reduced during the siege of Paris, and what kind of collodion was employed? I have tried to photograph a newspaper with the objectives of a best microscope, but I do not succeed.—E. B. F.

[47442.]—**Bicycle Touring in Scotland.**—Will some of your many bicycle correspondents give a description of a bicycle tour in the south of Scotland, say, from Newcastle to Edinboro', and if it is practicable to visit the country about Loch Lomond (and the places which should be avoided), so as to take the advantage of train or boat where convenient; and any information about the preparing for such a tour: hotels, fare, scenery, and the disposing of luggage, &c., &c., will be most thankfully accepted.—TOURIST.

[47443.]—**Medical Coil.**—To MR. FRED. WALKER.—Please say if correct sizes of above are given in "E. M." for June 9th, as I have made a reel $2\frac{1}{4}$in. dia., 3in. long, and $\frac{1}{2}$lb. c.c. wire would only be about 4 layers. Also, if every third helix means every third layer, and oblige a—MONGERIL.

[47444.]—**Boiler Corrosion.**—Can any of our readers inform me how I can make a cheap and efficient water-filter large enough to supply a six-horse Cornish boiler? I pump the water from a well into a cask. It flows from the cask to one of Hancock's inspirators, which forces it into the boiler. The water has a large quantity of lime in it (so I am told), and I get a large amount of corrosion on the boiler-plates, which I am anxious to stop.—E. M.

[47445.]—**Electrical.**—Can any of your correspondents give me a reply to the following questions?—What is the electromotive force of a Sutton secondary cell, and how is it calculated? What is the internal resistance of the battery? How many cells would be required to keep a 10-candle Swan lamp in action? How is the electromotive force of a Faure cell calculated theoretically?—NAVAL ARCHITECT.

[47446.]—**Photographic Enlarging.**—Will some reader kindly give the best method for making enlargements on paper of a good tone by means of artificial light?—J. NOON.

[47447.]—**Repolishing or Redipping Sheet Brass for Labels on Tinwork.**—I use a great quantity of sheet-brass for labels, and to make it soft for stamping on I put it in the fire, which takes the brightness off it. Would any kind reader let me know what to dip it in to give back the brightness to the brass?—BLOOD STOCK.

[47448.]—**Induction Coil.**—In my "E. M." for Sept. 9, 1881, there is a drawing of a coil made by Ritchie, of Boston, with tube curved, and a number of divisions like "Inductorium's" of some years back. The core and primary are, however, said to be inclosed in a "heavy glass tube closed at the ends." How would the battery be connected with the primary, and what kind of a contact-breaker could be used under such circumstances? The correspondent sending sketch, &c., was "Roi Ne Puis," &c.—B. H.

[47449.]—**Induction Coils.**—I am sorry to trouble Mr. G. Tolman; but I cannot find out the meaning of a sentence he used when kindly replying to query 46603, p. 288. He says (apropos of a primary of two layers of No. 16), "two layers of 16 only short-circuits the cell," and advises 3 of 18 or 2 of 20 instead. I cannot understand the "short circuit": does it mean that 2 layers of 16 do not offer sufficient resistance to the battery to give proper effect? I suppose the 2 layers of 16 represent about $\frac{1}{2}$lb., and that has a resistance of about 1-10th of an ohm. What the resistance of a bich. is I don't know, as the books I have (Jenkin and Deschanel) leave out the single-cell bich. altogether. If I am right in my supposition as to the meaning of the sentence, may I ask why a comparatively unchecked flow of electricity does not work up the energy of the core as much as a restricted flow? Of course, I see that you would get more coils, and thus more excitement, with the smaller wires; but I should not have thought this difference in a 9in. coil would have had much effect.—B. H.

[47450.]—**Repairing Mirrors.**—We have several large French plate mirrors that have scratches, frosty-looking, and other spots which spoil the glass. Can any of your readers tell me how to proceed in the matter?—D. C. MUKER, 321, Larimer-street, Denver, Colo., U.S.A.

[47451.]—**Improving Definition of Telescope**—I would like to ask Mr. Lancaster or any one able to give the desired information (if the same can be given). Denver is located about 12 miles from the foot-hills of the rocky mountains, making the altitude 7,000ft. above the sea. The snowy range is from 50 to 100 miles distant from the city. We have a dark blue atmosphere around the mountains; at times it will assume a grey misty colour even on clear bright days. This, so far, has obscured definition with the telescope, that it cannot be used. I have tried powers of 24—49, 88—130, 240, none of which gives satisfaction. My o.g. is $4\frac{1}{2}$in. aperture, 62in. focus. Now what I want to know, is there any way, under reasonable circumstances, to improve the definition?—D. C. MUKER, 321, Larimer-street, Denver, Colo., U.S.A.

[47452.]—**Pleurisy.**—To DR. EDMUNDS.—About a year ago, I (aged 18) fell ill with pleurisy in the left lung, and according to medical instructions, I applied iodine dissolved in spirits of wine to the side mentioned. For some time I appeared to be progressing favourably; but just as I was congratulating myself that I had recovered, the pains returned in full vigour. All through last winter I was never free from pain for more than a fortnight at a time, and during the same time my temperature was always above 100°. Thinking over the circumstances of the case, it struck me that the iodine might be injuring, instead of helping, my recovery, and many little circumstances then came to my recollection, which made me almost certain that it was so. Since the beginning of March I stopped using it, with the doctor's permission, and from that time till now my recovery has been most surprising.—Is it usual in cases of pleurisy to apply iodine, continually, for such a length of time (8 months), and may I not, with some justice, lay the blame of my protracted illness on the use of iodine?—ANONYMOUS.

[47453.]—**Varnish for Clay Pipes.**—Could any of your readers kindly give me the information as to what wash or varnish is used to give that glossy appearance to clay pipes? I have tried several different solutions, but when the pipe is hot it becomes sticky, and has an objectionable smell.—S. T. B.

[47454.]—**Bleaching Old Willow Baskets.**—Can any correspondent inform me how to restore to their original whiteness baskets that have become discoloured and turned yellow by the sun and weather? I mean the ordinary willow baskets.—F. T. MILNER, Bishop Auckland.

[47455.]—**Boiler-Tube Piecing.**—Will any one give a description of apparatus for brazing loco. boiler-tubes by gas; and if superior to coke-fire brazing, to state wherein it consists?—J. G.

[47456.]—**Canvas Boat Making.**—Which I am about to start, is intended to be about 12ft. long. How broad and deep should it be for safety? How strong should the ribs be, &c.? How long should the mast be?—would bamboo be best? What shape should the sail be? All information and diagram (if possible) would be of great help.—L. NELSON.

[47457.]—**Injector.**—My injector (a Friedmann's, Class 6), after three seasons' use, suddenly fails to work. I have taken it apart and cleaned it without avail. One-half the water comes out at the overflow. The passages are all clear, and the cones, as near as I can judge, are quite in line with each other. The water is full of mud and sand, as it always is at this season of the year, and the temperature is about 52° Fahr. Steam-pressure 50 to 75lb. There is no obstruction in pipes or check-valve between boiler and injector. As it is used on a steamer a filter is inadmissible. Is there a remedy?—BACKWOODSMAN.

[47458.]—**Reeds for Jacquard Loom.**—Could any of the readers of the "E. M." inform me if there are any improved reeds for a jacquard loom which spring out after the shuttle has passed, so as to make the weft cross the warp in a circular form, or rather in the form of a half-circle? Or if there are any reeds, or any other means of making weft cross the warp in the above manner?—A. T. J.

[47459.]—**Silvering Looking-glasses.**—Can any one inform me if Brashear's process is suitable for silvering ordinary looking-glasses (not specula), and if so, kindly give its method of application?—C. H.

[47460.]—**Weight of Dynamite.**—Can some reader give the weight and explosive strength of dynamite, as compared with gunpowder.—J. C., Pera.

[47461.]—**Black Transfer Paper.**—Which is the easiest method of preparing black transfer-paper?—J. C., Pera.

[47462.]—**Legal.**—To MR. WETHERFIELD.—Will you kindly say what I can do in respect to the following?—I bought a £1 2s. petroleum oil cooking-stove at an ironmonger's under the impression that it would bake, boil, cook, &c., as set forth in the circular to do; but found, when I came to try it, that I had been deceived. In fact, it is quite useless: taking $4\frac{1}{2}$ hours to bake a small tart enough for two persons, and over 1 hour to cook $\frac{1}{2}$lb. of steak. Have taken it back and tried it in the shop, but is no better; nor can it be made so, as the thing appears entirely wrong, not being heat enough. The proprietor of shop refuses to refund money, or even let me have other goods to the value of £1, and says the thing is no good to him, and that I am bound to keep it. I cannot afford to lose the money. Can I legally get the money refunded, or goods to the amount.—F. W.

[47463.]—**Change-wheels for Screw-cutting.**—Can any reader tell me how to calculate what change-wheels to use for any particular screw? For the common screws I know which wheels to use; but for any odd screw I am puzzled. The only way I can manage is to try, try, try again until I hit on a combination which will suit, and as out of 24 change-wheels taken four at a time, there are about 50,000 combinations, the chance of hitting on just what I want is, I feel, rather remote. Surely there must be some direct method of calculating this. What plan is used in engineers' shops?—TRY AGAIN.

[47464.]—**Wood Shrinking.**—I have to make a number of wood wheels about 2in. dia., and encircle each end with an iron ring about $\frac{1}{2}$in. wide. These wheels have to run at a great speed; and I find after shrinking the wood by putting them in a hot place for a couple of days, then driving on the ring, in a short time the wood closes in still more, leaving the iron ring quite slack. Is there a method of making the wood hard and tough, and shrinking it to its utmost, previous to driving on the rings? Any information respecting the above would be gratefully received by—ANXIOUS TO KNOW.

[47465.]—**Faded Daguerreotype.**—Can any one tell me if it is possible to restore a faded daguerreotype, and also where to get it done? The figures are just visible if held in a certain light.—F. E. B.

[47466.]—**Iron.**—What is the strength (elastic and ultimate) of wrought iron at a bright red heat, and what is it at temperatures intermediate between that and 212° Fahr.?—CASMORE.

[47467.]—**Observatory on House.**—I have a fixed telescope in my observatory, on the Romsey plan, in the country; but owing to my not living there regularly, I find it very inconvenient to make observations as often as I would like. Often the prospect is for a clear night, and when I get there it clouds up; and then again, when I do not go out on account of unfavourable indications, it clears up when it is too late; so I have been thinking of removing my telescope to the City, where my residence is more permanent. If I do, it will have to go on top of the house, as, owing to the surrounding buildings, there is too little sky from the ground. Now I should like the opinion and advice of some of your readers upon this point. I know that on general principles the top of a house is a bad place for a telescope, unless upon a pillar from the ground up; but situated as I am, it would be much more convenient to have it there, provided the tremors are not too great. In one of the back Vols. of the MECHANIC, I noticed where Mr. G. F. Chambers had such an observatory, and he said that it worked very well; but he gave no directions how to put it up. My telescope is a 4in. equatoreal, by Cooke, with driving clock, &c. There is no heavy driving in the immediate neighbourhood, an open square being in front, and after eight or nine o'clock very little of any kind.—AMERICAN.

[47468.]—**Transit of Venus.**—Would "F.R.A.S.," or any other of our astronomical correspondents, kindly advise me as to the following?—I propose going to Jamaica for the purpose of seeing the Transit of Venus in December next. I wish to observe the optical phenomena only, without reference to anything else, and would like to know the chances of a clear sky and good definition at the time; also, the local times of contacts as nearly as possible, and the elevations of the sun at the beginning and end of Transit at Kingston. Would it be better to use a fine $3\frac{1}{4}$in. Cooke refractor, or a 5in. silver-on-glass reflector with double sun diagonal in either case?—JAMAICA.

[47469.]—**Galvanising.**—Can any reader tell me how to prepare wrought and cast-iron to be galvanised, and what are the tanks made of to resist the action of the chemicals? Also, will glazed stoneware stand fire?

Perhaps "Jack of All Trades" could assist me. Expense is no object.—T. J. R.

[47470.]—**Watch Repairing.**—To "A FELLOW-WORKMAN" OR "ALFOJOE."—Would you say how to hold the cylinder while punching in the bottom pivot? I have a cylinder plug tool which is very good for punching them out. The material dealers have cylinder pivots partly shaped. If I were to get a gross assorted, could I select one ready for putting in cylinder, and then commence to turn in pivot?—X. Y. Z.

[47471.]—**Watch Repairing.**—Would "A Fellow-Workman" or "Alfojoe" kindly give a hint with regard to the best way for turning in foot or cock jewel-holes, also, cock jewel-covers? Do material-dealers supply minute-wheels with their pinions in them, or should I require to fit pinion in? Does the hour wheel hold the socket for the canon pinion? Instructions on the above will greatly oblige.—X. Y. Z.

[47472.]—**Indian Workmen, &c.**—Will "Gereb Admi" favour us with an account of some of the devices used by Indian workmen, to which he alludes in letter 20114?—O. V.

[47473.]—**Gas for Laboratory.**—I have obtained this by displacing air in a barrel by water, and bubbling it through petroleum spirit. The barrel soon fills, and I want a gas-jet burning the greater part of the day. I have a 1in. pipe running water all day at a pressure sufficient to throw a jet 20ft. Could I utilise this for driving a small Root blower. What would be the cost of the plant? What would be the best way to saturate the air with petroleum vapour?—D. B.

[47474.]—**Astro.-Eyepiece.**—To "ALDEBARAN."—I have made a very satisfactory positive eyepiece by following your instructions, and I have tested my object-glass in the way described by you. A faint, but perfectly-steady picture of the gas-flame was shown on the screen, no matter how rapidly or in what way the card was moved about. Your kind replies and evident desire to "teach the young idea how to shoot" tempt me to ask you to explain the use of what appears to be a raised ring about 1in. diam. round the centre of the o.g. It can be clearly seen by looking down the tube when the eyepiece is removed. Also, please tell me which is the focal length of the o.g.—viz., the distance (29½in.) from the field-glass of astro. e.p. when focussed to the o.g., or the distance (41in.) from the o.g. (with e.p. removed) to the screen upon which the picture of a gas-flame is sharply defined. In calculating the power, it would, of course, make a material difference which measurement is used.—TYRO.

[47475.]—**Sidereal Indicator.**—Would some kind reader give sketch and explanation regarding sidereal indicator? and much oblige.—D. Mc.

[47476.]—**Legal.**—To MR. WHETHERFIELD.—On taking a house I agreed to pay and keep paid a week in advance, and signed a document to that effect. I have not been able to keep the week paid in advance, but have paid every week as became due. On tendering the week's rent due last Monday, it was refused, and a notice served, demanding the week's rent in advance or threatening proceedings for recovery. What proceedings can be taken for the week in advance? Can the landlord distrain, or what? Can I be legally compelled to pay the week's rent which has been tendered and refused?—THREE YEARS' SUBSCRIBER.

[47477.]—**Waves.**—Can any of your numerous readers recommend me a reliable book on the height of waves and the numbers of waves running a minute with different winds in different localities?—THE SEA.

[47478.]—**Induction Coil.**—To MR. LANCASTER.—I have made reel-ends, and have also procured all wire, &c. I propose making the reel 8in. long, using two layers of No. 18 primary wire, and ¼lb. secondary No. 36 gauge—would it be enough? Would you kindly tell me what the diam. of core should be, and when finished? What length of spark should I get, and also what kind of battery would be the best to use? Could I use Bunsen or bichromate?—A YOUNG BEGINNER.

[47479.]—**Legal.**—To MR. WETHERFIELD.—A man in good circumstances makes a will, leaving so much to his wife, and so much to his son and daughters, with legacies to his two executors. At his death some years afterwards, things have changed, and he dies ostensibly in debt. Under these circumstances (the affairs being in great confusion) the two executors sign a paper foregoing their legacies, as they are told they might be responsible for debts; but shortly afterwards assets flow in, and the widow (the son being under age) to be able to get the money paid to her, takes out letters of administration, and signs herself sole executrix. Now what claim has the son upon the estate (he being now of age), and can the mother will away all the money as she likes at her death? Has she a legal right to the whole after the son comes of age? Was not the will rendered null and void, and, therefore, the son sole heir at age?—ADOLESCENS.

[47480.]—**L. & N.W.R. Compound Locomotive Experiment, F. W. Webb's Patent.**—Are the results of the indicator-diagrams taken lately on the above engine on her up journey likely to be given forth in a short time, and where? Also, are any further modifications or improvements contemplated?—V.

[47481.]—**Colouring Gold Jewellery.**—Will some correspondent inform me how to get gold a good dead colour without showing the soldering marks?—S. D. C.

[47482.]—**Telephone.**—Which is the best form of telephone transmitter and receiver to use, so that the sounds reproduced may be audible throughout a room? Have no "E. M.'s" before 1881.—CHURCHMAN.

[47483.]—**Mining Queries.**—1. What should be the dimensions of an engine suitable to raise 1,500 tons of coal in 10 hours in a 40° slope and 1,000ft. long? 2. What will be the area of three airways that will divide an airway passing 100,000 c. ft. of air per minute, the same velocity being maintained in the splits? 3. The total quantity of air passing in a mine is 18,000 c. ft. per minute with two airways to pass along of equal lengths and area 36 sq.ft., one a square, and the other a circular. What quantity will pass in each? 4. Show why a single airway half a mile long offers the same resistance to a given current of air, as do two airways of the same size, but one mile long? 5. A fan 30ft. in dia. making 40 revos. per minute. What amount of air would it exhaust, and what is the probable water-gauge area of airways 40ft.? 6. How would you calculate the size of a fan to be erected for a certain required ventilation? 7. What proportion should the upcast airway of a shaft be to be downcast? What should the limited number of splits or airways in a mine be, supposing the seam to be giving off a large quantity of gas?—CARBON.

[47484.]—**Bennett's Battery.**—Can any of your readers explain what are the best conditions of this useful battery? I want to know whether the iron borings or the caustic alkali solution should be in the larger proportion. For example, I have a number of tin-plate cans, some tall and narrow, others broad and shallow. If I use the former, the borings will, of necessity, be packed in a deep narrow annulus around the porous pot, which will have no great capacity. If I use the latter, the borings will be in a shallow broad annulus, and the porous pot will, or may, stand up from the centre to any convenient height. Could Mr. Lecky, or perhaps Mr. Bennett himself, say which arrangement is calculated to work best?—P. W. R.

[47485.]—**Legal.**—Would Mr. Wetherfield or other kind correspondent answer the following?—An old man dies, and with the exception of a few small legacies, leaves his property to charitable institutions. His nephews and nieces contest the will, and, as a consequence, the leaseholds are saved to them. The leaseholds put up to auction in several lots, and all but one sold. Some of the nieces are married. Marriage settlements having been executed with the usual clause about increments of property of £200 and upwards, if succeeded to "at one and the same time from the same source," following the original trust. Now, the total of those sold by auction will yield more per share than £200, but each lot, taken separately, will not. Is there any good ground upon which to take action on the plea that (as it is not by virtue of the will, but on the contrary) the separate amounts realised by the separate lots as sold to different people are not as from the same source, and, therefore, do not follow the original trust? I think this a point upon which many at some time during their lives may desire enlightenment.—MARRIED AND DONE FOR.

[47486.]—**Euclid's Axioms.**—Dr. Bain, in his "Logic," Vol. II., p. 209, says that Euclid's axioms 3 to 7 are not true axioms, because "they are all very easily deducible from the two first." How can they be so deduced?—A. J. SMITH.

[47487.]—**Translation.**—Can any of your readers tell me whether Dr. Pinner's "Repertorium der Organische Chemie" has been translated into English?—H. J. E.

[47488.]—**Dryness.**—Will Dr. Edmunds kindly give advice for dryness of mouth? My mouth is always very dry. Very little saliva, and that little thick and frothy—sometimes worse than others. I am a cornet-player, and so find it a drawback. Age 23; non-smoker, and moderate drinker, and always enjoy good health. The dryness is as bad in winter as in summer. Whether I play cornet or not, drinking water has no effect on it.—CORNET.

[47489.]—**Storage Battery.**—Could any reader kindly give me the formulæ for the chemical reaction in the secondary cell in its various stages, and oblige?—ERIN-GO-BRAGH.

[47490.]—**Loco. Engine with Broken Crank-Shaft.**—I saw an engine brought in from the main line, broken down, and she was running on leading and trailing wheels only, her driving-wheels being lifted about an inch above the level of the rail. On asking what was wrong, I was told that her crank-shaft was broken. Will any reader of the "E. M." explain to me the way in which they lift the drivers clear of the metals, and oblige?—A YOUNG MECHANIC.

[47491.]—**Magic-lantern Slides.**—Will any one accustomed to the work kindly inform an amateur how photographs taken on glass can be painted so as to serve for magic-lantern slides?—A. B. C.

[47492.]—**Moon's Line of Apsides.**—20260, page 426, "Her line of apsides goes right round the heavens in a little less than nine years." Will "F.R.A.S." kindly say when the moon was last apogee in Taurus? Also, when perigee last in that sign? And (if the calculations are made) when the moon will again be perigee in that sign?—W. M. GARDNER.

[47493.]—**Velocity of the Wind.**—In the ENGLISH MECHANIC of July 7, page 413, I observe that you give the pressure of the wind on a sq. foot at 50 miles per hour, as 49½lb. In Molesworth's pocket-book I find that the pressure at this velocity equal 12·304lb. per sq. foot, and at 100 miles per hour the pressure is given as 49·21b. How is this difference to be accounted for?—OCTURUS.

[47494.]—**Speed of Small Steam Vessels.**—Can anyone give me one or more reliable rules for finding the speed of steam launches from 30ft. to 80ft. long?—OCTURUS.

[47495.]—**Gun-barrels.**—Will someone inform me how the polish is put on gun-barrels after the process of browning? And how long should the barrel be kept warm after the browning solution is applied?—SPORTSMAN.

[47496.]—**Power of Batteries for Coils.**—Will any of our competent correspondents kindly tell me by what rule you can tell what amount of battery power you can safely use with a coil without injury to it, so as to bring out its full force, length of spark, &c.? Or what indication is given when you are using too strong a battery?—W. R. C.

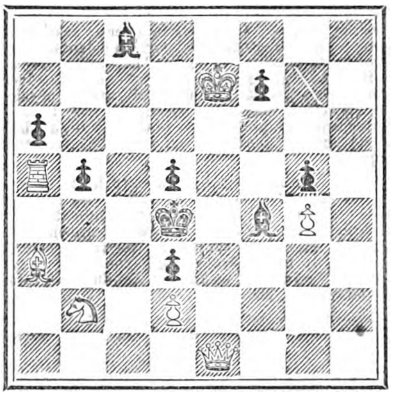
THE old Colony, U.S., Railroad people claim to carry in one of their trains running to Plymouth and wayside stations the largest number on the round trip of any train out of Boston. From 1,200 to 1,400 passengers are carried daily by this train. Boston has such thickly settled suburbs that the local trains on the roads entering it are no small part of their revenue.

CHESS.

ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLXV.—By C. CALLANDER.

Black.



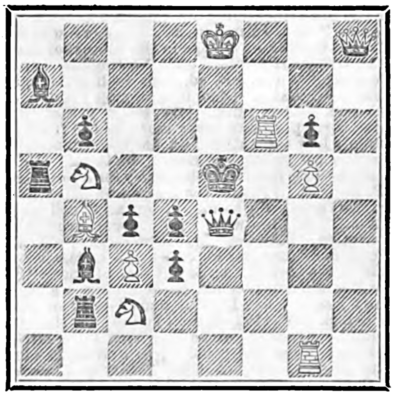
White.

White to play and mate in four moves.

PROBLEM DCCLXVI.—By S. LOYD.

From "Chess Strategy."

Black.



White.

White to play and mate in three moves.

RESPECTING problem 766, the author writes:—"A pleasing and somewhat curious way of preparing against a discovered check is shown here. I have employed it as a contingency in case the defence uncovers a check. The problem is carefully elaborated and rich with ideas and variations."

SOLUTION TO 761.

White.	*Black.*
1. Q to K B 5	1. Kt takes Q (a)
2. B to K 4 (ch)	2. K takes B
3. Kt mates	
	(a) 1. P takes Q (b)
2. P Queens, &c.	
	(b) 1. P to Kt 5 or B moves
2. B to B 4 (ch), &c.	

SOLUTION TO 762.

White.	*Black.*
1. Kt to K Kt 4	1. Anything
3. Mates accordingly	

In this position a P was accidentally omitted at Q R 4.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 759 by Celsus and Schmucke; to 760 by Celsus; to 762 by Schmucke.

Wells' Comet Seen at Mid-day.—Successful observations of the Wells comet were made at the Dudley Observatory, Albany, N.Y., June 11 and 12, at the meridian transit. The comet was seen to have a bright, perfectly-round, and sharply defined nucleus. The apparent diameter of this nucleus is about three-quarters of a second, or, after allowing for irradiation, about 200 miles. The observation, June 12, shows that the comet was still increasing in brightness, and that the vapours which surrounded the nucleus were becoming more dense and abundant. The observations also proved the Dudley Observatory ephemeris to be remarkably accurate.

ANSWERS TO CORRESPONDENTS.

◆◆◆

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, July 19, and unacknowledged elsewhere :—

G. WILLIAMS.—R. A. Lee.—W. Kitney.—Mottershead & Co.—J. Wood.—R. Mills.—P. C. Vendryes.—P. A. Fothergill.—G. Pearson.—G. R. Miles.—Albo Carbon Light Company.—Dr. Doberck.—Rev. J. M. Perry.—Counter Tenor.—Cornet.—W. R. C.—Neo.—Beta.—Rural.—Indigestion. —A Subscriber.—Blackwater.—Semper Fidelis.—A Fellow of the Royal Astronomical Society.—H. S. Frost.—E. L. P.—F. Walker.—Scotch Working Mechanic.—E.

ERRATUM. (By a more than usually stupid blunder, the address in Messrs. Lee and Hunt's advertisement in our last issue was altered by the printer from "Nottingham" to "Birmingham." Readers will kindly note that there is no change in the address of the firm, which is still Arkwright Works, Nottingham, as heretofore.)—ROGO. (2d. and 4d., can be had through any agent.)—J. LANE. (Too late to stop; better correct next week.)—GEO. LUFF. (We, too, wish that our geological correspondents came more to the front; they certainly lack the enthusiasm and persistence of their astronomical and microscopical brethren. We have heard nothing from Mr. Skertchley for a long time.)—T. P. BARKAS. (Thanks for the note on hailstones, but the forms are hardly so uncommon as to call for illustration.) A. RIDGWAY. (We have received the description, but not the illustration.)—E. WEBB. (We do not know, but we expect all engagements are made on the ground. An advertisement under "Situations," in the Sale Column, might bring you a reply.)—BLACK FACE. (See Dr. Edmunds's letter on acne, in No. 881, p. 513.)—IVANHOE. (You can try the effect of warmth, but it must not be employed in the shape of hot irons. Turn the table down in front of a fire.)—FIXUS LECTOR. (You will find plenty in *Engineering*. See the No. for May 12, for instance.)—H. G. (Directions for making medical coils have been given many times, the last so recently as p. 313.)—NORMAN COLLINS. (We really cannot devote space to an illustration of a Bunsen burner with a cap of platinum gauze. They are so common, they can be seen at almost any gas-fitters. In its simplest form it is a tube with air inlets at the bottom, just where the gas-jet enters; the gas passing along draws air in, and the mixture is ignited about 6in. or 8in. from the point of commingling.)—VERDENT. ("House Painting," by E. A. Davidson. Crosby Lockwood and Co., Stationers' Hall-court, E.C., 6s.)—T. H. B. (Heat the tube carefully along the side, tapping gently end on until all the air is expelled. Perhaps the tube is not clean, and the mercury hangs to the sides.)—A FACTORY LAD. (See p. 313, and read future numbers. He has promised to give details. If you intend using it upon yourself without proper advice, you had better let it alone.)—H. J. N. (It is usually done with gum.)—ELECTRICIAN. (Put it in the lathe and guide it with the hands; or, if you have not a lathe, mount it on a spindle with a crank and coil it that way, guiding with the hand.)—HIGHLANDER. (Surely you have no idea of the largeness of your query. To make useful analyses of soils involves considerable knowledge of chemistry, and the briefest instructions would of necessity occupy considerable space. If it is only one kind, it would be cheaper to send a specimen to an analytical chemist; but if you want to set up as an adviser, and an analyst, there is nothing for it but to study practical chemistry. In Vol. XXVI., p. 483, and Vol. XXVII., p. 72, you will, however, find the rudiments, or a "rough outline.")—ONE WHO IS ANXIOUS TO KNOW. (Your question is simply a sum which can be answered by a reference to any book on arithmetic.)—MATER. (You will find full particulars on p. 401, Vol. XII.; but the secret consists in adding white wax to the starch, and using it warm. At the place cited it is stated that the shirts are starched, then dried, then starched again, and ironed with ordinary irons; the finish is put on with a special iron, called a polishing-iron, which has a bevel at one end, and it is this bevelled iron, aided by the wax, that brings up the glaze. The proportions of wax stated are 2oz. to the pound of starch.)—JUMBO. (What you ask for has been given many times, though possibly not all at once. You must look through back numbers; see pp. 87, 111, 224, 289, 336 of this volume, for instance.)—VESTA. (Directions for making wax matches on p. 636, No. 416; vesuvians or fusees on pp. 202, 207, No. 346.)—FRANGIPANI. (You must state the "scents" required, for they are prepared as essences, oils, spirits, and waters. There is a book on the subject, we believe, by Piesse.)—ELECTRO. (Directions for making electric bells have been given over and over again, and as to a battery, see p. 6 or p. 308 of this volume.)—ONE IN NEED. (You mean one of the graph processes. See query 47286, p. 387, and reply on p. 410. Special inks are used. For full particulars, see p. 545, No. 750.)—WAVERLEY. (See p. 380, 386, Vol. XXXIII.; also replies 47278, p. 410, No. 902.)—W. Ll. (Are not the instructions given on p. 407 sufficient? If not, specify the difficulty.)—M. OLLINER. (1. Immerse in a solution of nitric acid, one to three parts water, and clean with a brush and bathbrick, using plenty of water. 2. Any good dictionary answers this question. 3. It is a tonic if anything, and should be taken before meals; but only a few drops at a time in water.) L. E. J. (Stanford, Charing Cross, publishes some useful handbooks giving an account of British Industries.)—THANKS FOR REPLY. (Consult the indices. Query answered many times.)—HOINOS. (Try aniline black.)

H. E. HUSSON—JAVELIN. (Your queries can appear only in the "Sixpenny Sale Column.")

W. H. R.—Nihil.—Tria.—Mitchell, Newcastle, and others have replied to queries already similarly or adequately answered.

THE Commission appointed by M. Ferry to report on the construction of the rotating dome for the large refractor of the Paris Observatory has held numerous meetings at the Conservatoire des Arts et Métiers, Colonel Laussedat, director of the establishment, being in the chair. Only two projects have been reserved for final choice. M. Eiffel proposes to use a saline solution in a horizontal circular channel placed on the wall to diminish the weight of the rotary roof.

THE preliminary surveys for the proposed reclamation of the Zuyder Zee have been finished, and the work of building the walls will soon begin. A dike about 24½ miles in length will be constructed of sand and faced with clay, reaching 16ft. above the level of the sea, which will make it about 6½ft. above the highest tide. The thickness of the dike will be such as will enable it to resist the heaviest seas. Operations will begin at four different points, and the calculation is to have it completed in from seven to ten years, at a cost of 46,000,000 dols.

DR. HERTZ has recently made experiments on the vapour-tension of mercury. The vapour-tension was measured at high temperatures, and values were obtained which likewise were smaller than Regnault's, but greater than those found by Dr. Hagen. From his values, Dr. Hertz calculated a formula, according to which he produced a curve of the vapour-tension of mercury with varying temperature; its zero point being at absolute zero —273 deg. C.—For low temperatures, 0 deg. C., 10 deg., and 20 deg., the values he deduces from his formula are under those obtained experimentally by Dr. Hagen for the same temperatures.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium 13s., or 16f. 50c.; to India (via Brindisi), 16s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

Holloway's Ointment and Pills exercise priceless power over lumbago, all pains of the muscles, nerves, and joints, and quickly reduce all swellings caused by accidental injuries, weakness or hereditary taints. The intelligible instructions enveloping Holloway's medicine give full counsel for using it most advantageously for regaining health, strength, and mobility.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words..	0	6

Front Page Advertisements Five Shillings for the first 40 words afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

OUR EXCHANGE COLUMN.

Photographic Apparatus (complete) wanted for Halse's ten-guinea Galvanic Machine, in good working order, for curing rheumatism.—WILLIAM ANDERSON, 3, Brookdale-avenue, Ilfracombe.

Wanted, portable **Dry-plate Camera,** background, and Camera suitable for copying, &c. Many useful offers, or part cash.—BETA, Belbroughton, Stourbridge.

10 by 8 Sliding **Camera,** dark slide, rising front, &c. Maker, Dallmeyer. Good condition. Exchange for Hickory Trolling Rod and Tackle.—W. B. GANNON, Baddow, Essex.

Patent **Weighing Machine,** no weights required, ½ oz. to 4 cwt. Makers, Hart and Co. Cost £10 10s. Sell for £7, or accept useful offers. Suit grocer or merchant.—37, Northcross-road, East Dulwich.

Safe, capital fire and thief proof, 24 by 18, with patent lever powder-proof lock. Cost £8 8s. Sell for £5, or would accept provisions, &c., in exchange.—37, Northcross road, East Dulwich.

Vertical Galvanometer, handsome Cylinder Machine, large Leyden Bunsen Batteries, Bellows, Camera, all fittings. Wanted, small Incandescent Lamps; handy form good Battery, small motor; Wire. Sell exceedingly cheap.—ERNEST CLOVER, Springfield, Sudbury, Suffolk.

"Cassell's Popular Educator," six volumes, bound in three new and unsoiled. Cost £2 5s. Offers in Electrical Batteries, Telescope, &c.—CONYNGHAM, Jun., Mahony's-avenue, Cork.

Wanted, **Fossils,** Coins, or any natural objects for a small collection of genuine Stamps, Monograms, &c., some rare.—J. BAILEY, Free Library, West Bromwich.

I have a large liver-coloured **Dog,** with fine tail, length from tip of nose to tail, 60in.; height, 24in.; straight coat, most excellent house dog. Very fond of water. Not 12 months old. Still growing. Will exchange for good Musical Box or Electric Apparatus.—Letters only, W. D. J., 78, Viaduct-street, London, E.

Photographic Apparatus, with all accessories. Lens by Dallmeyer. Equal to new. Cost over £10. Exchange for Tricycle.—D. S. ANDERSON, Chemist, Forfar, N.B.

Wanted, the first volume of the "**English Mechanic,**" unbound. Exchange.—27, Mount Pleasant-road, Lewisham.

Gun-metal **Slide-Valve,** cylinder bored 1in., 2in. stroke, one turned crank shaft 3½ inch stroke, one gun-metal pump casting. Exchange.—L., 31, Fairfield-road, Bow.

Electrical Machine preferred. "Bedford's Easy Method" of Learning Banjo, Piano, Violin, with or without learning music. Cost 9s each.—17, Shirley-street, Cliftonville.

Treadle Lathe, all iron, and **Watchmaker's Throw.** What offers?—11, Queen-street, Belgrave Gate, Leicester.

Good old **Violin,** bow and case, complete, £3 10s., or exchange to £5. Offers.—HEWSON, 11, Great Crown-court, Haymarket, London.

Quantity professionally-made **Organ Fittings,** nearly a complete organ. Keys, pipes, soundboards, &c. Cost £7. What offers in exchange?—TANNER, Rusham-road, Horsham.

Whole-plate **Camera** and Portrait Lens, cost eight guineas. Would take Lancaster's "Le Meritoire," half-plate size, in part exchange.—TANNER, Rusham-road, Horsham.

Wanted, ¼-plate **Camera,** with focussing and dark slides. Give in exchange a 5 mm. Revolver, six-chambered, in walnut case, fittings complete.—"SIGMA," 69, Albert-street, Crewe.

I have a gentleman's Silver Geneva **Watch,** cost 30s. What offers in exchange for it?—36, Lea-road, Luton, Beds.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

◆

FRIDAY, JULY 28, 1882.

SCIENCE AT SOUTH KENSINGTON.

THE general public, whose ideas of science teaching at South Kensington are mainly derived from the newspaper reports of the field-days at that remarkable institution, would probably experience a feeling compounded of surprise and indignation were they permitted even the briefest peep behind the scenes, at the wonderful Brompton focus of jobbery and place-making. To read the fulsome way in which "the butter-boat" is passed between Mr. Mundella and certain of the most prominent and leading spirits among the vast staff of hangers-on of the "Department," could scarcely fail to impress the conviction upon the uninstructed outsider that great and valuable educational work in science was being performed at Brompton, at a relatively insignificant national cost; and that the oft-reiterated complaint that the British artificer was wofully behind his Continental confrère, was in a very fair way, indeed, of being speedily remedied. Now, *in limine*, the total amount distributed in the shape of grants to successful candidates, may be taken roughly to amount to £40,000; a sum which the nation need scarcely grudge, were it devoted to a legitimate end. The total annual cost of the Science and Art Department, however, is £337,181, and if we halve the sum devoted to these subjects jointly, it needs but very rudimentary arithmetical acquirements, indeed, to deduce the fact that three-quarters of the sum annually voted by the State for teaching sciences is swallowed up by the staff of leeches who batten on this most singularly constituted establishment. But, even then, do we get our "hapor'th of bread" in connection with this "intolerable quantity of sack"? We wot not. Artificers proper are extremely scarce among the competitors; and such subjects as machine construction and applied mechanics are taken up by a totally insignificant proportion of the competitors. Pupil-teachers are the people who figure most conspicuously among the candidates, for a reason which must be at once apparent to all school managers and others having anything to do with the administration of the Education Code. To meet this state of things, there has arisen a wretched system of cramming from a series of textbooks (many of them compiled by members of the overgrown and overpaid staff at Brompton themselves), by the aid of which a considerable percentage of candidates contrive to pass in various fancy subjects in the elementary stage. Should one of them manage, by dint of more than usually energetic cram, to pass in the advanced stage, he forthwith receives a certificate entitling him to teach the subject in which he has gone out; and so hordes of scientifically blind teachers of the blind are scattered broadcast over the country. We cannot better illustrate the kind of information communicated by this most faulty system than by quoting a series of actual answers given by various students in the new-fangled subject of "Physiography"—a subject expressly invented to create a berth at Brompton for one of the creatures of the department. We have received them direct from a quondam examiner, and pledge ourselves as to their absolutely genuine character and literal transcriptions (1.) "The negro race have a very thick skull, at which the back of the head goes quite straight up to the forehead. Their hair is of a black, woolly colour, and their perplexion (*sic*) is rather black. The part of the world in which they live is India. The negroes are very strong, and if you wanted to kill one of them, the best place to hit them would be in the body. The tenderest place of the negro is the back of the leg, just below the knee." (2.) "Climates are those vast plains which are very cold and frosty." (3.) "On the west coast of Europe the climate is very cold compared with the east of America. This is owing, in some measure, to the Ural Mountains." (4.) "The chief rainless districts are Europe, Asia, and Africa. They are caused by the sun shining so much on the countries, and, therefore, draws up more water." (5.) "During an eruption the crater gradually gets lifted up until it reaches the top and flows over the side of the volcano." (6.) "A great circle must be something that we cannot see the end of, like a rainbow, which when it is seen in the heavens appears to reach from one end of the sky to the other." (7.) "A great circle is called an oblate spheroid." (8.) "The Equator is the line showing the centre of the Earth," and (9.) (Finis coronat opus) "The increase of civilisation of the British Island is rectified by the many indentations in the coast, which proves the commercial pursuits carried out; for the ships coming in gradually wears the coast away. Africa has the least indentation in its coast, and is the most degraded." Such are, *verbatim et literatim*, a few of the replies given at some tolerably recent Science (?) Examinations at South Kensington. We do not, of course, pretend that those who penned them passed, even in the elementary stage. Our purpose in quoting them here is to invite a careful perusal of them in connection with that of certain notorious textbooks, in order that the reader may see for himself just how and where such astonishing blundering has had its origin; and exactly how the miserable examinees have muddled up the ill-digested mass of facts which have been crammed into them from these compilations. Such a comparison will show that, in a large proportion of cases, the very words of the textbooks have only been sufficiently distorted or misapplied to just make nonsense of the answer. This, then, is the outcome of the system of cram and sham, for which the British nation is annually called upon to pay such an exorbitant sum. Even did the cost of the staff bear some reasonable proportion to that of the actual grant, a system which encouraged such a form of scientific education (Heaven save the mark!) as all this indicates, must stand self-condemned. Mr. Mundella may flatter Professor Huxley, Professor Huxley may flatter Colonel Donelly, and the gallant Colonel may "pass it on" to Mr. Mundella again; but the day must come when all this sham will be found out. Then will an indignant public learn that all these examinations, certificates, scholarships, et id genus omne, are but an excuse, cloak, and blind for the maintenance of an enormous horde of overpaid hangers-on and parasites at Brompton; and that if a clean sweep were made to-night of the entire party, British Science could not fail to be in an infinitely sounder, healthier, and more prosperous condition for it.

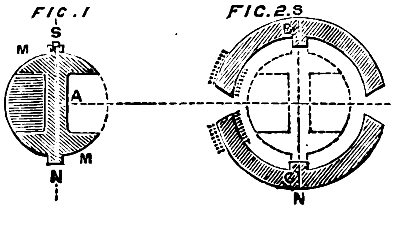
THE BOILER EXPLOSIONS ACT.

THE Act which is "to make better provision for inquiries with regard to boiler explosions," came into force on the 12th instant, and within an hour of its coming into operation a case occurred which will show how the Act works in practice. The term "boiler," as used in the Act, includes any closed vessel in which steam is generated or water or other liquid is boiled, or any vessel into which steam is admitted; but the Act does not apply to boilers used exclusively for domestic purposes, or to those on board ship or used in mines, or on railways, because, except in the case of domestic boilers, special provision has been made for inquiries into explosions in those classes by separate Acts of Parliament. The fact that the Bill was about to become law created considerable excitement, not so much perhaps amongst boiler owners as amongst boiler insurance and inspecting companies. As our readers are aware, there are rival associations, some of which merely inspect and report the condition of boilers, while others inspect and insure the owners against loss by explosion. The latter class, it will be understood, stand on a similar footing to fire-insurance companies; it is their interest to receive premiums and have as few losses as possible; but it is not unlikely that in their desire to secure premiums they are not so strict in their requirements as societies which merely inspect and report to the owners; or, if as strict, the work of periodical inspection is perhaps often neglected, the expenses being heavy and the "risk" slight, when spread over a large number of boilers. From July, 1864, to the end of last year, the number of boiler explosions in the United Kingdom amounted to 865, by which 1,034 persons were killed, and 1,718 were injured more or less seriously. The numbers for last year were respectively 34, 40, and 47, figures which it will be seen are below the average for the preceding 17 years; but still far too high to be contemplated with equanimity. The number of explosions during the past five years averaged 38·2 per annum, while in the preceding five it was 58·2, so that it is permissible to hope that the decline was due largely to the exertions of the different societies, and to the greater care exercised by non-insuring owners. So long, however, as steam-boilers are used, there will always be some liability of explosion; for though the boilers themselves may be safe, it is impossible to entirely eliminate the element of carelessness. Of the 34 explosions which happened last year no fewer than 10 are attributed to negligence or mismanagement: that is to say, they would not have occurred if ordinary care and skill had been used; but many of the other explosions were also caused by negligence indirectly, because corrosion and other sources of disaster were allowed to go on unheeded. In one case, it may be remembered, 16 persons were killed and 11 injured, and as the evidence disclosed gross negligence on the part of the owner, he was convicted of manslaughter and sentenced to twelve months' imprisonment. That case is exceptional for its common-sense verdict; for if coroners' juries had some years ago brought in verdicts of manslaughter, or at least, something different to "accidental death," Mr. Hugh Mason would not have found it necessary to bring in his Bill, and would scarcely have passed it if he had. The provisions of the new Act, which it will have been seen from an advertisement in our columns, is supplied gratis to users of steam-boilers, are peremptory in some of the sections; for instance, on the occurrence of an explosion the owner or user of the boiler shall, within twenty-four hours, send notice thereof to the Board of Trade, and give certain particulars, which are set forth in the schedule, under a penalty for neglect of a fine not exceeding £20. On receiving the report, the Board of Trade may appoint competent engineers to make a preliminary inquiry, or without such inquiry they may institute a formal investigation, which is to be made by a court consisting of not less than two commissioners appointed by the Board of Trade. This court will have all the powers of a court of summary jurisdiction, and in addition will either as a body or in the person of its officers have full power to enter and inspect any place or building which appears likely to throw any light on the explosion. The court may also summons and examine any persons it thinks necessary, and may require and enforce the production of all books and documents it considers important. The court will administer oaths, and require witnesses to declare the truth of their statements, such witnesses being paid on the scale usual if attending a court of record; but the court may order the costs and expenses of the preliminary inquiry or of the formal investigation to be paid by the person summoned. The court making a formal investigation will report fully and clearly to the Board of Trade the causes of the explosion, and all the circumstances attending the same, adding any observations which it may deem necessary on the evidence. The Board of Trade, whether a formal investigation or merely a preliminary inquiry is made, will make the report public in such manner as it thinks fit. The two commissioners appointed by the Board of Trade are to be respectively a competent engineer and a competent lawyer, and one of them is to be president of the court. The notice of the boiler explosion is to be given in the terms indicated by the schedule, one item of which is the name and address of any society or association by whom the boiler was last inspected or insured. It will be noted that, with the exception of the penalty for not giving notice, no fines are specified by the Act, but the court may order the expense of the investigation to be paid "by any person summoned before it." To say the least, that is a very large power, for literally, it means that the court may order anyone to pay the expenses. No doubt it means, as will be found in practice, that the court will order the owner, or the person intrusted with the boiler, to pay the cost and expenses; and as even that will not clear the user of the boiler from the clauses of the Employers' Liability Act, an explosion will be found to be a rather expensive disaster—much more costly than several repairs, and a great many inspections. Added to the loss occasioned by damages to the premises, and the liability to conviction for manslaughter, these provisions of the Act should be sufficient to prevent wilful carelessness; but looking at the wording of the Act, it would appear that the court may order a boiler-tenter to pay the costs of an investigation if any disaster occurs which can be clearly traced to his neglect. The working of the Act will be watched very closely, especially by those owners of second-hand boilers who do not insure, and who, for reasons well understood, decline to call in the inspectors. The case above-mentioned is not a very important one; but from the facts already published it is an example of many explosions which, it may be hoped, will not often occur when the Act becomes known. The boiler in question exploded at Facit, near Rochdale, was at once reported to the Board of Trade, and Mr. Traill and Mr. Carlisle were appointed to make the investigation. The boiler was of the vertical type, 4ft. 8in. in diameter, by 8ft. 6in. in height, worked at a stated pressure of 60lb. The shell tore the base-plate, through the ring seam of rivets, and after soaring up to a considerable height, fell at a distance of 120 yards. Other pieces were scattered in different directions, the smoke-tube having rent across at the root of the flange attaching it to the fire-box crown, at which part it was grooved to a depth of one-eighth of an inch. In such a case, occurring, perhaps, in a busy neighbourhood, it is clear that considerable damage might be done by the flying shell, to buildings as well as to individuals; but experience teaches that not one coroner's jury in a thousand would bring in any other verdict than "accidental death," which is tantamount to saying that the explosion could not have been prevented. We shall see what report the court makes to the Board of Trade as to the cause of the Facit explosion. It may not be easy to discover, but, at least, we expect some reasonable explanation; for although it may be impossible to altogether prevent boiler explosions, a study of their history reveals the fact that with proper precautions they would become sensations by their rarity. That "insurance" does not mean proper precautions is very clearly shown by the report of an expert sent down by the Board of Trade to inquire into the Radcliffe explosion which happened on May 1st. The expert was Mr. T. J. Richards, who, in his report to the Home Secretary, writes: "Thus, during the whole time the boiler was insured, about fifteen years, no thorough examination had been made to ascertain if it was safe, notwithstanding the fact that during the last five years at least it was known that the boiler was subject to the effects of dampness." "The owners of the boiler cannot be excused of neglect, in omitting to give the insurance company facilities for making a thorough examination; but, on the other hand, although the insurance company were, as shown by the letters, aware of the damp state of the flues, we find no intimation to the owner that any further delay in making a thorough examination was dangerous; but, on the other hand, the insurance of the boiler was continued." Mr. Richards says also, "there appears no reason to regard the case of the Radcliffe exploded boiler as an isolated one"—an opinion which we are afraid is unfortunately correct. In this case, three men were killed, and the coroner's jury found a verdict of accidental death; appending to it, however, an opinion that compulsory examination of steam-boilers once a year by certified inspectors should be enforced by the Government. In some respects, this Radcliffe explosion is unique, for the insurance company appear to have been quite aware of the risk, and wrote letter after letter to the owners, and at last, when the latter were prepared for a thorough examination, the company's officers could not attend, as the notice was insufficient. A few months afterwards the explosion happened. Users of boilers ought at least to know something of them and of their defects; but it is perhaps excusable if a busy firm puts off the thorough "inspection" when they find the company willing to continue the insurance. They are apt at least to think that there is no serious danger, and work their boilers until something goes wrong, which too frequently culminates in a verdict of "accidental" death. It is probable that, but for more pressing matters, the question would have been taken up by the Government, and something larger than Mr. Mason's Bill would have been passed. As it is, however, that measure will help to make both users and insurance companies cautious, and should any explosion unfortunately occur, the reports of the court will afford valuable facts upon which to base further legislation.

GRISCOM'S DYNAMO-MACHINE.

We have previously given general descriptions of Griscom's little dynamo-machine, which has, however, been chiefly exhibited as a motor driving sewing-machines, lathes, &c. Some improvements have been recently patented in this country, and the descriptions, with the illustrations, will afford useful information to those who wish to construct small dynamos or electric motors. The invention relates to improvements in armatures for magneto-electric and dynamo-electric machines and motors, and has especial reference to armatures of the type known as Siemens; but it is applicable to the poles of all other magnets or armatures. It consists in dividing the bipolar extremities of such armatures into two or more sections concentric with each other, one or more of such sections being at such a distance as to utilise the magnetic lines of force which fill the space between the two poles of the field-magnets, whilst the other section or sections are arranged so as to pass in close proximity to the poles of the field-magnets, and thus utilise the powerful attraction between the poles of the armature and magnet as the one approaches the other.

Figs. 1 and 2 represent a transverse section of a magneto-electric dynamo or electro-magnetic armature and a field-magnet constructed according to the invention. Referring to Fig. 1, A is an armature of the before-mentioned type having its bi-polar extremities divided into two or more sections concentric with each other, one or more of such sections M revolving or working at such a distance within the field-magnets B and C (see Fig. 2) as to utilise the magnetic lines of force which are generated and disseminated in the magnetic field or space between the two poles of the magnets.



The other section or sections P before referred to, are longitudinal ribs or projections concentric with, but extending or protruding above or beyond, the peripheries of the other sections M, so as to pass, when the armature is revolving, in closer proximity to the poles of the field-magnets B and C than do the sections M, so as to economically utilise the lines of magnetic force between the poles of the field-magnet. The interior surfaces of the field-magnets B and C are formed or provided with projecting ribs or pieces arranged so as just to clear the projections P upon the armature A when it is revolving. In this manner the poles are caused to utilise certain magneto- or electro-inductive influences upon the extremely close approach of iron to iron, while the polar surfaces are arranged for utilising the induced lines of force extending across the magnetic field of the magnets B and C. The size and quantity of wire coiled on the armature and field-magnets obviously depend on the dimensions of the machine to a certain extent, and absolutely on the resistance, &c. The best size and number of coils will therefore be a matter of calculation and experiment; but possibly some of our readers can give the results of practical trials.

ASTRONOMICAL NOTES FOR AUGUST, 1882.

The Sun.

Day of Month.	Souths.				At Greenwich Mean Noon.								
					Right Ascension.			Declination. North.			Sidereal Time.

† Near approaches. ‡ Stars below the horizon. § Star rising.

The Moon.

Enters her Last Quarter at 4h. 13·0m. a.m. on August 6th, and is New at 9h. 10·0m. on the night of the 13th. She will enter her First Quarter at 54·8 minutes after midnight on the 21st, and be Full at 9h. 18·6m. p.m. on the 28th. High tides may be looked for about the 29th.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.
1	17·2	1 20·7 a.m.
6	22·2	5 48·0 ,,
11	27·2	10 9·3 ,,
16	2·6	1 48·0 p.m.
21	7·6	5 30·6 ,,
26	12·6	10 7·2 ,,
31	17·6	1 49·9 a.m.

The Moon will be in conjunction with Saturn at 2 a.m. on the 7th; with Jupiter at 6 a.m. on the 9th; with Mercury at midnight on the 13th.; with Mars at 6 a.m. on the 17th; and with Venus at 10 o'clock on the same night.

Mercury

Is a Morning Star during rather more than the first third of the month; but comes into superior conjunction with the Sun at midnight on August 14th, after which he becomes an Evening Star. He is too close to the Sun to be satisfactorily observed, is nearly round, and his diameter varies very little from 5″ during the entire month.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	7 47·5	21 37·4	11 7·7 a.m.
6	8 29·1	20 19·1	11 29·5 ,,
11	9 11·4	17 58·1	11 52·1 ,,
16	9 51·8	14 50·2	0 12·6 p.m.
21	10 28·9	11 14·6	0 30·0 ,,
26	11 2·8	7 26·5	0 44·1 ,,
31	11 33·9	3 36·2	0 55·5 ,,

Starting thus from the confines of Gemini and Cancer, Mercury will cross the latter constellation and the greater part of Leo. He will be a little south of γ Cancri on the 5th, and south of Regulus on the evening of the 17th. He will be in conjunction with Uranus at 8 p.m. on the 28th.

Venus

Is an Evening Star during the whole of August, and is becoming an interesting telescopic object. Her angular diameter increases from 14·8″ on the 1st to 19″ by the 31st. She is still slightly gibbous, and will not be dichotomised (or present the appearance of a half moon) until next month.

Day of Month.	Right Ascension.	Declination	Souths.
	h. m.	° ′	h. m.
1	11 20·5	5 13·0 N.	2 40·1p.m.
6	11 41·3	2 41·6 ,,	2 41·1 ,,
11	12 1·8	0 8·4 ,,	2 41·9 ,,
16	12 22·1	2 25·2 S.	2 42·5 ,,
21	12 42·3	4 57·9 ,,	2 43·0 ,,
26	13 2·3	7 28·5 ,,	2 43·4 ,,
31	13 22·4	9 55·5 ,,	2 43·7 ,,

Thus Venus travels from Leo into Virgo. She will be about 1½° South of η Virginis on the 14th, and rather more than 1° North of Spica Virginis on the 30th. She will be in conjunction with Mars (only 5′ North of that planet) at 11 a.m. on the 2nd.

Mars

Has left us until 1883.

Jupiter

Will scarcely be visible, for the purpose of the ordinary observer, until next month.

Saturn

Is a Morning Star, but he rises soon after 11 p.m. at the beginning of August, and between 9 and 10 o'clock at night towards the end of the month, so we resume our Ephemeris of him. He will be in quadrature with the Sun at 10 p.m. on the 18th. His angular diameter increases from 15·8″ to 16·8″ between the 1st and the 31st. No sensible change in the opening of his rings will be noted since he disappeared in the Sun's rays in February.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 32·6	16 53·8	6 53·4 a.m.
6	3 33·8	16 57·2	6 35·0 ,,
11	3 34·8	17 0·0	6 16·4 ,,
16	3 35·8	17 2·1	5 57·6 ,,
21	3 36·5	17 3·7	5 38·7 ,,
26	3 37·1	17 4·6	5 19·6 ,,
31	3 37·4	17 4·9	5 0·3 ,,

The very short path of Saturn this month lies wholly in that blank region in Taurus to the south and slightly to the west of the Pleiades.

Uranus,

Like Mars, has departed until next year.

Neptune

Is in quadrature with the Sun at 3 p.m. on the 11th; but it will be useless for us to furnish any Ephemeris of him until October.

Shooting Stars

Are more numerous this month. We need scarcely remind the student of the shower of August 10th, which has been known from remote antiquity. Mediævally, the Irish Roman Catholics designated the meteorites "St. Laurence's Tears." They are now somewhat more scientifically called the Perseids, from their apparent radiation from a point in the constellation Perseus, and have been shown by Schiaparelli to be connected with (or to fill the orbit of) a brilliant Comet which appeared in 1862. Watch should be kept on the nights from the 9th to the 11th inclusive.

Greenwich Mean Time of Southing of Nine of the Principal Fixed Stars on the Night of August 1st, 1882.

Star	Souths. h. m. s.	
α Ophiuchi	8 48 5·85	p.m.
γ Draconis	9 12 25·91	,,
Vega	9 51 24·58	,,
ζ Aquilæ	10 18 23·03	,,
Altair	11 3 18·33	,,
α^2 Capricorni	11 29 43·13	,,
α Cygni	11 55 32·67	,,
α Cephei	12 33 48·24	,,
ε Pegasi	12 56 21·69	,,

The Method of ascertaining the Local Instant of Transit of either of the Stars in the above List, as also that of determining the Greenwich Mean Time of its Meridian Passage on any other night in August, wlll be found on p. 392 of our XXXIVth. Volume.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By JOHN WATSON WARMAN,

Associate of the College of Organists, London.

A FEW *Remarks* must now be made on the Advantages and Defects of the eight foregoing points of difference between the present and the first Treatment given.

Difference 1 (this and the two which follow it are stated at *m*, ante, 1st parag.) The *Advantages* of this are that less Workmanship is involved; and that for the Great-Organ a Backfall can be employed instead of two Squares, *without* necessitating the front-ward and so less accessible posit of the Pallett-Pulls (see *l*, ante, 3rd parag.)

The *Disadvantage* is that the Player is brought closer to the Pipes. In the present Instrument, however, the Manual Soundboards are kept well up,—viz., at 6ft. above the Platform-top, measuring to the under-face of the Wind-chest beneath the Soundboard (see 43, *k*). [By this it is not meant that the Faringdon Organ was faulty in such respect; for, confined as was the height in that case (see *l*, ante, 4th parag.), the corresponding dimension was made only 2in. under the said 6ft.]

Difference 2. This may be regarded as an *unmixed Advantage.*

Difference 3. This, though still leaving the *Pipe Order* of the Swell Org. defective (see *q*, next, 2nd parag.), may yet be looked upon as an *absolute improvement*; for the Swell Tone is—as will just have been seen—now less obstructed, the Conveyancing to the Front Pipes is at least *not more* extended than it was before, and the "Whole" Roller-Board rendered necessary partly cuts off the Pallett-Pluck from the player's touch (see *l*, ante, 3rd parag.). As connected with this last point, it may be just mentioned that the Manual Palletts in the present Instrument are of the *Boat* (Flexible-Face) kind; but that such Type affords no palpable relief until a [Soundboard] Groove is reached which is of a certain sufficient width: see fully on this matter in *Department* WINDCHEST.

Difference 4 (this and the four which follow it are stated at *m*, ante, 2nd parag.). The *Advantages* of this are;—that less workmanship is involved in the Backfalls and their Beam; that the two Roller-Boards can be of exactly the same Sett and Make; that it becomes practicable to employ the Wire-driven Form of Coupler Man.-to-Man. (see again *m*, ante, 2nd parag.),—which Form is, on the whole, superior to that necessitated in Nicholson's Instrument (see next parag. but one); and that a Clear Coupler (see *r*, next, 2nd parag., and on) is rendered possible, because the keeping of the Great-Org. Backfalls parallel will allow the Great-to-Ped. Stickers' being Wired into *them.* [In this last case the Backfalls of the said Great-to-Ped. will be a little extended at their rear ends, and the said Stickers—carried by such ends—will run straight up between the Noses of the Squares which rest on the Swell Key Tails,—such Stickers being set at the areal point which would otherwise be occupied by the Driving-Wire of the Man.-to-Man. Coupler (see *m*, ante, 2nd parag., Diff. 5), such Coupler being, of course, now compelled to be of some form which is placed between the two Manuals. (Still, however, there will exist the obstruction afforded by the feet of the Great-Org. Stickers; see on this point at *q q q q*, next, 4th parag.)]

The *Disadvantages* of Diff. 4 are; that a second Whole Roller-board becomes inevitable; and that, owing to the Keys of one Manual having been Skewed out of agreement with those of the other, it is necessary to employ a second Skew in one of the Key-Actions, in order to restore such agreement. If this last be not done, then the advantage is sacrificed of having both of the Manual Roller-boards set-out and made just alike.

---

* All rights reserved.

Difference 5. The chief *Advantages* of this Wire-driven Form of Coupler Man.-to-Man. are;—that Friction is lessened,—that at the Sticker-Block having of course departed along with the latter itself; that there is less chance of an unbidden Sounding through the warping of a Backfall or a Sticker; that the absence of the Sticker-Block just mentioned favours the taking out of such Sticker itself; that there is no necessity for Skewing either the Key, or any portion of the Action of it or of Coupler; that a slightly shorter Coupling-Backfall suffices; and that the Front Regulation of such Coupler becomes quite practicable without employing any special tool, or, with a simple Modification to be directly (at *p*, next, 4th parag.) described, quite practicable without a Tool at all,—and with using but one hand.

The chief *Disadvantages* of this Form of Manual-to-Manual Coupler are;—that Retention of its Regulation becomes impracticable on the taking of its Mechanism apart (such Retention, however, being *partly* secured when the *Modification* just spoken of is employed,—see *p*, next, 7th parag.), because the Driving Wires cannot well be Number-marked; that such taking apart is itself rendered more difficult (though here again the said Modification assists, —see *p*, next, 6th parag.); that a Regulating Button on the Great-Org. Sticker Top will, when used, not only disturb the Regulation of the present Coupler, but may, by destroying the interchangeability of such Stickers, still further injure its Retention of Regulation just stated, (it is quite true that *these* Stickers can be easily *numbered*, but this obviously will involve more labour, in respect of such numbering, and of the care required to avoid inserting a Sticker into its wrong place); that this Form of Coupler cannot be used with Fanned Backfalls; that the Skew of the Coupling Backfall is of an *anomalous* amount,—*i.e.*, that of a *fraction less* that the Half Semitonal Key-tail distance, because such Backfall commences at a little way along on one of the lines of two Actions that are converging to one same point; and that the extra workmanship of the Wire and its two Buttons will probably slightly overbalance the gain by abolition of the Block on front Sticker and Button on rear Sticker.

[It will be noted that all these objections are more or less trivial;—in particular, the Regulation at the Great-Organ Sticker will directly be seen to be unwise under the present—which may be regarded as almost a *Normal*—Arrangement; and Fanned Backfalls are not generally to be recommended unless Space is really restricted (see at *l*, ante, 3rd parag.).]

Difference 6. Here also we may consider that we now have nothing but *Advantage*,—as follows:—The shortening of the Sticker slightly lightens the Key-Action, besides giving practically more vertical room for the [Whole] Roller-board of the same Manual (see at *u u u*, next, 3rd parag.). The absence of the Driving-Block from the Sticker has already been seen to facilitate the Removal of the latter. The widening of such Stickers at the point of their passing through the higher Manual (the absence of the Driving-Block obviously rendering such a widening unnecessary at the upper part of the Sticker) is another of those little things which show Willis' complete mastery of his Profession (here see at *h*, ante, 5th and 7th parags.): and the trifling additional length of the Notching in the Key side does not involve any palpable increase of workmanship, and is not in such a direction as to weaken the Key body. The absence of the Regulating Button from the Great Org. Sticker, which at first thought appears to be a defect, is really an evidence of the very greatest sagacity; for any Regulation made at the top of this Sticker has already been shown to disturb the Regulation of the present form of Manual-to-Manual Coupler, and it has been also seen that such disturbance will be aggravated if such Stickers, which inevitably become, in use, of non-uniform virtual length, do get interchanged in their positions. Remember also that the Front Regulation of the *Swell* Manual is already almost sure to be sacrificed (see *g*, ante, 2nd parag.); and this being so, and such Key-board therefore having to be Regulated from the inside of the Organ, it is just as well that the Great Org. Key-board likewise be Regulated at the same time;—for the two Manuals are almost certain to require such Adjustment together. And yet again, observe that the difficulty as regards the Inside Regulation of the Great-Org.-Keys which was exhibited in the Faringdon Organ is not existent in the present Instrument. Yet once more,—the saving of the Screw and Button is a consideration, and so is the avoidance of the trouble of numbering the [Great-Org.] Stickers, and of observing such numbering in putting latter in place. In this connection note also that the provision of a Clear Coupler, as just indicated (at *m*, ante, 8th parag.), will obviously demand that the Wire at top of the present Sticker be a smooth, and therefore an un-Tapped, one.

Difference 7. This, though so essentially good in itself, as allowing the easy removal of the Swell Org. Keys (see 89, *e*), is *not*, in the Hoddesdon Organ, an *unalloyed advantage*, because, while the want of Participation of the Coupling Swell to Great is there *retained*, the Participation of the Coupling Swell to Pedale is *sacrificed* (see here for how to be recovered,—ref. *p*. next, 3rd. parag.). There is also a decrease in the approximation to Key-length Uniformity (see 89, *g*): but this is a comparatively trifling matter.

Difference 8. The *Advantages* of this have already been seen to consist of a diminution in the chances of an unbidden sounding of the Instrument, and the avoidance of any possibility of the Great-Org. Key's being *fore-lifted* in its actuations by the Pedals.

The *Disadvantages* are; that such a posit of the Square-Nose is not favourable to its access, should its treatment for Regulation be desired; and that either the Backfall or the Key of the Great-Organ becomes lengthened, because there is now more overlap of the one by the other.

n. We must now definitely indicate the actual blemishes exhibited in the Hoddesdon Manual Treatment. Those points which are matters of General Arrangement,—viz., Differences 1, 2, and 3, have already been considered in Detail (at *m* ante, parag. 4 and on), and will be virtually summarised in the succeeding Treatment No. 4 (at *q*, next, 1st. and 2nd. parags.).

Among the *Differences* 4, 5, 6, 7, and 8 we find existent the following five real Defects:—

1: Non Participation of the Swell-Org. Key in its Coupling either to the Great or the Pedale Section (see *m*, ante, 11th parag.)

2: Impracticability, *without* the Modification mentioned, (des. at *p*. next, 4th parag.), of Regulating the Coupler Swell to Great without at the same time employing something to prevent the turning round of the Wire by which such operation is performed (see *m*, ante, 10th parag.). This is sometimes very inconvenient.

3: Impossibility of Removing the Backfalls of this last-named Coupler without first taking out all their said [Driving] Wires (see *m*, ante, 11th. parag.) This point, however, is not of very great moment.

4: Certainty that, in the act of such taking out of Coupler Wires, their adjustment to Regulation will be destroyed, (see again at *m*, ante, 11th parag.).

5: The Skewing of one of the Manuals. This is here objectionable because the Pipe-Order and the Soundboard length are *alike* in the two Manual Sections; and it therefore becomes desirable to avail oneself of the opportunity so afforded for making one Set-out serve for both of their Roller-boards, and so simplifying the labour; and this in its turn calls for correspondence as regards right and left in the Tails of the two Manuals (see *p*, next, 8th parag.) And here, remember, there exists no Crossing of the Manual Actions to furnish a reason for such Skewing of the Keys. See, however, at this point, what is said (at *q*, next, 2nd parag.) with reference to the *general* undesirableness of having both of the present Sections planted in one same Pipe-Order.

The absence of Front Regulation for the Swell Manual of course continues in the present Treatment. See for this at *g*, ante, 2nd parag.; and for the obtaining of it at *h*, ante, 9th parag. and on.

As a *Summary* of this No. 3 *Treatment* we may say that it is certainly, on the whole, a very excellent one, and that the five points just stated are, all of them, of only inferior importance; but that they still are of sufficient weight to render it unadvisable to ever copy the Design in its unaltered entirety. For the Corrections of the same we proceed now to the next *Treatment*.

o. [See, however, first with respect to the Coupler Swell to Great being made of the *Part* kind (ref. *qqqq*. next, 1st parag. and on),—what is there said applying equally in the present case.]

p. *No.* 4 *Treatment*.—This consists, as just intimated, in the Correction of the Five Defects last stated.

The Arrangement and Structure of the Organ itself are assumed to be exactly as in the preceding Treatment No. 3,—as shown in the Differences 1, 2, and 3 (given at *m*, ante, 1st parag.).

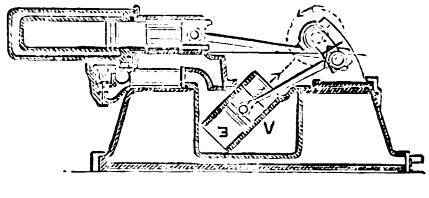
Defect No. 1 (stated at *n*, ante, 3rd parag.). This is cured exactly as before,—viz., by Forking the Tails of the Swell-Org. Keys, and inserting into them the Noses of their Action-Squares (see 89, *o*), the Stickers of the Coupler Swell-to-Pedale of course remaining Wired into such Squares (see 89, *p*).

Defect No. 2 (stated at *n*, ante, 4th parag.). The present writer's device for obviating this defect—and at the same time getting rid of the two following ones (stated at *n*, ante, 5th and 6th parags.)—consists simply in forming the lower end of the Coupling Wire into a longish square Loop or Stirrup, for carrying the Coupling-Backfall Nose within it (instead of treating such Wire as is described at *m*, ante, 2nd parag. Difference 5). The clear inner [horizontal] width of this *Nose-Stirrup* will be $\frac{1}{4}$in., and its clear inner height not less than 1in. The Fore-Nose of the Coupling Backfall will be left, in the first process of making, at the vertical width of not less than $\frac{7}{8}$in.; and will, at its proper Driving point, receive (instead of a Piercing) a vertical *Cut*, extending from its under edge to within about $\frac{1}{4}$in. of its upper edge. (The posit of the Fulcrum center of this Backfall will of course be made to correspond with such top finish of the Cut, so that the Stirrup contact will properly cross the line of Centers; see for this in *Departments* COUPLING-ACTION and KEY-ACTION.) Into the said Cut will be hitched the bottom portion of the Nose-Stirrup, and the Coupling-Wire will thus, when in action, do its work (as usual) by lifting the Coupling-Backfall Nose, and, when out of action, be free to ride up and down inside the Cut,—of course without being able to release itself from the latter. The width of the Cut should be such, that when it is lined with suitable *Cloth*, the actual space existent will just accommodate the Wire (No. 15) of the Stirrup, while yet allowing to such Wire a perfect freedom for the *riding* just spoken of. The said Cloth will be cut to almost the full width of $\frac{1}{4}$in.: and the fore Nose of the Backfall should be thinned to only a trifle over $\frac{1}{8}$in., so that the edges of the Cloth will be slightly *projectant*, and thus keep the Stirrup from actually touching the sides of the Nose. If preferred, the latter may be also *slope-cut* away on each side of the Cut proper, so as to prevent its end of the [Coupling] Backfall from being too heavy.

(*To be continued.*)

IMPROVEMENTS IN THE OTTO GAS-ENGINE.

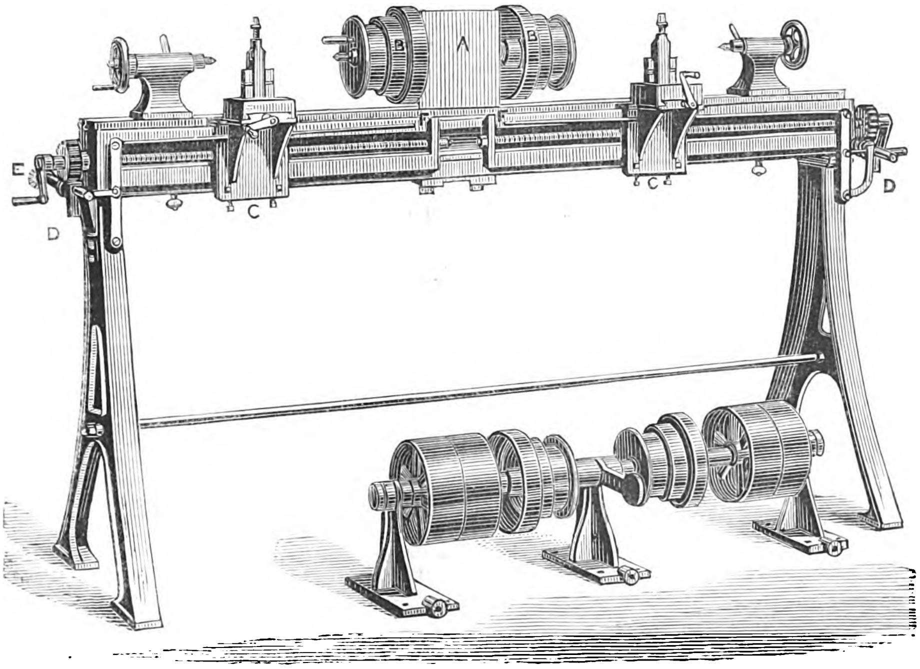
SOME improvements in the Otto Gas-Engine have been recently patented by Mr. F. W. Crossley and Mr. H. P. Holt, of Manchester (5469, 1881), the value of which are fairly shown by the diagram annexed. The invention relates to modifications in the construction and arrangement of the well-known Otto-Crossley gas-engine, by means of which during one complete revolution of the engine the combustion of the charge,



the expulsion or withdrawal of the products of combustion, and the introduction and compression of a fresh charge of air and gas are effected. The invention also consists of an apparatus for regulating the supply of the combustible. An exhaust pump or cylinder E is placed at a suitable angle in the bed of the engine, and is worked in the usual manner by a connecting rod and piston driven by the crank-shaft. The cylinder has at the side a port governed by valves (not shown in the Fig.), worked by the usual arrangement, which are so proportioned and moved that as the piston approaches the completion of its outstroke, the cylinder is put into communication with the vacuum chamber V, which is just being rapidly exhausted by the quick movement of the piston in the exhaust pump E. Simultaneously with this withdrawal of the products of combustion, just as the piston is finishing its outstroke, the gas and air supply valves admit a fresh charge at the other end of the cylinder, which, as it were, follow up the outgoing products of combustion, and fill the cylinder with a fresh charge. The ports next being closed, the piston makes its instroke and compresses the charge, which is then fired in the usual way, and another outstroke is made. There is thus an explosion for every outstroke of the piston. The supply of gas is regulated by means of a cam actuating a tappet on a lever connected to the governor, and also to the supply valve. The drawing shows the principal feature of the invention, the base acting as a water tank in connection with the casing around the cylinder.

LATHE WITH DOUBLE-HEADS FOR SLIDING TWO SHAFTS AT ONCE.

WE give an illustration of a lathe, made by the Britannia Company of Colchester, with double-heads for sliding two shafts at once. It is a very economical tool, and will, the makers assure us, soon save its cost in any shop where quantities of shafts are required.



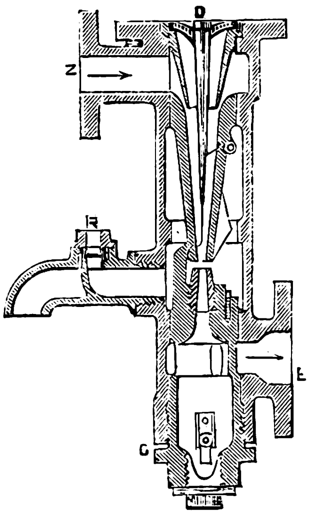
A is a square cast-iron box containing two pair gear-wheels, which drive the back shaft E E, which is connected with the leading screw which drives the rests. B B are the driving pulleys. C C traversing rests, resting upon a double-V slide on the front of lathe-bed. D D handles for working the rests back. E E back shafts. F F are two rods upon which slides run, which can be fixed at any distance, so as to stop the traverse of the tool. As the rests press against them, it withdraws a pin, causing the feed at D to be thrown out of gear.

COLOURING GOLD.

THE following directions for colouring gold alloys are given by Herr E. Schlosser, of Vienna:—

Gold alloys, particulary those containing copper, acquire through repeated heatings during their manufacture, an unseemly brown or brownish black colour, caused by the oxide of copper, to remove which they are boiled or pickled in very dilute sulphuric or hydrochloric acid, according to the colour they are to have. If we have an alloy containing only gold and copper, either sulphuric or hydrochloric acid is employed, for gold is not attacked by either of them, while the oxide of copper dissolves so easily that after the pickling the articles have the colour of pure gold, for the surface is covered with a thin film of gold. If the alloy consists solely of gold and silver, the liquid employed is nitric acid, and the articles are left in it a very short time; the acid dissolves a small quantity of silver, and the articles acquire the colour of gold. If the alloy contains both copper and silver, besides the gold, the method of pickling can be varied to suit the colour it is desired to give to it. If, for instance, it is put in sulphuric acid, the copper alone is dissolved, and the colour obtained is that of an alloy of gold and silver, for the surface consists of the two. If nitric acid were used, both copper and silver would be dissolved, and in this case the colour obtained would be that of pure gold. The articles are gently heated and allowed to cool again before boiling. The object of the heating is to destroy any grease or dust that adheres to it. If they are soldered with soft solder, they cannot, of course, be heated, and must be cleansed from grease and dust by first putting them in a strong lye, then washing with water and putting them in the acid. The acids are used dilute, usually in the proportion of one part of concentrated acid to forty parts of water. The articles are laid side by side in a porcelain or earthenware dish, and the dilute acid poured over them. From time to time one is taken out to see if it is yellow enough. When the proper colour has been reached they are washed in clean water and dried. While this pickling is merely to bring out the colour of the gold, the colouring of gold has for its object the imparting to inferior goods of the appearance of fine gold. Different mixtures can be employed for colouring gold, two of which are given below as giving very good results. Mix together two parts of saltpetre, one part of table salt, and six parts of alum, with six and a half parts of water, and warm the mixture in a porcelain vessel. As soon as it begins to rise add one part of hydrochloric acid, and bring the contents of the vessel to a boil, stirring in the meantime with a glass rod. The articles to be coloured, suspended on hooks made of strong platinum wire, or of glass, are first dipped in sulphuric acid and then put in the slowly cooking solution last described and moved to and fro in it. In about three minutes they are taken out and dipped into a large vessel of water so as to see what colour they are. If the desired shade is not yet attained they are dipped in again as often as necessary until they do have it. In the subsequent dippings they are only left in the liquid for one minute. Articles coloured in this way have a light yellow colour, but matte appearance. They are repeatedly washed in water to remove the last trace of the liquid, and then dried in soft sawdust that has been warmed. Instead of drying in sawdust they can be dipped in hot water the last time and left in there a few seconds, and when taken out the water that hangs on them will evaporate almost instantly. The second method of colouring gold alloys is by means of a mixture of 115 parts of white table-salt and 230 parts of nitric acid, with enough water added to dissolve the salt. This is boiled down to a dry mass of salt. The salt is put in a porcelain dish and 172 parts of fuming hydrochloric acid poured over it and heated to boiling. As soon as the suffocating odour of chlorine is perceived the articles to be coloured are dipped in, and the first time they are left eight minutes in the liquid. In other respects the treatment is the same as above described. Articles polished previously do not require polishing again. Care must be taken not to inhale the dangerous gas; the operation must be conducted under a draught or out of doors.

AN INJECTOR WORKED BY EXHAUST STEAM.



SUCCESSFUL attempts to utilise exhaust steam in working injectors have been made in this country, but in practice we believe a portion of live steam is used with them. *The American Machinist* gives the following account of an injector which forces water of 175° Fahr., and needs only the exhaust steam. By the aid of the sectional view we will describe its parts and their operation. The working parts are inclosed within a case open at both ends and provided with a water branch Z, and a sealed overflow R. The combined steam and water pass through the delivery branch E to the boiler. The usual check valve is interposed between the injector and the boiler. The reader will observe that this injector consists of three fixed jets or nozzles: a steam nozzle, a mixing nozzle and a receiving nozzle. The mixing nozzle consists of two parts. The fixed part being divided longitudinally for about two-thirds of its length and a short part hinged to it. The injector standing in a vertical position, the loose part falls aways from the fixed part when the injector is not working. The reason for this arrangement is substantially this: the large opening thus created permits the free entrance of a large body of water to condense the steam and insure the automatic starting and working of the injector. As soon as the injector starts, this hinged nozzle closes to its fixed size shown. The exhaust steam pipe connects with the upper end D of the injector. This injector will not *draw* water, but will work positively under a head of one foot. The water supply to the injector is regulated by the water regulator, which is permanently set when the working conditions are once ascertained. The exhaust steam pipe is connected with the exhaust pipe as near the cylinder of the engine as possible, in order to utilise all the available heat of the exhaust steam. *No live steam from the boiler is used*, so this injector catches and utilises the waste power of the engine as it is about to escape into the open air. This injector is of special value where exhaust pipes are of insufficient capacity to convey away the exhaust steam. Many instances of this kind may be found in our cities. If there is a back pressure in the exhaust pipe, as soon as the injector starts the back pressure will be greatly reduced, and in many cases a partial vacuum be produced, the injector acting as a jet condenser. To make this clearer we will refer to certain experiments, with their results, which we recently witnessed with this injector at the works of William Sellers and Co., Philadelphia, where they have a No. 6 exhaust steam injector in practical operation. The feed water showed a temperature of 64° when the exhaust steam valve was opened. The back pressure of steam in the exhaust pipe was was half a pound per square inch. Steam first came out of the overflow, then water, after which the injector went to work forcing water at a temperature of 168° to 175°, against a boiler pressure of 65 pounds. Immediately upon the starting of the injector, the back pressure in the exhaust pipe disappeared, and the vacuum gauge indicated half an inch to one inch of vacuum in the pipe. By repeated trials it was found that the injector would break and start automatically with a vacuum of one inch in the exhaust pipe, forcing water against a boiler pressure of 68¾ pounds. Upon trial, it was found that the injector would work against as boiler pressure of 98 pounds before the steam broke. It then started automatically. For higher pressures, from 75 pounds up to 150 pounds per square inch, a second steam nozzle is introduced, and a very small quantity of live steam is used from the boiler to help out with the exhaust. It will be understood that this injector at once takes the place of a heater and feed pump, the power to operate it costing nothing. It, moreover, increases the available power of the engine, to which it is attached by its action as a condenser in removing the back pressure. We noticed, at the trial alluded to, that the vacuum gauge several times indicated a vacuum of 4in. in the exhaust pipe before the steam broke. This experiment was repeated several times. Another and equally interesting experiment tried was to turn on the water at 8 pounds' pressure in the feed pipe, and upon opening the throttle the injector went to work reducing the pressure in the the feed pipe to 2 pounds. The feed water was turned into a tank, having a head of one foot. The overflow from the tank and the injector were about equal. As soon as the injector started, the overflow from the tank ceased, proving that about double the quantity of water passed through the injector when working that could escape from the overflow when it was not working. The injector with which these experiments were tried was a No. 6, with a steam pipe 2½in. in diameter; overflow, 1¼in. delivery, 2¼in., feed water, 1¼in.—throwing 600 gallons of water per hour.

An injector known as the Binary is made by a Manchester firm, but as its name implies, boiler steam as well as exhaust is invariably used.

THE GEOGRAPHY OF PLANTS.*

EXPERIMENTS made to prove or disprove spontaneous generation reveal the fact that vegetation may be said to be almost ubiquitous; wherever soil, heat, light and moisture are found, there the plant will appear; the very bodies in which we dwell, nay, even the bread intended to nourish them, is not unfrequently converted into a field teeming with vegetable life. On the earth, however, although plants may be said to grow everywhere—in tropic heat and arctic snow—their kinds, number and size depend on certain conditions resulting from the varying proportions in which soil, solar influence and moisture are supplied to them. Of these, the effect of a change of soil was probably first observed; the influence of the solar rays, varied by proximity to mountains, or distance from the equator, could not long escape observation, and, finally, moisture and atmospheric influences would be noticed. These together with human and animal agencies constitute the causes of vegetable distribution, but, in attempting to form a conception of the present appearance of the terrestrial flora, we must not lose sight of the principle of community of origin, the real key to geographical distribution, which tends to *aggregate* groups of related forms, as the former agencies tend to segregate, to disperse, or, as Darwin says, to modify.

The first question that suggests itself to him who attempts to trace the distribution of plant-life on the globe, a task, to some extent impossible, because of the immense tracts of land—and those with the most varied and copious vegetation—of the natural products of which our knowledge is still most deficient, is this: What was its origin? Were plants *created* where they grow, or did they spring up from seeds brought to their present locations by accident or design? If the former, all attempts at accounting for their appearance there are vain; but if the latter, the question arises, whence were they first brought? What shall we regard as the centre of creation, the home of the vegetable world? Closely connected with these inquiries is the question of the origin of species to our knowledge of which Darwin has contributed so much. Accepting the prevailing interpretation of Gen. i. 11, "God said, Let the *earth* bring forth grass," &c., we see no difficulty in accounting for the appearance of plants wherever the conditions of soil and climate are favourable; and Creative Wisdom would call only those that are adapted to any district, or to the conditions of the earth at large into existence. Hence the essential likeness of vegetable forms would be in proportion to their degree of proximity, and we would expect to find well-defined areas of vegetation distinguished by similarity of features—of form and appearance, as we find a certain resemblance among the inhabitants of the same region. Such we may suppose to have been the case in the beginning; but the earth has undergone changes, and these have modified the existing forms. Geologists speak of ages, and they also speak of America as the "old world." A close comparison of the Flora of the Arctic regions might lead to the belief that it is American in origin, whence it spread westward to Asia and Europe, for, as we travel from Northwestern Europe toward and through Asia, we find its traces getting stronger and stronger, notwithstanding that Scandinavia would according to older rules have been regarded as the centre of creation for the Arctic lands, and may now be termed the chief centre of preservation within the Arctic circle. The influence of physical and genetic causes has produced of this great northern, three secondary floras. Of these, the Arctic-Alpine Flora (consisting chiefly of plants of small stature, slow growth, and limited means of dispersion, compensated by long lives and great powers of endurance), is perhaps the most interesting. Hooker, estimating the whole Arctic flora at 762 species, found that 379 belonged to Arctic America, of which 269 are common to Scandinavia. Arctic Europe contains 616 species, and of these 586 are Scandinavian. The icy temperature of the glacial epoch would attract this flora towards the equator, but with the genial warmth of succeeding ages, an orderly retreat towards the poles would begin. Not all the species, however, would regain their original home; some would find congenial abodes even on the hills and mountains of the tropics, so that the remarks of Hooker, that "the Scandinavian flora is present in every latitude of the globe, and is the only one that is so," is found to be literally true.

Descending to an examination and description of the vegetation constituting this flora, we find it composed almost entirely of cryptogamous plants, mosses, lichens, and fungi. Among the mosses, the pioneers of vegetation, the polytricha are used for mattresses by the Laplanders, and the plains of Siberia have put on a dense cloak of these cosmopolitan, interesting little evergreens, to protect them against the Boreal blasts. The lichens, those beautiful children of nature sunning themselves in the dazzling rays that illumine Tropical Chimborazo, and clothing the icy surface of the Polar regions with a garment convertible in rainbow hues or healing balms; or into the staff of life for Tartar or Laplander for Sir John Franklin and his unfortunate companions. The fungi, or mushrooms, proverbial for wonderful rapidity of growth — puff-balls have been known to grow 6in. in diameter in a single night—unlike other plants, absorb oxygen and exhale carbonic acid. They abound in Sweden, which has produced more species upon a given area than any other known locality, except perhaps the Southern U.S. The larger fleshy forms, presenting an endless variety of graduated tents, exhibit, on being broken, beautiful changes of gorgeous hues. They are used as food and intoxicants by the inhabitants of Northern Europe and Asia, and as delicacies in more Southern climes. These, together with stunted forms of the willow birch, Azalea, and rhododendron, constitute the flora of the Arctic regions, adapted to prepare the soil for the production of grasses and herbs; for where now the tall sons of the forest joyously rear aloft their leafy coronals, the humble lichen lately clothed the naked rock. But, look beyond the lowly heads of the dwarfish Alpine shrubbery that forms a gloriously tinted border-land: a race of giants now approaches, and the flora of Irkutsk, richer than that of Berlin, presents a varied vegetation of mixed origin and most extended geographical range. Forest and prairie in delightful alternation constantly vary the prospect, and the Conifers—wholly confined to the Northern hemisphere—the pine, the spruce, and the fir, whose perpetual green enlivens the landscape, declare to the people of the North, that though snow and ice cover the ground, the inner life of plants, like Promethean fires, is never quenched. At their base is found the flax, the rice of the Indians, and oats, and the currant, the cranrasp and strawberry; the meadow grass, the prairie, "the gardens of the desert, for which the speech of England has no name."

The temperate zone, at which we next arrive, with its mean annual temperature varying from 40° to 60°F., extends from 35° to nearly 60° N., embracing the Northern U. S., Europe, from the Alps to St. Petersburg, and Asia between the Himalaya and the Altai mountains. This is the zone of deciduous trees, and of the food-plants of civilised nations. The most numerous of the remaining characteristic orders are the umbelliferæ and the cruciferæ, of which the latter are almost confined to the Northern hemisphere. Here abound "The monarch oak, the patriarch of the trees." Here, too, is found the weeping willow, named the Salix Babylonica.

The numerical proportion of 500 species of phænogamous plants, collected by Clauss and Gœbel on the steppes of Southern Russia, was: grasses one-eleventh, compositæ one-seventh, and crucifera one-ninth; the glumaceæ are one-seventh, the compositæ one-eighth, and the crucifera one-eighteenth of all German phænogamous plants.

The warm zone, the zone of winter foliage, is situated between the temperate and the tropic of Cancer, and has a mean temperature of from 60° to 72°F. Its characteristic vegetation consists of trees and shrubs which retain their foliage throughout the year, though their growth is interrupted during the winter. The leaves are in general tough, stiff, and glossy, but lack the delicate tints which adorn the foliage of deciduous trees in spring and summer, and the more gorgeous hues of autumn. Here are found the live oak, myrtle, laurel, and oleander, and the box, invaluable in the arts: with the cotton, the mulberry, and the olive; the tea of China, the cup that cheers, but not inebriates. The rice, originally from India, was introduced to Europe by the Macedonians, and is now successfully cultivated in our Southern states. Characteristic of this region are the fig, the orange, the pomegranate, the almond, and the choicest varieties of the vine. This is the zone of the Southern U.S., Southern Europe and Northern Africa, that is, the shores of the Mediterranean, between the Alps and the Atlas, and Southern Asia. This is the vegetation that accompanies, and and always has accompanied, the flower of art and civilisation.

But we must hasten to cross into the tropics, the zone of palms and bananas, whose mean annual temperature varies from 72° to 82° F. Luxuriance of growth, great development of foliage, and immense variety of species distinguish the vegetation of this equatorial belt. The frail and delicate ferns of our acquaintance assume the proportion of trees rivalling the palms in the beauty of their crown of foliage; the grasses of the temperate zones here become the sugar-cane, and the gigantic bamboo whose hollow stalk furnishes the principal building material. Grasses with joints at intervals of 17ft., palms attaining an altitude of 180ft., to which belong the palmettos of our Southern states, the most interesting in the vegetable kingdom, whose towering stems and enormous foliage impress a peculiar grandeur on the landscape of the countries they inhabit; bewildering in its fecundity, a single spathe of the date-palm contains about 12,000 flowers, and another species has been computed to have 600,000 flowers upon a single individual. Nor must we forget the cocoanut-palm of the East Indies. The Cingalese builds his house of its trunk, and thatches the roof with its leaves; his children sleep in a rude hammock made of the husk of the fruit; his meal is scraped cocoanut, boiled over a fire of cocoanut-shells and husks, and is eaten from a dish of its leaves with a spoon of its shell. In his canoe, made of its trunk, he carries a torch of its leaves, and fishes with a net of its fibre; with its juice he quenches both his natural and artificial thirst, and dances to the music of cocoa castanets. He anoints himself with cocoanut-oil, and cures himself with medicine made from the tree. Yea, over his cradle, and over his grave, a bunch of cocoanut blossoms is hung to charm away evil spirits. The comparative exuberance of their foliage may be understood if we conceive our white and fragrant water-lily transformed into the Victoria regia, whose leaves, from 6ft. to 12ft. in diameter, afford a sure footing for aquatic birds watching for their prey, and whose flowers measure from 12in. to 16in. across, and of their fruit, from the Talipat-palm, whose leaves are 30ft. in breadth, and whose single crop of fruit feasts a whole country.

Especially striking is the variety of plants growing in the same locality; the forests are not composed of single families like the pine or the oak of the temperate zones, but rather of a matted vegetation of forest trees, bamboos, coarse grasses, creeping and climbing plants, o'ertopped by columns of graceful palms, waving to and fro, a forest above a forest.

Time will permit me merely to glance at a few general facts touching the distribution and migration of individual plants:—I. The present condition and distribution of terrestrial vegetation is the result of previous geological changes in the condition of the earth, modified by changes introduced by the agency of man, the lower animals and the elements. Lichens in the North and portulaca in the tropics clothe the naked rock and form layers of vegetable mould to be succeeded by grasses, herbs, and shrubs, until at last the majestic oak or the slender palm lifts up its head, thus exhibiting a most striking parallel to the sucessive stages of society, and clearly showing how the superior civilisation rests upon and grows out of the successive inferior. The extent of the habitat of plants depends on the degeee of cold they can endure. Perhaps the best exemplification [illegible] this can be found in the humble grass Trisetum [illegible]bspicatum, which is found from 54° S. to 72° [illegible]N., or in a range of 127° latitude extending [illegible] Terra

---

* Part of a paper read before the Lancaster Plant Club, by Prof. R. K. Buehole, of Lancaster, Penna., U.S.A.

Del Fuego, along the Andes and Rocky Mountains to Iceland and across Europe, along the Alps, and the Altai in Asia to Kamtschatka. But this seems to be equally and the only inhabitant of the opposite polar regions. Its counterpart is furnished in the range of the peach transported by the agency of man from China through Asia and Europe to California, or of the wheat cultivated B.C. 2700 by the Celestials, and now belting the two Continents until its harvests in the golden state surpass in value the product of its auriferous mines.

An idea, although inadequate, of the modifications of the existing flora which man has produced, may be had if we consider, not only the changes in individual plants brought about by cultivation, but more especially the utter annihilation of the forests and prairies of our own country, and the consequent occupation of the soil by the cereals. Can we realise the thousands of species thus destroyed? And this war of extermination has continued at least since the dawn of history! Nor has the destruction been limited to those directly exterminated, but others dependent upon these have also perished; moreover, the destruction of the forests has materially changed the climate, and this in its turn has brought death to others: thus man's destructive agency may well be called unceasing, and the whole creation groaneth and travaileth until now, waiting for its redemption.

II. This brings us to the fact that the forms of organic beings are mutually dependent, hence if in any particular locality, the number of species of a certain family, as of the compositæ, is known, an approximate conclusion can be formed of the number of any, and of all the phænogamia; that is, the number of the compositæ determines the number of the leguminosæ, and so of the rest, and of all. The numerical proportion of seven large families in the temperate zone is as follows:—Glumaceæ, including the grasses one-eighth (grasses alone one-twelfth); compositæ, one-eighth; leguminosæ, one-eighteenth; labiatæ, one twenty-fourth; umbelliferæ, one-fortieth; amentaceæ, one forty-fifth; cruciferæ, one-nineteenth. In examining the increase or decrease of any particular form of plant life, the rate must also be taken into account. Thus the leguminosæ decrease from the equator towards the north pole, in the first 10° they stand at one-tenth, between 45° and 52° at one-eighteenth; 67° and 60° one thirty-fifth. The rubiaceæ, the euphorbeaceæ, and the malvaceæ decreased the same direction, while the glumaceæ, the ericaceæ, and amentaceæ decrease in the opposite direction. The compositæ, labiatæ, umbelliferæ, and cruciferæ decrease from the Temperate Zones, both directions, towards the pole and towards the Equator, the umbelliferæ and cruciferæ most rapidly towards the latter. The cruciferæ are three times more numerous in Europe than in the United States. The labiates are represented by one, the umbelliferæ by two, and all the phænogamia by 315 species.

III. As we recede towards the limits of vegetation, whether in latitude or altitude, the order seems to be trees and vines, shrubs, herbs, grass and cryptogams, mosses and lichens. Of pharenogamous plants, the grasses are the outposts everywhere, and they reach 18½° nearer the North than the South pole. Dr. Eights, visiting the South Shetland Islands, latitude 62° S., found a small grass, the Aira Antarctica, the most Southern flowering plant known. Cockburn Island, 64° 12′ S., which produces only cryptogams; mosses and lichens seem to be Ultima Thule of Antarctic vegetation. There is also a difference in the number of species belonging to Antarctic phænogamous vegetation at equal latitudes. Iceland has five times as many phænogamous plants as the southern Lord Auckland and Campbell's Island group; but Antarctic plant life, though more uniform, is richer in sap and more luxuriant. In the most northern portion of the plain of Siberia, the northernmost limit of trees and shrubs, of coniferæ and amentaceæ, is found on Admiral Wrangel's beautiful chart at 67¼° North latitude; but towards the west at the Lena at 71°, and Walden island 80½° North, has ten species of phænogamous plants.

MEASUREMENT OF CURVATURE AND REFRACTIVE INDEX.[*]

By C. VERNON BOYS, A.R.S.M., Demonstrator of Physics at the Normal School of Science, South Kensington.

OF the methods best known for measuring the curvature of surfaces, that depending on the spherometer is both accurate and convenient in the case of surfaces of sufficient diameter and where the curvature is not too small. The reflection-test, depending on the observation with a telescope of two images projected on a scale, is certainly not convenient, nor is it capable of giving very accurate results. While endeavouring to find some more satisfactory way of examining the curvature of the surfaces of lenses that would be both accurate and simple, I discovered the method which I am about to describe. Though, from its great simplicity, I can hardly expect it to be new to every one, yet I have never heard of its being employed, nor do those to whom I have shown it remember to have seen it before. Therefore, even if it should be shown that this method is not new, it is certainly so little known that I think it worthy of attention.

The centre-of-curvature test known as Foucault's test, which is used to examine the figure of the mirrors of reflecting telescopes, gives, perhaps, the most delicate means of examining form that exists. By its means the expansion by heat of a portion of the surface produced by touching it with the finger is rendered evident, as an apparent mountain standing out of the glass, which takes from five to fifteen minutes to disappear; and the warm air leaving a hand held between the centre of curvature and the surface has the appearance of flames of fire. In each of these cases no other system of observation could show in so striking and conspicuous a manner effects depending on so slight a cause.

The examination at the centre of curvature is carried out in this way:—The mirror is placed in a convenient support so that its surface is vertical; and in front of it is placed a lamp with an opaque chimney, through which some pin-holes have been made. If one of these holes is near the centre of curvature, the light leaving it and reflected by the surface is brought to a focus on the other side of the centre. This focus is then found; and the lamp is moved till the focus is as near the chimney as will allow of its observation. A piece of thin sheet-metal, with a straight edge, is then placed so that it may be moved to or from the mirror or laterally. Now, if the edge of this is sufficiently on one side to let the light pass the focus, an eye immediately behind the focus will see the mirror filled with light; but if it is gradually moved across while the eye still watches the mirror, the illumination of the latter will appear to die away in the same direction as, or in the opposite direction to, the movement of the edge, or uniformly, according as the edge is between the mirror and the focus, or between the eye and the focus, or at the focus. By this means, and by this means only, can the different radii of curvature of the successive zones of a parabolic mirror whose radius of curvature is twenty times its diameter be accurately measured. The close contact between the parabola and circle is due to the fact that it is one of the third order. I think it worth mentioning that the formula given by Dr. Draper in the 'Smithsonian Contributions to Knowledge,' vol. xiv. (1865), for testing the true parabolic form, gives only half the deviation from the sphere, as was pointed out by a correspondent of the ENGLISH MECHANIC who signs himself "Orderic Vital," and was confirmed by Mr. E. H. Liveing and myself.[*] I have gone thus fully into the Foucault test, as my method involves the same general principle—viz. making the rays return along the path whence they came.

Before considering the general case applicable to any kind of lens, I think it best first to show the simplicity of the method in a particular and common case—that of a thin equiconvex lens. Fix an ordinary spectacle-lens in a clip, with its principal plane vertical; in front of it place a card with a small hole in it; and illuminate the hole with a candle-flame. It will be found that, when the lens is at a certain distance from the card, there is an inverted image of the hole formed on the card. When this is the case, the light leaving the hole and meeting the front surface of the lens is refracted and meets the back surface normally: most of the light passes through; but a small portion is reflected back along the path whence it came, and is sufficient to produce an image easily visible in the day. This distance of the card from the lens, which is the apparent radius of curvature of the back surface seen through the front surface, is throughout this paper called f. The true focal length, F, of the same lens may be observed in the usual way; but it is more conveniently found by fixing a plane surface of glass behind the lens, when it will be found that another image may be produced when the lens is about twice as far from the card as it was before. Since an image is produced, the light must have returned along the path whence it came, and must therefore have struck the plane surface normally—that is, have left the lens and returned to it as a parallel beam; therefore, the card is at the principal focus. For a plane glass surface a piece of plate glass blacked at the back, or the surface of a prism may be used. The observations of the distances F and f can be easily and accurately made; then the radius of curvature may be found from the formula

$$R = \frac{Ff}{F - f},$$

as I shall presently show.

Before doing so, however, I think it well to describe the most accurate method of observing the distances F and f. The card with the pin-hole is convenient; but it is difficult to find the place with great accuracy where the focus is most sharply defined, and to measure the distance when found. All difficulty is completely avoided by the following plan:—Take a piece of thin sheet-metal, of the size and shape shown in Fig. 1, and fix in front of it, in the position shown by the dotted line, a small reflecting prism, so that when a small bright flame is placed on one side of the prism a beam of light leaves the slit in the plate. Replace the card by this plate and prism, and move the lens till the aërial image of the slit is formed in the corner, close by the edge of the prism. To examine the position of the image with greater precision, an ordinary positive eyepiece will be found convenient. When the image and the slit are equally distant from the lens, there will be no relative movement on moving the eye; if there is relative movement, the distance between the lens and the plate must be increased or diminished according as the plate or the image appears to move with the eye. When the distance has been properly adjusted, it is easily measured by resting a scale on the continuation of the lower edge of the slit, and moving it till it touches the surface of the lens. The position of the edge of the prism or of the slit may then be read with great accuracy; and it will be found that, on repeating the observations several times, a discrepancy more than a tenth of a millimetre between any of the measures need not occur.

Instead of observing the position with an eyepiece, the Foucault plan may be adopted. Place the eye immediately behind the edge of the prism, so that all the light forming the image enters the eye. Move the prism laterally towards the image, which, of course, moves to meet it, and observe whether the light which fills the lens dies away uniformly, or whether it seems to retreat from one edge of the lens. If the retreat is in the same direction as the movement of the prism-plate, the distance is too small; if in the opposite direction, too great. Either of these systems will give accurate results; I prefer the first, as tiring the eye less and being, especially with snall lenses, the more accurate.

A convenient support for the lens is made by boring a hole, with a less diameter than the lens, in a piece of thin parallel-sided wood. The lens may be slipped under two clips, so as to rest against the edge of the hole on one side of the wood. On the other side a piece of plate glass, blacked at the back, is cemented or held in a similar way by clips. If this piece of wood is fixed vertically on a horizontal slide, it may be moved away from the prism-plate, and the distances f and F determined in a few minutes. Fig. 2 is a horizontal section of the arrangement when the principal focus F is being determined. The dotted line shows the position for f.

If instead of a lens a single surface only is to be measured, there is, of course, no difficulty in the case of a concave surface; but a convex surface may have its curvature determined in the following way:—Arrange the prism-plate and flame as before. At a distance in front of the prism-plate, more than its focal length, fix a converging lens, preferably achromatic. Observe the position of the aërial image on the other side of the lens, and make it coincident with the edge of a plate of metal, m. The positions must be so adjusted that the distance of m from the lens is greater than the radius, of curvature of the given surface. Now place this surface between the metal plate and the lens, and move it till an image is formed accurately by the side of the prism. Then the light impinging on the convex surface has been reflected back along the path whence it came, and has, therefore, struck that surface normally; therefore, the place m, where those rays would have met had they not been intercepted, is the centre of curvature of the convex surface. Its radius of curvature can, therefore, be measured by suitably-formed callipers. Fig. 3 is a horizontal section of the arrangement.

I have stated above that $R = \frac{Ff}{F - f}$ in the case of a thin equi-convex lens. This must now be proved, and the more general case of any kind of lens treated next. First, consider that the lens is so thin that any normal to either surface cuts each at points appreciably equally distant from the axis. Since the image which is produced is partly formed of rays which are near the axis, these rays meet the axis at angles so small that the tangent, the sine, and the arc are convertible terms. If the lens is large and not of very long focus, this will not be true of rays from near the edge of the lens; but as these rays are not necessary for the image, the central ones alone may be employed, and by them the curvature of the whole surface, if spherical, determined.

On the front surface take any point p, and through it draw a radius mR of the back surface. Join p with f, the apparent centre of curvature of the back as seen through the front surface. Draw also through p a radius ab of the front surface and a line dc parallel to the axis. Then the angles mpd, dpb, apc are equal to one another. Call these angles θ. The angle $apf = \mu \times$ angle $mpb = \mu 2\theta$; therefore, the angle $cpf = \mu 2\theta - \theta$. But the angle $ep\mathrm{R} = \theta$;

---

[*] From the *Philosophical Magazine.*

[*] ENGLISH MECHANIC, Vol. XXXI., pp. 89, 184, 207.

$$\therefore \frac{\mathrm{R}}{f} = 2\mu - 1, \text{ or } \mu = \frac{\mathrm{R} + f}{2f}.$$

By the property of equiconvex lenses, $\mu = \frac{\mathrm{R}}{2\mathrm{F}} + 1$;

$$\therefore \frac{\mathrm{R}}{2\mathrm{F}} = \frac{\mathrm{R} - f}{2f} \text{ and } \mathrm{R} = \frac{\mathrm{F}f}{\mathrm{F} - f}$$

or, in a thin equiconvex lens, the radius is equal to the product divided by the difference of the principal focal length and the apparent radius of the back as seen through the front surface.

It might be expected that, as this formula has been deduced from a specially simple case, a more complicated one would be necessary if the two sides of the lens were not equally curved, or if one surface were plane or concave. But such is not the case; the same formula applies in every possible case, though, as will be shown, experimental difficulty occurs in the case of a diverging meniscus.

The proof of the formula in the case of a thin lens which is not equiconvex is similar to that already given. Make the same construction as before, and let R_1 R_2 be the centres of the surfaces 1 and 2, and f_1 the apparent centre of 1 seen through 2. Also let $\mathrm{R}_1 = n\mathrm{R}_2$. Call each of the angles mpd, $cp\mathrm{R}_1$, θ; then the angles $dp\mathrm{R}_2$ and apc will each equal $n\theta$. As the angle $apf_1 = \mu \times$ angle $mp\mathrm{R}_2 = \mu(1 + n)\theta$, $\therefore$ angle $cpf_1 = \mu(1 + n)\theta - n\theta$. But angle $cp\mathrm{R}_1 = \theta$;

$$\therefore \frac{\mathrm{R}_1}{f_1} = \mu(n + 1) - n.$$

Substitute $\frac{\mathrm{R}_1}{\mathrm{R}_2}$ for n, and it will be found that

$$\mu = \frac{\mathrm{R}_1(f_1 + \mathrm{R}_2)}{f_1(\mathrm{R}_2 + \mathrm{R}_2)} \quad \ldots\ldots\ldots\ldots\ldots(1)$$

A similar proof will show that

$$\mu = \frac{\mathrm{R}_2(f_2 + \mathrm{R}_1)}{f_2(\mathrm{R}_1 + \mathrm{R}_2)} \quad \ldots\ldots\ldots\ldots\ldots(2)$$

By the property of lenses,

$$\mu = \frac{\mathrm{R}_1\mathrm{R}_2}{\mathrm{F}(\mathrm{R}_1 + \mathrm{R}_2)} + 1, \quad \ldots\ldots\ldots\ldots(3)$$

where F is the principal focal length.

By combining (1) and (3),

$$\frac{1}{\mathrm{R}_1} = \frac{1}{f_1} - \frac{1}{\mathrm{F}}, \text{ or, } \mathrm{R}_1 = \frac{\mathrm{F}f_1}{\mathrm{F} - f_1} \quad \ldots\ldots(4)$$

By combining (2) and (3),

$$\frac{1}{\mathrm{R}_2} = \frac{1}{f_2} - \frac{1}{\mathrm{F}}, \text{ or, } \mathrm{R}_2 = \frac{\mathrm{F}f_2}{\mathrm{F} - f_2} \quad \ldots\ldots(5)$$

By combining (1) and (2),

$$\frac{1}{\mathrm{R}_1} - \frac{1}{\mathrm{R}_2} = \frac{1}{f_1} - \frac{1}{f_2} \quad \ldots\ldots\ldots\ldots(6)$$

It is not a little surprising that, whatever the refractive index of the material of the glass, or the curvature of the front surface, the curvature of the back surface can always be obtained from an expression in which both apparently are omitted. They are both, of course, involved in each observation, F and f, which accounts for the possibility of their being eliminated.

It is interesting to follow the changes which occur between the two extreme limits of form—a double convex and a double concave lens. Take a double convex lens, and suppose one of the surfaces to be gradually pushed in; when it has become plane we have the first particular case—a plano-convex lens. Call the flat surface 1 and the convex surface 2; then, by (4),

$$\frac{1}{\infty} = \frac{1}{f_1} - \frac{1}{\mathrm{F}};$$

$\therefore f_1 = \mathrm{F}$, or the apparent centre of curvature of the flat surface seen through the round surface is at the principal focus. By (5),

$$\frac{1}{\mathrm{R}_2} = \frac{1}{f_2} - \frac{\mu - 1}{\mathrm{R}_2},$$

since $\mathrm{F} = \frac{\mathrm{R}_2}{\mu - 1}$; $\therefore$ $\mathrm{R}_2 = \mu\, f_2$, or the apparent radius of 2 is less than the true radius in the ratio of μ to 1.

If the pushing-in process is continued, the surface 1 will become concave. Four observations can then be made—F, f_1, f_2, and R_1; therefore, R_2 may be found by either of the equations (5) or (6). As the surface 1 becomes more concave, its apparent centre on the other side of the lens will retreat to an infinite distance; and then the concave side will appear flat when viewed through the convex surface. This is the case when $\mathrm{R}_1 = -\mathrm{F}$, as may be shown by making $f_1 = \infty$ in (4), or as is obvious from a diagram. When R_1 becomes less than this, f_1 becomes an imaginary point on the other side of the lens, such that, if rays were sent so as to converge upon it, they would return as though they had come from it. Its position could be determined experimentally by the method given for a convex surface; but as the true radius can be determined directly, there is no necessity to find this imaginary apparent radius.

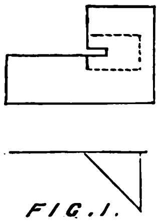


FIG. 1.

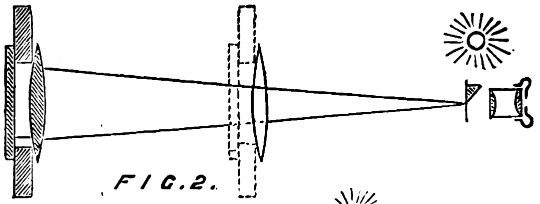

FIG. 2.

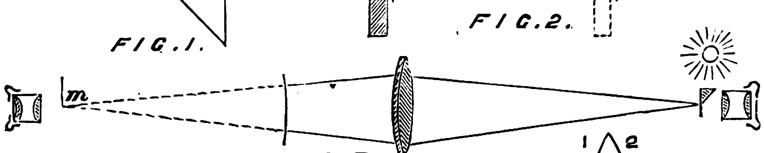

FIG. 3.

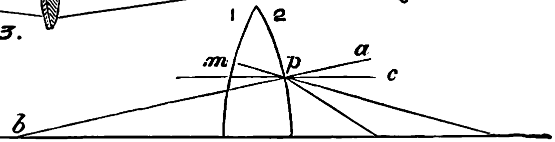

FIG. 4.

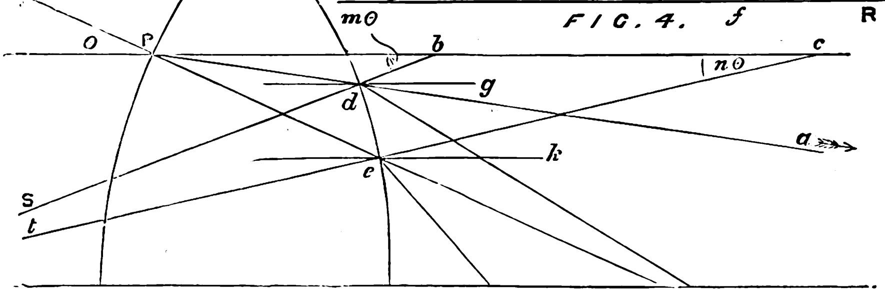

FIG. 5

Let the concavity of surface 1 increase; the next particular case is that of a watch-glass, where $\mathrm{R}_1 = -\mathrm{R}_2$. Then F becomes infinite, and the two points f_2 and R_1 become coincident. When the surface 1 becomes still more concave, F becomes negative and virtual, and R_1 and f_2 pass one another. The experimental determination now becomes more difficult; for neither can F or f_1 be observed directly; but still the equations (5) and (6) hold. They may each be found by the method for a convex surface, which is less convenient than the direct method.

If the concavity of the surface 1 continues to increase, another limit will be reached, at which f_2 becomes infinite. This is obviously the case when $\mathrm{R}_2 = -\mathrm{F}$; that is, when the focal length has been so shortened by the increasing concavity as to be equal to the radius of the convex surface. When this is the case, the surface 1 seen through 2 appears plane. When the concavity passes this limit, f_2 becomes negative and imaginary, and the experimental difficulty is still further increased, for R_1 only can be directly observed; but still the equations (4), (5), and (6) are true. No further increase in the concavity of 1 will produce any new conditions. Now, the curvature of 1 remaining constant, let 2 become flatter; when it has become plane, there is no occasion to observe F. f_1, or f_2 to determine the form of the surfaces. When 2 becomes concave also, the curvature of each surface can be directly measured; and all difficulty is removed. Every possible case has now been considered; and though the equations are always true, experimental difficulty only occurs in the two classes of diverging meniscus.

If a parallel beam of light falls on the lens, it will be refracted at the front surface, partly reflected from the back, and again refracted at the back surface, and be brought to a focus at a distance from the lens equal to half the apparent radius.

As the light, in its passage to and from the apparent centre f_1, is twice refracted by 2 and once reflected by 1, it would seem at first sight that the value of f_1 might be obtained by combining in the usual way the expression for twice the focal length of an equiconvex lens with surfaces having the same curvature as 2 and the radius of 1; thus

$$\frac{1}{f_1} = \frac{1}{2\mathrm{F}} + \frac{1}{\mathrm{R}_1}.$$

But this operation, depending on a false assumption, leads to an erroneous result. It makes $f_1 = \frac{\mathrm{R}_1\mathrm{R}_2}{\overline{\mu - 1}\,\mathrm{R}_1 + \mathrm{R}_2}$, instead of $\frac{\mathrm{R}_1\mathrm{R}_2}{\overline{\mu - 1}\,\mathrm{R}_1 + \mu\,\mathrm{R}_2}$. The error arises in this way:—When a double convex lens is employed, either to bring or to hurry light to a focus, the bending-powers of the two surfaces depend on the angles they make with the ray in the lens. Now, if one of these angles great, the other must be small; so that, as a combination, they have the same focus-shortening power, however the light falls on them. But when a ray passing from and returning to the apparent centre f strikes the front surface, that surface makes an angle with the ray in the lens which is greater than the mean in the ordinary way; therefore the surface produces a greater diverting effect; and hence the distance f is less than it would be if the supposition made were correct.

All that has been shown at present is only true when the thickness of the lens is inappreciable. When this is not the case, rays, whether from the principal focus F or from an apparent centre f, will not cut the two surfaces at points equidistant from the axis. First, consider the case of an equiconvex lens. Let Fig. 5 represent a portion of a thick equiconvex lens. As before, since the central rays are sufficient to give an image, arcs, sines, and tangents may be considered identical. On one surface take any point p. Through it draw a radius $p\mathrm{R}$, and the line pbc parallel to the axis. Now a ray of light parallel to the axis, meeting the surface in the point p with an angle of incidence equal to θ, will be refracted so that the angle dpe is equal to $\frac{\theta}{\mu}$; therefore the angle $bpd = \theta\,\frac{\mu - 1}{\mu}$. Therefore the line pd continued will meet the axis in a point a such that

$$pa = \frac{\mu\mathrm{R}}{\mu - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

But this ray is diverted at the point d, and bent down so as to meet the axis at the principal focus F. It is required to find the length $d\mathrm{F}$, or, shortly, F—that is, the distance of the principal focus from the surface. Since the line pa has cut the front surface at a point d nearer the axis than p, the inclination of the normal, bs, at d will be less than θ, and will equal $m\theta$ if

$$m = \frac{pa - t}{pa} \quad \ldots\ldots\ldots\ldots\ldots(2)$$

t being the thickness of the lens. Now the angle pds = the angle dbp + the angle $bpd = \theta\left(m + \frac{\mu - 1}{\mu}\right)$; therefore the angle $bd\mathrm{F} = \mu\theta\left(m + \frac{\mu - 1}{\mu}\right)$, and the angle

$$gd\mathrm{F} = \mu\theta\left(m + \frac{\mu - 1}{\mu}\right) - m\,\theta = \theta\,(\overline{1 + m}\,\overline{\mu - 1}) \quad \ldots\ldots\ldots\ldots(3)$$

Since the lines $d\mathrm{F}$ and da leave the same point d with different inclinations, they will meet the axis at distances which are inversely as these angles. Therefore

$$\frac{da}{\mathrm{F}} = \frac{\overline{1 + m}\,\overline{\mu - 1}}{\frac{\mu - 1}{\mu}} = \mu\,\overline{1 + m};$$

therefore

$$\mathrm{F} = \frac{pa - t}{\mu\,(1 + m)} = \frac{\mathrm{R}\left(\frac{\mu\mathrm{R}}{\mu - 1} - t\right)}{2\mu\mathrm{R} - t\,(\mu - 1)} \quad \ldots\ldots(4)$$

by (1) and (2). This is the distance of the principal focus from the surface of the lens.

The distance ef of the apparent centre from the surface may be found in a similar way. The normal at e makes an angle $n\theta$ less than θ, such that

$$n = \frac{R - t}{R} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The angle $pet = (n + 1)\,\theta$; the angel $cef = \mu\,(n + 1)\,\theta$; and the angle $kef = \theta\,[\mu\,(n + 1) - n]$. Therefore

$$\frac{ef}{R - t} = \frac{1}{\mu\,(n + 1) - n}, \text{ and } ef = \frac{RR - t}{(\mu - 1)\,(R - t) + \mu R} \quad \ldots\ldots\ldots (6)$$

This is the distance of the apparent centre from the surface. By (6),

$$\mu = \frac{(R + f)\,(R - t)}{f\,(2R - t)}.$$

Substitute this value of μ in (4); on simplifying, it will be found that

$$R^2 - R\left(\frac{f^2}{F - f} + 2t\right) = \frac{Ff^2}{F - f} - t^2, \ldots\ldots (7)$$

from which R may be found if F, f, and t are given. If t is made equal to 0, equation (7) gives

$$R = \frac{Ff}{F - f}, \text{ or } -f.$$

The first result is the same as that already found for a thin lens; while the value $-f$ seems to have no physical meaning.

If the thick lens is not equiconvex, there are five observations possible—the distances of the two apparent centres from the surfaces, the distances of the two principal foci from the surfaces and the thickness; but there are only three things to be determined—the two real radii and the refractive index: therefore the equations for R_1, R_2, and μ must be capable of solution. The following are the expressions which may be found by a similar treatment of Fig. 5 to that already employed in the case of the equiconvex lens, if it be remembered that all the angles made by surface 1 are $\frac{R_2}{R_1}$ times those made by surface 2 at the same distance from the axis. They are

$$F_1 = R_2 \frac{\frac{\mu}{\mu - 1} R_1 - t}{\mu\,(R_1 + R_2 - t) + t},$$

$$F_2 = R_1 \frac{\frac{\mu}{\mu - 1} R_2 - t}{\mu\,(R_1 + R_2 - t + t},$$

$$f_1 = R_2 \frac{R_1 - t}{\mu\,(R_1 + R_2 - t) - (R_1 - t)},$$

$$f_2 = R_1 \frac{R_2 - t}{\mu\,(R_1 + R_2 - t) - (R_2 - t)}.$$

The first two of these equations give

$$\frac{F_1}{F_2} = \frac{\mu - R_1 t\,(\mu - 1)}{\mu - R_2 t\,(\mu - 1)};$$

and the second two give

$$\mu = \frac{\overline{R_2 + f_1}\;\overline{R_1 - t}}{f_1\,(R_1 + R_2 - t)} \text{ and } \mu = \frac{\overline{R_1 + f_2}\;\overline{R_2 - t}}{f_2\,(R_1 + R_2 - t)}.$$

By these μ may be eliminated. The solution for R_1 and R_2 I have not obtained; but I do not think there is any difficulty.

The following application to the case of liquids of the principle of making the rays return along the path whence they came, forms a neat though impracticable method of determining their refractive index when greater than $\sqrt{2}$:—Replace the cross-wires of a telescope by the prism-plate, as already described, but in which the slit is longer and adjustable. Fix opposite the object-glass a piece of parallel-sided plate-glass, with its plane at right angles to the optical axis. The correctness of this adjustment may obviously be determined at the eyepiece. Let the glass plate form the bottom of a trough in which the liquid may be placed, and let there be under this a dish containing mercury. Now, there is a certain inclination of the telescope at which the beam from the illuminated slit, rendered parallel by the object glass, is refracted at the free surface of the liquid, and again at the surfaces of the glass plate, so as to leave the latter vertically; then, striking the mercury, it returns along the path whence it came, and may be viewed by the eyepiece. Under these conditions the beam of light on either side of the prism is at right angles to the opposite side; therefore they make equal angles with the adjacent sides, and the prism is at minimum deviation. Calling the inclination of the telescope θ, we have $\sin.\,\theta = \mu \sin.\,\frac{\theta}{2}$; therefore, $\mu = \sqrt{2\,(1 + \cos.\,\theta)}$. The telescope may be first inclined on one side and then on the other, and half the angle moved over taken as θ. I have found it utterly impossible to get the sodium-line to keep still for a moment, or to be even fairly defined, as every movement in the neighbourhood produces a tremor on the surface of the liquids, which in the Science Schools at Kensington at any rate, is so continuous as to make it impossible to observe with accuracy. I should have said that the top of the prism must be covered in with a glass plate, to prevent the evaporation and consequent superficial cooling of the liquid forming the prism, which causes striæ in the liquid, spoiling definition even more than the continuous tremor.

Helmholtz and others have shown that, during accommodation of the eye for near objects, the cornea does not change in curvature, the front surface of the lens becomes more curved and advances, and the back surface does not appreciably change. The proof given is that the images of a light produced by reflection from the cornea and from the back surface of the lens do not change, while that produced by the front surface of the lens advances and becomes smaller. Now, it would appear at first sight that these observations prove a flattening of the back surface of the lens during accommodation; for if it did not change in curvature, the rays of light passing twice through the more curved front surface would sooner come to a focus; but since they do not apparently sooner come to a focus, it would seem that a flattening of the back surface must have occurred to counteract the shortening influence of the more curved front surface. In the case of ordinary lenses this would be so; but it so happens that in the crystalline lens the focus by reflection is formed within it, and so the more curved front surface magnifies the smaller image, which therefore appears unchanged.

While on the subject of reflection in lenses, I think it worth while to mention that convex lenses silvered at the back make excellent and easily-constructed concave mirrors. Since both surfaces conduce to bring light to a focus, flatter curves may be used than are necessary for a plain concave reflector of the same focal length; also, since the two surfaces are not parallel, false images are not produced; so that the advantage of glass silvered at the back remains, without the usual disadvantage. A spectacle-lens of about 5in. focal length, silvered at the back and mounted, forms an eye-glass (I mean a glass for examining the eye) which every one who works in metal should possess. I have found by its means specks of metal thrown from the lathe, which were utterly invisible by other means, but which were nevertheless exceedingly painful.

RECENT ADVANCES IN PHOTOGRAPHY.—II.*

By Capt. ABNEY, R.E., F.R.S.

I NOW propose to bring before you another developer, which is also able to work without a restrainer; but before I do that, I should like you to take note of an improvement, which has been lately introduced by Mr. Berkeley, in the ordinary alkaline developer. With the pyrogallic acid solution is mixed four times the weight of sulphite of soda. The action, apparently, is this—the sulphite of soda absorbs the oxygen with greater avidity than does the pyrogallic acid, thus leaving the pyrogallic acid free to do its work, and, consequently, we have a developer which remains uncoloured for a very long period indeed. I hold in my hand a bottle which was presented to me by Mr. Berkeley, some time ago, which I read was made up on October 13th, 1881. This contains four times the quantity of sulphite of soda that it does of pyrogallic acid. Here is another bottle of pyrogallic acid, made considerably later—some time in January—and you will see the difference in colour between the two. The one is slightly yellow in tint; the other, a deep muddy brown. I consider that this introduction of sulphite of soda into the developer is one of the most remarkable improvements in alkaline development, and I hope that those practical photographers present will not hesitate to try the formula which Mr. Berkeley has lately published.

I now propose to show you the practical use of the developer to which I referred when I commenced. It is a new one, but has not been used to any very great extent, I am afraid, on account of the high price it used to fetch. I refer to hydrokinone; the first quantity I bought cost me 12s. a drachm; but, I am happy to say, it is now only 8s. an ounce, and one grain of it goes so far that it is as active as two grains of pyrogallic acid, for it is a much more powerful absorber of oxygen than pyrogallic acid; an advantage with it is, that you are able to use it without any restrainer. You can even develop chloride of silver without adding any soluble alkaline haloid to it, which photographers know is essential when using even a very weak pyrogallic and alkaline development. To illustrate this, I have an opal glass plate which is covered with a film of collodion containing chloride of silver. Until quite recently, this was a film which it was almost impossible to develop by the alkaline or iron methods; but, thanks to Dr. Eder, we are able now to develop chloride of silver exactly in the same way as we can bromide of silver. To save time, I gave the plate a short exposure just before the lecture. In this cell I have now simply dydrokinone and ammonia, and I think you will see that it develops the plate without the slightest trace of fog. I have taken the opal glass as the back-ground, so that you will be better able to see the result; it come out very gently and gradually. Thus you see that this new developer works without any restrainer whatever, even when such a troublesome salt as silver chloride is used. Not having any restrainer, it is able to give a better detail, and allow a shorter exposure in the camera than if the ordinary alkaline developer was used. This development is applicable not only for collodio-chloride, but for collodio-bromide plates, or for gelatino-bromide plates—in fact, any plate with which you work, even iodide. [The perfectly developed image was then shown.]

I promised last lecture that I would show you how very easy it was to develop iodide of silver with either the alkaline or the ferrous oxalate developer. You saw in my last lecture how we could develop the iodide with silver and gallic acid, but it becomes a very different thing—at least it was always so considered—when you have to develop a plate containing simply iodide with nothing but an oxalate developer, such as I have here. In this frame I have a paper which is coated with pure iodide of silver—not a particle of bromide or chloride in it; I will give it a slight exposure, and I propose to develop it on the screen before you. I will simply immerse it in water, and use some of the same ferrous citro-oxalate which I introduced to your notice last week. It will be apparent with what facility the iodide of silver can be developed. The paper, where viewed in the yellow light, is apparently colourless, although really it is yellow. If everything be correct, you will see that we get an image developing out rapidly, which is formed of pure metallic silver, produced from the sub-iodide at first, and then led, as it were, from the adjacent iodide. [The picture was fully developed.] We now have a practical demonstration that you can develop iodide just as easily as you can bromide, which is a desideratum when you come to consider the composition of gelatine plates, with which we may have to deal more fully in subsequent lectures. Having fulfilled my promise with regard to this, the next point I wish to call the attention of the meeting to is the action of sensitisers. I should like to explain to some of you who are not initiated in the mysteries of photography, what a sensitiser is. I will throw a diagram on the screen, and then you will be able to understand better what I mean. When you have chloride of silver, for instance, exposed to light, you have a new compound formed, which is called sub-chloride, or argentous chloride ($Ag_2\,Cl_2 = Ag\,Cl + Cl$), and chlorine liberated. This chlorine is a very obstinate thing to eliminate, if you do not give it something that can take it up; for instance, if you place perfectly dry chloride of silver in vacuo, without any trace of organic matter present, you will find, if it is exposed to brilliant sun-light for months, you get no darkening action. If such a white powder was submitted to you, to test by its darkening, you would say at once that it was not chloride of silver, because it was not darkened, since one of the tests of chloride of silver, amongst chemists, is, that it shall darken in the light. Here I have a little bulb of it which was prepared, dried carefully, and sealed up, the vacuum being made by means of a Sprengel pump. This tube has been exposed for months to light, and it is as pure a white as the very first day it was put into the bulb. Another experiment was made at the same time; a bulb was prepared, but in using the Sprengel pump, unfortunately, as I then thought, a small globule of mercury got in the vacuum, and was sealed up with the chloride; the consequence was, that the chloride of silver immediately darkened; although the mercury was not in contact with the chloride of silver, the chlorine flew to the mercury, and formed chloride of mercury. This is an instructive experiment, showing that merely in the presence of something that will mop up the chlorine, chloride of silver will darken. Here is another darkened bulb, which is chloride of silver, which was sealed up, not in *vacuo*, but in hydrogen. Now, hydrogen, as you are perfectly aware, can combine with chlorine to form a gas, which we call hydro-chloric acid, so, when the chlorine was in the presence of hydrogen, it combined with it, instead of returning to re-combine with the sub-chloride of silver.

$$Ag_2\,I_2 = Ag_2\,I + I.$$

On the screen is a diagram showing these reactions of the two other haloid salts of silver. I have already shown you the diagram of silver chloride, and its splitting up by light.

Silver iodide splits up into silver sub-iodide and iodine.

$$Ag_2\,Br_2 = Ag_2\,Br + Br.$$

Silver bromide, when exposed to light, splits up into silver sub-bromide and bromine.

---

* Condensed from a series of Cantor Lectures delivered before the Society of Arts.

New, in order that there shall be a ready darkening of either of these, you must have something which will absorb the iodine or bromine (or in the case of the latter, allow it to escape), whichever you expose to the light. Now, the image which you just now saw developed on the iodide is, before development, precisely the same as the darkened image on the chloride; it is a matter simply of degree. Of course, if you took a few shot, and hid them in a bushel of flour, you would not be able to know that there was anything black in the flour; in the same way, if you alter two or three particles of iodide into sub-iodide, or chloride into sub-chloride, you do not notice it, because they are so mixed up with the particles that are not altered. It is these little altered particles that are the nuclei for the developed image. In order to show the use of sensitisers, I have prepared a sheet of paper, a quarter of which has been washed over with that vulgar beverage, beer; another quarter with potassium nitrite, and another quarter with gum, the fourth quarter has nothing on it. Now, all these are—but in greater or less degree—absorbents of iodine and bromine, and you will see, when I expose the paper and develop, that there is a decided increase of sensitiveness where those substances have been applied. You may say, "according to what you have said already, that the particles not coated with anything ought not to develop," but you must recollect that we are in contact with air, and air contains moisture, and if you have chlorine, for instance, in the presence of moisture, light is able to split it up into hydrochloric acid and oxygen, so that, in the case of a paper like this, you have a sensitiser present, but only a feeble one. This paper is the bromo-iodide paper that I introduced to your notice some little time ago. I have marked on the different quarters of it what is the sensitiser on each. I will brush it over with the ferrous citro-oxalate developer, and we shall see if there is any difference in the rapidity of coming out. The part coated with nitrite in coming out very rapidly, it has a very inordinate affection for iodine and bromide; the vulgar beverage beer does not seem to be doing its duty as it ought to be; now the gum is flashing out; now the beer is coming out. You see the nitrite came out first, then the gum, and then the beer, finally that in which the sensitiser was merely the air and the paper, and you will see, when the picture is finished, there is a vast difference in the amount of development. If there had been no moisture in the atmosphere, if it had been exposed in dry air, there would have been no action whatever where it was not coated with some sensitiser. Here, then, we have a proof that a sensitiser is necessary in order to give the greatest possible sensitiveness, and I hope that this will explain to you what I shall have to allude to further on.

I next have to call into use the spectrum. Here we have it on the screen, and I have produced it by the same arrangement of apparatus as if I were going to use it for photography. You will see that we have a tolerably clear spectrum. We have the light, A, and a lens, L, to throw the image on the slit B, and then the lens C, to make the rays parallel, then a single prism, D, then a photographic lens, E, which focusses the spectrum on the screen S. Now I want to point out to you not only that we have red, green, yellow, blue, and violet rays, but we have rays beyond the violet also which we cannot see, but which by an artifice I shall be able to show you. For instance, if I place this card on this screen, you see we have a vast extension of the spectrum beyond the violet, but if I take it away, it is absent. The reason of that is, that I have brushed on this card a solution of sulphate of quinine, which lowers the wave light of the ultra-violet rays, making them visible. I was anxious to bring this spectrum before you, for this reason, that it is the principal part of the spectrum which is useful to photographers, though I do not believe they are aware of it. When we expose one of these haloid salts of silver to the spectrum, it behoves us to know what part of the components of light it is that acts upon this haloid salt. Now, a very simple way is, of course, to place a film containing the haloid salt in the spectrum. But what I want first to point out to you is, that we must go upon scientific principles in dealing with the facts that come before us, and the main principle is the principle of work. When you have what you call light radiating from a source, be it the sun or be it a gas flame, it is only when its radiant energy is stopped or absorbed that you are able to get any work out of it all; that is to say, supposing you have a transparent glass plate, you know that the light, as you call it, passes straight through the plate, without leaving a very visible effect on the glass. But if you have a red glass, why does it appear red? Simply because a part of the rays have been stopped; but what becomes of those rays that are stopped? they must take one of two forms, or rather, the work they do must take one of two forms. The work they can perform may be shown by the heating the glass, or else the energy must be exhausted by doing chemical work upon the substance on which it acts. The effect, then, is this, if you have a haloid salt of silver, the principal part of the energy which is radiated, and which is absorbed, does chemical work, and it is only those regions of the spectrum which are absorbed which are capable of doing chemical work. I cannot show you a better example than I have upon the screen. The second part of the slide shows the whole spectrum, taken with a substance which I shall be able to show you by-and-by. You see the darkening caused by the light; at the far end we have the ultra-violet rays, and at the other end we have the red rays. In front of the slit of the spectroscope was placed a cell of bichromate of potash, and you see it cuts off, not only the blue and the violet, but a part of the green, and leaves the red and yellow intact (B, Fig. 2).

FIG. 1.

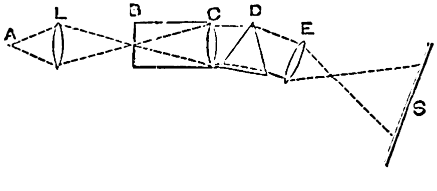

FIG. 2

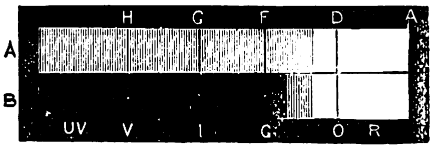
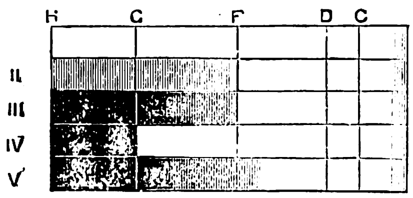


Now, photographers know that those beautiful prints that go by the name of carbon prints depend for their manufacture on the fact that bichromate of potash is altered by light in the presence of organic matter. Here we have the spectrum taken on carbon tissue, in which you will see the absorption exercised by bichromate of potash exactly coincides with the work done on the bichromate (A, Fig. 2); notice that the part of the spectrum which is impressed ends exactly where the bichromate absorption begins. I think that is a very excellent illustration of the work done by radiation. I propose now to pass two or three films through the spectrum (I., Fig. 3), to see what kind of work we may expect to be done with them. First, we have a film of chloride of silver (II.), and you will see that the violet part of the spectrum towards the yellow is subdued, whilst the other parts pass through. Next, we have a bromide film (III.) in which you see some parts of the spectrum are cut off which before were visible. Next, I take iodide (IV), where you see the violet is cut off entirely, leaving a trace of blue, which was not the case with the bromide. Here, again, we have the bromo-iodide (V.) cutting out the blue, going right into the green. That is interesting, because I propose to show you next the fact that the absorption coincides with the work done on the films themselves.

FIG. 3



I have here a board with four strips of paper upon it—the first coated with chloride of silver, the second with bromide of silver, the third with iodide of silver, and the fourth with bromo-iodide of silver. I will expose each of them for twenty seconds to the spectrum, and develop them before you. In order to recognise the parts acted upon, there are strings put across the different parts of the spectrum. [The exposures were made, and the strips damped and placed on the developing board.] I brush each strip over with the ferrous citro-oxalate developer. [The prints developed rapidly, the chloride taking rather longer than the others to appear.] The chloride sometimes takes a little longer to develop, and I ought to have given it a little longer exposure because it is not quite so sensitive as the other salts. Here are the four spectra (Fig. 4). The maximum sensitiveness of the chloride, A, is about the line H on the spectrum. The iodide, C, goes as far as G; the bromide, B, half-way between G and F, and extends down as far as B; the bromo-iodide, D, extends as far as F in the spectrum. I think I can show you this more directly by photographs taken in the spectrum in a more accurate manner than is possible in a lecture experiment. When I passed the different silvers over the spectrum, I only passed the haloid salts in the state in which they are usually prepared photographically, but now I wish to show you how different coloured salts of silver can be obtained. Let me take bromide, for instance. Here you have the ordinary form of bromide, such as you saw developed on the screen—the red or orange bromide. By boiling it, as you do with gelatine emulsion, you can change the molecular condition into a grey blue form, such as you see here. From what I have told you of the principle of work and absorption, you will be quite prepared to learn that these particular forms are sensitive to different parts of the spectrum; so they are, but their maximum place of sensitiveness is but very slightly changed; that is a point worthy of attention. Again, we have two forms of chloride, the ordinary form, which, as a rule, is decidedly yellow by transmitted light; and the other is the blue molecular form, which is got by boiling. Once more we have the iodide in the yellow form, and also the blue form. Now, I will show you photographs which were taken to show the maximum of the different haloid salts (Fig. 5). The first one is the red form of chloride (No. 1), and you see that the maximum sensitiveness is half-way between H and *h* in the violet part of the spectrum; if we go to the boiled chloride (No. 2) you see it has the same place of maximum intensity as the orange, and that the intensity is very great as far down as the yellow line, D. We next come to the red form of bromide (No. 3), and we see that its maximum place of sensitiveness is half way between G and F. When we come to the blue form (No. 4) we have an immense extension towards the red, but still it retains nearly the same place of maximum sensitiveness between G and F. Next, we have the yellow form of iodide (No. 5), and it shows that it ends sharply at G. There is no spectrum impressed beyond G. In one case where I gave it a very prolonged exposure, I got what is called a reversal of the image, but still the iodide spectrum is cut off at that particular point (No. 6).

FIG. 4

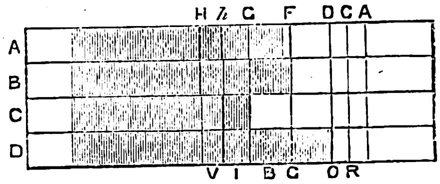


FIG. 5

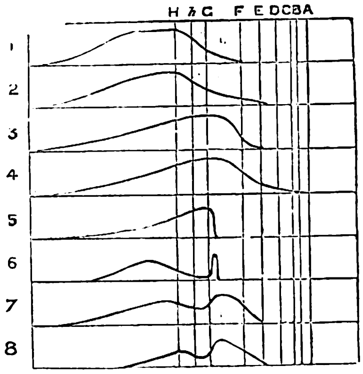

(*To be continued.*)

The Electric Gas-Lighter.—The following description of Clarke's patent gas-lighter was given at a visit to the works:—It consists of a chloride of silver battery of novel and powerful construction; the chloride of silver being applied to the silver plate under great pressure. The induction coil, the wire of which, instead of being of copper as usual, is ordinary iron wire wound over a bobbin with interlayers of cotton thread, in place of the usual copper wire insulated with silk or cotton; this layer of wire is then covered with paper saturated in paraffin to produce more perfect insulation. The condenser is composed of discs of tinfoil and paraffin-paper. The whole is inclosed in an ebonite handle about a foot long; and from this a brass tube of any desired length is run, carrying the positive and negative wires. The current from the battery induces a current in the coil, which passes to the points of the spire, and by the pressure of a button on the handle, the spark which ignites the gas is produced.

SCIENTIFIC NEWS.

NEWS reached Cambridge on Saturday last that the recently-appointed Professor of Animal Morphology had been killed by a fall in Switzerland while mountain-climbing. Prof. F. M. Balfour was in the prime of life. He was a fellow and tutor of Trinity College, Royal Medallist in 1881, and President of the Cambridge Philosophical Society. He was a Fellow of the Royal Society, and an hon. LL.D. of Glasgow. Last term he was elected to the new chair of Animal Morphology. On page 270 of our last volume we reviewed the second volume of Prof. Balfour's treatise on "Comparative Embryology," a work which will prove a fitting monument to his memory, and an indication of the great loss which the scientific world has sustained by his untimely death.

Captain Gillies, of the R.M.S. *Neva*, reports to the *Buenos Ayres Standard* the observation of a comet on June 19, while in lat. 28° 48′ S., long. 48° 17′ W. The comet is described as bearing N. 60 W. (true) 10° above the horizon, with a tail about 5° in length, extending towards the zenith.

An ephemeris of the comet of 1812 (Pons), has been prepared by MM. Schulhof and Bossert, and is circulated by the Observatoire de Paris. By a new discussion of the observations, MM. Schulhof and Bossert find the most probable elements give a revolution of 71·7 years; and they have reason to believe that the comet will come again to perihelion about the middle of 1883. The uncertainty as to the period of revolution being about three and a half years, it is desired that systematic researches should be commenced at once.

From four observations of comet Wells, Herr Thraen, of Dingelstadt, Thuringia, has computed a set of elliptic elements which give a period of 3,617 years. Mr. L. Boss reports to the *Astronomische Nachrichten*, that on June 11, with a power of 180, the true nucleus was seen as a perfectly round and sharply-defined disc of moderate illumination. The nebulosity of the coma was quite uniform and faint, and about 10″ diameter. On June 12 the comet was a very easy object, but the nucleus proper could not be seen.

Under the superintendence of Prof. Van de Sande Bakhuijzen, director of the Leyden Observatory, have at last been published the observations of Mars made by Schröter at Lilienthal.

The Lens Committee have reported to the Council of the Photographic Society, recommending that the aperture of the standard unit diaphragm should have a diameter equal to one-fourth the equivalent focus of the lens, and that those with smaller openings should have apertures diminishing in area by one-half, and be marked 2, 4, 8, &c., thus indicating that if the unit stop needs an exposure of one second on any given paper, the use of a smaller stop would need a number of seconds corresponding to the number of the stop. Flanges and camera-screws are recommended to be threaded with a standard series. The Council have adopted the report, and have ordered the construction of a series of standard flanges and camera-screws to be kept in the custody of the Society.

Under the title of "Light: a Course of Experimental Optics, chiefly with the Lantern," Mr. Lewis Wright has issued, in a revised and enlarged form, his articles on "Optics with the Lantern," which appeared in Vols. XXXII. and XXXIII. The volume, which is illustrated by several coloured and other plates, besides numerous woodcuts, is published by Messrs. Macmillan.

Mr. Forney, at a recent meeting of the Master Carbuilders' Association of the United States, said that 1,500 railway employés are killed and 10,000 injured every year in the States. The committee on automatic couplers and draw-bars reported that out of 3,000 patents they were unable to select and recommend any of the devices as a standard.

The Belgian Academy offers a prize of 3,000f. for the best essay on the pollution of rivers and the destruction of fish. The essays should state what are the polluting matters; give a list of Belgian rivers which have been rendered uninhabitable by fish; indicate the means of purifying the waters; and give a special account of the causes of death of fish. The essays should be sent in before October 1, 1884.

It is stated that M. Jablochkoff has invented an electric motor which is very simple and powerful. The details are not yet available, as some of the patents have not been completed.

At the Trocadéro, Paris, an ethnological museum, containing about 44,000 specimens, has been organised; and the classification, which was undertaken by Drs. Gaudren and Hamy, is now nearly completed.

The velocity of chemical actions has been engaging the attention of a Russian chemist, M. Kœjœnder. His experiments consisted in dissolving marble or magnesium in water acidulated to various degrees with different acids. The curves of velocity of dissolution have a striking resemblance to those representing electric conductivity. The solubility increases with the quantity of the acid up to a certain point, beyond which it decreases. It is remarkable, too, that the velocity of the reaction referred to the proportions concerned is greater the lower the concentration. Thus 1 of sulphuric acid dissolves in a second more than half what 2 will dissolve, and still more than a third what 3 will dissolve. The phenomenon becomes more and more pronounced.

A new class of colouring matters has been described in the Berlin Chemical Society by Herren Fischer and Rudolph. It is based on the discovery that acetanilide under the influence of chloride of zinc at a temperature of 250° to 270 C., gives a beautiful yellow. The name of Flavaniline is applied to this new product, which shows a fine moss-green fluorescence, specially brilliant on silk fibres. The composition is $C_{16} H_{11} N_2$.

While the white of egg has various industrial uses, almost the only one for the yolk is the dressing of skins. According to M. Carles (*Jour. de Pharm.*), this industry finds the yolk as efficacious when in complete putridity as when fresh. The yolks are collected in wine-stores and manufactories of albumen (where they are rejected as useless), and brought in casks as "mucilage" to the leather-dresser. While the latter is indifferent to freshness, he attaches great importance to homogeneity and richness in fatty matters. The former is affected by various causes, but especially the action of air, which is not mere drying, but involves a chemical process. For remedy, some collectors of the yolk apply water, and, to raise the density (thus lessened), a few handfuls of marine salt; others have recourse to alkaline sulphates, alum, &c., to retard putrefaction. None of these matters seriously affect the skins; but they undoubtedly diminish the value of the mucilage by lowering the proportion of oil of the egg. To ascertain the purity of the mucilage measurement of density is of course fallacious. The presence of foreign salts is best detected by comparing equal quantities of typical yolks and of suspected mucilage. But the surest, if not the quickest, plan, is to determine successively, in a few grammes, the quantities of water, organic matter, and mineral salts; lastly, the proportion of fatty matter.

There is a general tendency at present (we learn from a German military paper) to adopt smaller bores for portable arms. Thus the Swiss rifle has a bore 10·4mm. (about ·416in.), and the rifles of the Servian and the Swedish infantry have a bore of 10·15mm. (·4in.) Prof. Hebler, of Zurich, goes still further, adopting for his rifle a bore of 8·6mm. (·344in.) The transformation of arms at present in service in Europe into arms on the Hebler system can be done by a simple tubage; the inventor has thus already transformed the Swiss Vetterli and the German Mauser. Experiments with these two altered rifles have proved clearly how false is the idea that a long and thin projectile must lack stability in the air. The cartridge is 86mm. long (3·4in.); the ball 32·8mm. (1·3in.) The weight of the cartridge (an important point) is only 35 grammes, and 96 Hebler cartridges weigh no more than 80 Mausers. Each (German) soldier might carry about 21 more cartridges than at present. The advantages of greater tension of trajectory, greater extent of the dangerous zone, and longer range, are distinctly proved for the Hebler rifle. The firing with it is more accurate. There is no reason to fear lack of penetrative force. Experiment is still desired as to whether solidity is not too much diminished, and cleaning rendered too difficult.

An interesting illustration of the general usefulness of electricity in these times is afforded by the new opera house at Frankfort-on-the-Maine. Besides bell-calls and signals throughout the building, there are no fewer than eight different services to which electricity is put: These are: (1) fire-alarm, (2) tell-tale arrangement with clock, (3) door-closing arrangement, (4) heat telegraph, (5) lighting the chandelier, (6) lighting the soffit-lights, (7) lift-counter of the ventilator, (8) time-beater. A detailed account of these arrangements, with illustrations, is begun in the *Electrotechnische Zeitschrift*.

The sand which is used in grinding glass plates, and so is mixed with glass-dust, is utilised by M. Motte, of Dampremy, near Charleroi, for production of keramic ware, such as solid or hollow bricks, simple building stones, or ornamental stones. These products have great firmness, a pleasant, unalterable colour, like that of French sandstone, and small specific gravity (under 1·5). They are produced by the ordinary method; the moistened sand can be easily moulded.

From a recent report by Herr Wienlig on a visit to ironworks in this country, it appears that while England shares to the extent of 47 per cent. in the whole pig-iron production of the world, Germany, with Luxembourg, figures with only 13 per cent. England consumes, per head of the population, about five times as much iron as Germany. The production of English iron ores is about four times the German. The English coal production is about 63 per cent. of that of the whole world. That Germany, with its unfavourable position for transport, and the great distances between the sources of coal and ironstone, should compete as it does with highly-favoured England in the world-market, is regarded by the author as a thing to be proud of.

We may here note some facts about the iron industry in Sweden. A review of the period 1860-80 shows, that while the production increased, the number of places of production (pits, furnaces, forges) decreased quite remarkably. From about 417,000 tons of iron ore in 1860, the production rose to about 775,000 tons in 1880. The number of workmen in 1860 was 5,249; in 1880 only 5,038. Thus, a workman in the latter year produced nearly twice as much as one in the former. This is attributed chiefly to improved means of blasting.

On the occasion of the fourth International Congress of Hygiene, an exhibition of objects of any kind relating to hygiene and statistics of population, will take place at Geneva from 1st to 15th September this year. Inventors, &c., of all nationalities are invited to take part.

The signal officer at the summit of Pike's Peak, Sergeant Day, has lately observed a curious phenomenon. On opening the door at 8.45 p.m., the line on the summit was seen distinctly outlined in bright light, which was thrown out from the wire in beautiful scintillations. These, seen nearer, had the appearance of little electrified brushes or inverted cones of light, with their points to the line, whence they issued in little streams about the size of a pencil lead of bright violet colour, while the cone of rays was of a brilliant rose-white. These cones pointed in all directions, and were constantly jumping about. There was no heat to the light, though one could not touch one of the little flames, for as soon as the finger was brought near, they would instantly vanish, or jump to another point of the line. Passing along the line with finger extended, these little jets of flame were successively "puffed out," to be instantly relighted in the rear. Every exposed metallic point or surface was similarly tipped or covered. The cups of the anemometer appeared as a solid ring of fire, with a loud hissing noise. On bringing the hand near the instrument, no heat was felt; but the hand instantly became aflame, and on raising it and spreading the fingers, each of the latter became tipped with cones of light. There was a feeling as of a current of vapour escaping, and a slight tingling sensation. Other parts of the body were lighted up also.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

λ AND τ OPHIUCHI AND ξ URSÆ MAJORIS — RAILWAY SIGNALS — ANOTHER MAN OUT OF HIS ELEMENT — DEWCAP — PHYSICAL OBSERVATIONS OF JUPITER—THE TRAPEZIUM IN ORION — SMEATON'S BLOCK — FORECASTING THE WEATHER—OBSERVATION OF DOUBLE STARS IN TWILIGHT—HAZE AND TELESCOPIC DEFINITION — OBSERVATORY ON HOUSE – TRANSIT OF VENUS—"SIDEREAL INDICATOR"—MOTION OF THE MOON'S LINE OF APSIDES.

[20308.]—I am sorry that I cannot give Mr. Beaven (letter 20265, p. 427) any very recent measures of the three stars concerning which he asks in his concluding paragraph; but, judging from the last time I looked at them, I should say that the components of λ Ophiuchi must now be some 1·6″ apart; and those of τ, a little more widely separated. These are pretty severe tests for a 3in. telescope, which will probably show that they actually are double, and that is about all. ξ Ursæ Majoris is opening. The two stars must now be nearly 2″ from each other. Mr. Beaven's telescope certainly ought to split this pair. Assuming him, as he says, fairly to have resolved these three objects, I must congratulate him on the excellence of his instrument. After his description of what he has effected with it, his assurance that it is "not a five-pounder" partakes somewhat of the nature of surplusage.

Does Mr. Stooke (letter 20267, p. 427) propose that engine-drivers should carry protractors or clinometers to be held between the eye and the signal-post, while travelling at the rate of some 50 or 60 miles an hour? Because I have myself had very considerable personal experience in the measurement of angles; but I confess that I should not like to risk much money on my power of discriminating between an angle of 43° ("Danger"), and one of 47° ("Clear") as exhibited by a broad arm on a tall distant post, with nothing but my unassisted eye to guide me in the determination.

It is a great pity that the author of the cock-and-bull letter, quoted from the *Mining Review* by Mr. Romanes (letter 20278, p. 429) cannot be added to the quorum of the Committee on Solar Physics at Brompton. The narration of his experiment (?) is so thoroughly in the vein of certain quack advertisements of the splitting up of the elements in this country, that it seems a thousand pities that the originator of such announcements should be deprived of the aid of so valuable a coadjutor as "Dr. D. P. Kayner" would undoubtedly prove. "Taking certain proportions of the three baser metals, combining them with such other substances as would represent as near as possible nature's alchemy, luting the whole together .... to represent the confined state of minerals and gases in the earth." Who does not recognise in this peculiar phraseology—the "certain proportions," "nature's alchemy," et id genus omne—the true ring of the Brompton mendicant sham?

If "Tyro" (query 47406, p. 436) can use a soldering iron, he may very speedily make himself an effective dewcap. All he has to do is to buy a plate of thin tin, and out of it to cut a square piece which shall roll into a cylinder to fit tightly over the end of the telescope, and to project at least 8in. beyond it. Should the outside diameter of the end of his telescope tube be 3½in., then the plate for his dewcap may be 11⅛in. wide. This will allow about ⅛in. for overlap, which, with careful soldering, will make a neat joint. Finally, he must blacken the inside of his tube with any alcoholic varnish mixed with lampblack, leaving, of course, the outside bright, and his dewcap will be complete.

Observers of the planet Jupiter will welcome the republication, from the *Annales Astronomiques de l'Observatoire Royal de Bruxelles*, of the splendid series of observations made by M. L. Niesten during the opposition of 1878. N. Niesten employed the Merz equatoreal, of 5 9in. aperture and 8ft. 6in. focal length, which is mounted in the Eastern dome of the Royal Observatory at Brussels; using chiefly powers of 180 and 270, although on rare occasions of superlative definition he employed higher ones still. As a result, we have 47 minutely-accurate sketches of the planet, made during the period extending between July 16 and November 2 in the year referred to, and a 48th, constituting a kind of key-plan to the various regions on Jupiter's surface. 31 pages of letterpress give the most ample details as to the position angles of the various bands, the equatorial and polar diameters of the planet, and the intervals between the bands, &c., all micrometrically measured, together with notes of the colours of the various markings upon them. Four supplementary pages deal with observations of the famous Red Spot. The sketches of the planet, to which I have referred above, were all drawn directly on the stone by M. Niesten's own hand; and exhibit, as I have said, the most minute accuracy of detail. The publisher's name on the title-page is F. Hayez, of Brussels; but I presume that any of the foreign booksellers in London would be able to obtain it. Anyone personally engaged in the study of the giant planet will certainly do well to make the experiment of ordering M. Niesten's brochure forthwith.

Another recent work, too, which I have been reading with great interest is Professor Holden's excellent monograph on "the Multiple Star Σ 748" which forms appendix II. to the Washington Observations for 1877. The Star which forms the subject of this exhaustive essay is otherwise known as θ^1 Orionis, but is probably most familiar to a large proportion of your readers as the Trapezium in Orion. Visible to the naked eye, as one star of the fourth magnitude, it was split into three by Huyghens, who subsequently (January 8, 1684) saw the fourth star. Hooke, however, would really seem to have seen the fourth, and that infinitely more difficult object the fifth star, somewhat prior to this. Struve appears to have re-discovered the fifth Star; and the sixth was first picked up by Sir John Herschel on Christmas Day in 1832. That these two last-mentioned objects are variable I think that no one who has watched them for any length of time can doubt. Prof. Holden gives a list of observers who have seen these objects with instruments of small aperture; which (assuming that two alleged observations of the fifth Star were really objective ones) places its variability beyond any question. The chief part of the monograph is devoted to a very elaborate discussion of a most extensive series of measures in position and distance of the four principal components of this wonderful system, made by Prof. Hall at Washington in 1877 and 1878, with somewhat less numerous ones of its two more minute constituents. As a result of the exhaustive discussion of which I have just spoken, Prof. Holden pretty confidently predicates actual physical association among the members of this strange object.

Will Mr. Franks (letter 20289, p. 450) forgive me for pointing out that my sole object was to indicate the *principle* on which an equatorial movement was obtained by the aid of a bevelled block of wood, without entering into any details of construction? Had I intended to supply any, I should have given a copy of the engraving which appeared on p. 402, in the instructive letter (20242), by "Orderic Vital."

Without attempting to travel over the somewhat heterogeneous and disconnected series of arguments and assertions employed by Mr. Gardner, in letter 20305 (p. 453), it may suffice here to call attention to the fact that if the Moon really influenced the weather in the slightest degree by her power of attraction, weather-changes, like the tides, must be semi-diurnal.

In answer to query 47438 (p. 460), I may tell "Rigel" that all very close double Stars are much more easily resolvable in twilight than when it gets darker; inasmuch as the brightness of the background to a great extent obliterates the diffraction rings which in a dark sky envelop the components. In saying this, I am, of course, not referring to cases in which the companion to the larger star is very minute as well as close. In such a case, if the *comes* is to be seen at all, ex necessitate the night must be dark before it could even become visible as an isolated object.

Mr. Muker (query 47451, p. 460) may rest assured that the sole remedy for the impairment of the definition of his telescope by such an atmospheric haze as he describes is to take it up above the region in which that haze is formed. I perhaps may add, though, that some of the finest nights we ever get in England for telescopic purposes are those in which there is a slight mist rising from the ground. I have had most astonishing views of planetary detail under these circumstances.

If "American" (query 47467, p. 460) determines on erecting his telescope at the top of his house, let me urge him to have two massive beams of timber built into the opposite walls of it and a heavy stone slab laid across them as a foundation for the pillar of his equatorial mounting. If, then, he has the flooring of the room laid upon joists independently of this arrangement (in fact, so as not to come in contact with it at all), I think that his trouble from tremors will be practically nil.

I really cannot give "Jamaica" (query 47468, p. 460) any replies to his questions which would be worth his perusal, with the limited time at my disposal. Imprimis, I know nothing about the meteorological conditions obtaining in Jamaica, although the experience of Mr. Maxwell Hall would seem to point to its being a good observing climate. In the next place, the calculation of the times of contact of Venus with the Sun's limb is very much too operose to be performed currente calamo on the day on which his query appears. Any professional computer would furnish him with them, though, for a very small charge. As for the Sun's altitude at the beginning of the Transit at Kingston: taking this out in the roughest possible way on an envelope, I do not think that it can be much more than 29° or so. It will be about 2° less at the time of last contact. "Jamaica" should certainly employ his Cooke refractor for the kind of observations he proposes to make. He will find it more satisfactory than the reflector.

What does "D. Mc" mean (query 47475, p. 461) by a "Sidereal Indicator," and whence did he get the name?

Mr. Gardner (query 47492, p. 461) will find, on reference to the *Nautical Almanac*, that the Moon was in apogee in Taurus from October 3rd, 1879, to September 25th, 1880, at which date her apogee passed into the confines of Gemini. She was in perigee in Taurus from June 2nd, 1875, to January, 1876, when her perigee shifted into Gemini as before. The perigee performs one sidereal revolution accurately in 3232·575 days, or 8yrs. 310d. 12h. 29m.; but the motion of line of apsides is not equable through a lunar month: for when the Moon is in syzygies, the line of apsides advances in the order of the signs, but retrogrades in the quadratures. The line of nodes takes 6798·279 days —i.e., 18yrs. 223d. 15h. 58m. to make a complete sidereal revolution: whence it is obvious that it by no means follows that at the end of the period of which I have spoken, the line of Lunar apsides will point to the same stars in the sky. The Moon will again be in perigee in Taurus in May 24th, 1884, and the perigee will remain in that constellations until Dec. 2nd. It will have passed into Gemini by the end of the year.

A Fellow of the Royal Astronomical Society.

BIRMINGHAM'S NEW VARIABLE IN CYGNUS.

[20309.]—For some reason which I am unable to explain, I failed to detect this interesting object for some time after its discovery, about fourteen months ago, and subsequently it has either been extremely small, or concealed by the trees which limit the view from my telescope-house. But the sight which I had of it last night was so gratifying that I am induced to mention it for the sake of any amateur observers who may not as yet have made its acquaintance. It lies in a comparatively open space, about 3° (more accurately 2° 51′) N. of α Cygni, and will be at once recognised by its beautiful red tint, which during the short time at my disposal attracted my attention so much, that I took no especial note of its comparative brightness. I should suppose, however, that it would fall between 8 and 9 mag. (a common size, by the way, for some unexplained reason, for ruddy stars). The eminent and accomplished observer to whom we owe this discovery will, I hope, before long, be induced to favour us with another and enlarged edition of his most interesting Red Star Catalogue. **T. W. Webb.**

Hardwick Vicarage, July 20.

AN APOLOGY.

[20310.]—I have to apologise for having mistaken the planet Mars for a new object. I deeply regret that my note was not in time to stop the publication of my letter (No. 20286, page 449), which was sent directly I had received a reply from a gentleman (with whom I had communicated nine days previously), informing me of my mistake. I feel that it is due, Sir, to you and to your readers that I should offer some explanation of my conduct. When I swept this object into the telescope I thought it might be Mars, and not having an ephemeris within reach, I referred to the "Astronomical Notes" for July (page 369), where it is stated, "This is a month quite remarkable for the absence of the Major Planets from the night sky, Mars, Jupiter, Saturn, Uranus, and Neptune being none of them visible," and turning to the Notes for the previous month (page 254), this statement, "Mars is now too near the Sun to be fairly seen"; and so I concluded that as Mars was invisible, what I had observed could not be that planet, but a new object. In making these quotations I do not wish to clear myself from all blame, and I greatly regret that by attaching a meaning to the "Astronomical Notes" in this journal, which I believe they were not intended to convey, I have been the means of disseminating an erroneous statement by the aid of your valuable journal, for which I am very sorry, and can only hope that your readers have not been greatly inconvenienced thereby, and be assured that next time I announce a discovery it will be of something more recent than that of the planet Mars. **J. Lane.**

PTOLEMÆUS.

[20312.]—My thanks are due to Mr. E. S. Beaven (letter 20265, p. 427) and Mr. Herbert Ingall (letter 20288, p. 450) for their interesting communications on the subject. The floor of Ptolemæus is covered by a close network of light-streaks, and from the size and favourable position of this walled plain, special facilities are given for ascertaining their apparent nature. From numerous observations, extending over a period of more than a year, it seems quite certain that the streaks are elevations, which differ from ordinary ridges principally by their great breadth, compared with their very low elevation. This being the case, it will be clear that the spaces between the streaks will really be slight depressions, and more than half of the curious hollows shown in Mr. Ingall's drawing seem to occupy such situations. Several, however, are apparently right in the path of some of the brightest streaks.

None of these depressions, however, appear to be precisely the same as those seen by Schröter and myself. At the time of the observation of June 23rd, 1882, the two pits were nearly as conspicuous as the large crater A, and there was nothing else visible upon the floor at all resembling them. The appearance of the little crater B seems very curious; it always appears easy to me, even with the 2¾in. refractor. The floor also has never appeared to me *perfectly* smooth. The little mound N.W. of the crater A is probably the highest portion of a curved ridge, which incloses, with the other ridge, running north from A—a considerably depressed surface. Under a high illumination it appears as a bright spot.

Until lately neither of Schröter's large depressions had been seen, except under a very low illumination; but on June 25th, 1882, though the form of neither pit could be certainly traced, yet a little shadow was suspected under what would be the place of the west wall of the southernmost one; and on June 26th this pit was seen as a slightly darker patch, a little shadow being also suspected under the west wall; again, on June 27th, an ill-defined dark patch was seen in the place of this object.

Mädler and Kunowski saw the whole surface as if covered with low, short ridges; but sunrise on November 28th, 1881, gave the impression rather of an immense number of very minute peaks, in addition to the low elevations of some of the more prominent streaks. The floor of this fine formation is certainly deserving of very careful attention, for recent observations seem strongly to confirm the existence, not only of an obscuring medium, but also of real physical change. It is difficult to imagine that the temporary reduction of one of the brightest spots on the floor to the brightness of a comparatively faint one close by can be due to anything but actual change.

It may be remarked that Schröter's two principal pits have a very striking resemblance to Hyginus N., in form, size, and appearance.

A. Stanley Williams.

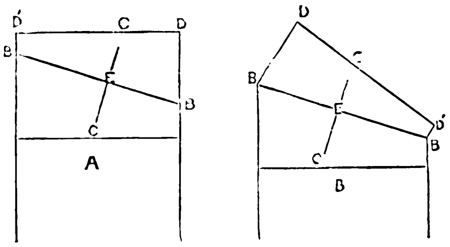
West Brighton, July 22.

SMEATON'S BLOCK.

[20313.]—In your No. 903, July 14, 1882, p. 425, I read: "Smeaton's block, concerning which 'J. C. A.' puts query 47294 (p. 387), is nothing in the world but a wooden cylinder with its top bevelled *at an angle equal to the co-latitude of the place of observation.*" Such a block is *not* Smeaton's block; it is a far more scientific thing than that which "F.R.A.S." describes. In Dr. Rees' "Cyclopedia," I read: "The plane of contact of the two halves of the block is so sloped as to make an angle exactly *equal to one-half of the co-latitude of the place of observation*, with a horizontal line, in which the underface of the block is supposed to be by its position." (Art. "Equatoreal.")

The Smeaton's block is this: The altazimuth position is A; the equatorial position is B; the planes of contact, "*whose angle is equal to one-half of the co-latitude*," are B B; the axis of rotation is C C. The telescope would, of course, be mounted on and above D D. Let our readers cut two pieces of cardboard to the angles of the above diagram, and run a needle through the centre of, and at right angles to, the line B B at E into the cardboard in the direction of its plane surface, as shown above. They will at once see, on reversing its position—i.e., turning it half-round from D′ to D without the dash — the beautiful principle of Smeaton's block. If the lower half is prolonged, and turned to the diameter of a gas or water-pipe —say 4in. inside and 5ft. or 6ft. long—and the pipe sunk into the ground, you have a compact, steady, and most useful stand, either altazimuth or equatoreal. **N. S. Godfrey, F.R.A.S.**

St. Bartholomew's Vicarage, Southsea, 15th July.



CHLORIDE OF NITROGEN.

[20314.]—In letter 20306, J. H. Huxley makes further comment on the properties of chloride of nitrogen. That principle which, more than anything else, science of the last 50 years has tended to establish—viz., conservation of energy—seems with Mr. Huxley to carry small weight. I confess that, to my mind, a perpetual motion is entirely unthinkable. I can in no way picture to myself such a combination. But, to come more closely to the subject of this letter, let us take the ordinary process of making chloride of nitrogen. We act on (say) ammonium chloride with chlorine gas. Now, ammonium chloride is a perfectly stable body; when, however, chlorine comes in contact with it, in virtue of its affinity for hydrogen, it tears away the hydrogen, and leaves the nitrogen and chlorine feebly linked together. Now, here is precisely a case of the rule quoted by Mr. Huxley in his letter: "Whenever we produce an elementary body it is necessary that an equivalent of some other body should be burned." We have, in fact, conferred the potential energy of free chlorine upon the loosely-linked compound NCl_3. Further, we may note that for decomposition to commence it is necessary to touch it with one of certain substances, nearly all of which contain hydrogen, which may start the decomposition by its affinity for chlorine. Similar cases may be found. I may mention one recently under my notice. I found that a plate covered with peroxide of lead, when placed in dilute acid with a plate of carbon, the circuit being complete, a galvanic couple is formed which is precisely opposite in its action to ordinary couples. In these one plate is oxidised, and free hydrogen liberated on the other, whilst in carbon and peroxide couple. free oxygen is given off at the carbon whilst the hydrogen combines with the peroxide. If we were to jump to a conclusion, we might say that here we had an anomaly; for, ordinarily, by oxidising a substance it develops heat; thus, we might say that heat was developed and work done by the lead being oxidised, whilst, by allowing it to deoxidise, further heat is produced in the electric circuit. By closer examination of facts, we find that work has to be done by some oxidising agent, in order to form lead peroxide, and that, when formed, it is sufficiently unstable to be reduced by sunlight.

I do not pretend that this explains everything with regard to nitrogen chloride; but, nevertheless, I believe that nature has no such anomalies, and that it is only owing to our imperfect knowledge that we cannot show the general laws to hold good in every case. **Ll.B.A.**

DAGUERRE AND HIS DISCOVERY OF THE DEVELOPMENT BY VAPOUR OF MERCURY.

[20315.]—In the account given in your last number, of Capt. Abney's description of M. Daguerre's "fluke" discovery of the process of the development of the Daguerrean image by vapour of mercury, there is some discrepancy which I would seek to amend. "Fluke" in a certain sense, no doubt it was; but the interesting part of the matter is left out by Capt. Abney, possibly through the quantity of material at his command.

First of all, I would call attention to the fact that, although mercury does throw off vapour at a comparatively low temperature, it is not sufficient to make the image upon the daguerreo type plate take a positive form. We must suppose, therefore, that the cabinet in which Daguerre kept his bottles was unusually hot, and, therefore, unfit for the purpose, or that there is some mistake or oversight in Captain Abney's description. The description I read some time ago, but in what publication I cannot now say, but think it was a publication by Lerebours and Co., of Paris, during Daguerre's lifetime, and to the following effect: Daguerre had made a camera image upon a silver plate, prepared with vapour of iodine. This image was, of course, a negative one, the light having converted the yellow iodate into the blue sub-oxide. A process of fixation without, at the same time, destroying the image, was unknown to Daguerre at this time, and what he must have most earnestly longed for was a positive image, because his and Nièpce's surfaces were opaque. So, in order to preserve the image he had made, he put the Daguerreotype plate, with the impression upon it, into a small drawer, that it might be kept from the action of the light; that in this same drawer there was, or had been, a bottle of mercury which had been upset, and the particles of mercury had become diffused very generally over the whole inside of the drawer, by its having been continuously opened and shut; that on his again going to look at the image on the plate he saw a positive image where the molecules of mercury had attached themselves, and that was the very part upon which the light had acted, and which before had formed the dark lines of the image. It is not difficult to imagine what the feelings of an enthusiastic experimenter were at that instant, especially when it is remembered that the man was a French artist, and that the image formed by the light before the means of development was discovered was, although scientifically important, practically worthless, because so feeble and evanescent that it could scarcely be used even for copying from. I am pleased to see that although Captain Abney calls M. Daguerre's discovery a "fluke," he at the same times gives him the credit of being a systematic experimentalist, for of this there is plenty of contemporary evidence.

There are a great many similar flukes on record; but I believe that such things happen only to those who patiently labour and watch for them, and may therefore be accepted as the rewards that Nature sometimes gives to her faithful servants, rather than the result of either accident or luck.

Thos. Sims.

3, The Grove, Clapham Common, S.W.

MR. SCOTT RUSSELL AND THE VIENNA DOME.

[20316.]—"J. W. W.—s" seems (see page 451) to doubt my assertion, "that the principal expansion and contraction of a conical dome would be in an upward and downward direction." But it is easy of comprehension, that when under sunshine there would be vastly more surface of roof than of the retaining-ring under the direct action of the sun. It would be interesting to know what steps were taken in order to prove that the said, or any similar ring, "does not" (?) expand and contract; and I am certain that many of "ours," including myself, would like to see a diagram of what he terms "heading-joints," and which he states can be, and are, used in some forms of straight girders, as well as circular ones, so as to confine the expansion and contraction to each section of plate employed in its construction. I maintain "that the said, and 'all' other metallic rings and girders, however constructed, do expand and contract, in proportion to their length, every day and night in the year." And being aware that any ordinary chimney stalk of, say, 90ft. high, will sway with perfect safety, in an ordinary breeze of wind, say 1ft. out of the perpendicular, without starting a joint, I am quite satisfied "that this Vienna dome does expand and contract regularly, as the temperature varies, without displacing any of its fastenings."

Liverpool. **J. J. A.**

TRICYCLES.

[20317.]—It seems to me that there is something wrong in the position in which the handles on a tricycle are placed.

My idea is, that they should be much more forward. In their present position you cannot pull at the handles like you can on a bicycle, and, in my opinion, it is a decided improvement to have the handles (bicycle) bent forward at least a couple of inches.

If the tricycle handles were placed vertically over the centre of the crank-shaft (or even a little more to the front), I fancy a great deal more power would be obtained.

As I ride a tricycle only by way of a change—preferring the two-wheeler—perhaps it is fancy on my part; but, I think, if the backward position was advantageous, we should soon hear of bicycle-handles being bent back. I have seen such an arrangement, but I think it must be a mistake.

H. A. White.

[20318.]—As in most cases the right leg is stronger than the left; the force exerted on the crank must vary accordingly. In a "Sociable," as ordinarily constructed, this variation in driving power is doubled. Why not place the cranks so that the two riders are "out of step"—i.e., when one has his right leg raised his companion has his left foot up.

The work would then be equal during each semi-revolution, supposing riders to be equally strong. With such long cranks as are generally fitted the necessary action is anything but becoming to a lady. This objection might be reduced by shortening one crank, and having the other (the gentleman's) its full length. Of course, leverage is lost, but I doubt if the lady's help is worth considering. **Glatton.**

THE NEW WATER-GAS LOCOMOTIVE.

[20319.]—I send you the following account of a trip made by the Holland hydrogen engine, as it is called, and description of the locomotive, taken from the *New York Tribune*:—The arrival was ahead of time. The oil gauge showed a cost of 2·52dols. for the twenty miles run, which is not much, if any, cheaper than full rate on the long and closely managed trunk lines when coal is cheap. It is more than double the highest consumption of the "C. Holland" during a few weeks previous, when it had been doing heavy freight work. The principle of the apparatus is the decomposition of water at a high heat by mingling it with a small proportion of oil, without air, in iron retorts; the hydrogen set free being instantly burned, and all the heat of both unions—the carbon with the water-oxygen, and the hydrogen with the air-oxygen—being confined and utilised in the boiler, making steam. The retorts are four in number. They resemble half a peck-measure in size, and are set near the door of the furnace, a little above the level of the burners, which cover a floor about 3ft. by 8ft. in extent. The burners are as pin-holes along the lengths of a close series of 1in. iron pipes covering the floor of the fire-chamber and connected with a central gas main, which is supplied by pipes from the retorts. These pinholes being pitched towards each other in pairs, the gas-jets meet accordingly in pairs and mingle in combustion with jets of air coming up through 1¼in. holes just under each conjunction of gas. The number of gas-jets is 518.

The boiler, as originally designed and built, was intended to improve upon the ordinary conditions of gas-heating, but on being tried, was rejected, and the ordinary boiler pattern was restored, with a few modifications in the firebox and smoke-pipe. In April last the new boiler and heating apparatus were satisfactorily tested, and in the last of May the complete engine was delivered to the Erie Road. After a few standing trials it was set at work on the freight business, until yesterday, when it entered on its calling as a passenger engine. Very little time is now consumed in firing up; probably not more than half the average with ordinary locomotives. Rapid motion has been an aid to the fire, which formerly it tended to suppress. The dimensions of the engine are as follows: weight with all on board, 48 tons; length over all, 62ft.; diameter of driving-wheels, 5ft.; cylinders, 17 by 24in. **R. B.**

New York, July 12.

RAILWAY SIGNALS.

[20320.]—Railway signals, according to H. Stooke (letter 20267), sometimes show different angles for the danger position; this, I have no doubt, is because of the expansion and contraction of the rod or wire. Some years ago I wrote, in consequence of a sad accident, and on one occasion went to a station when I found a white light was reflected down the line, although I knew the signalman intended danger instead.

I think only two signals are used where lock systems are adopted, the "danger," and "clear."

If the horizontal position could be reliable, by means of a spring or stop, at or near the signal itself, it would prevent any miscalculation respecting 44° as danger, and 46° as clear.

My patent automatic apparatus for interlocking, and other signals (Model 21, Alexandra Palace Exhibition), when released by the passing train, would be actuated to "danger" by the weight at signal, because then independent of the rod or wire from the locking lever in the signal-box.

Well-street, Hackney. **J. Harrison.**

MORGAN'S PAPER FOR PHOTOGRAPHIC PURPOSES.

[20321.]—In your last volume, p. 379, mention was made of the many inquiries as to the nature of Morgan's sensitive paper, and of the effects produced with it. The following facts may therefore interest your readers.

A patent was applied for by Mr. W. T. Morgan, of Greenwich, in December last, but it received provisional protection only. In the provisional specification the invention is described as one relating to the manufacture of sensitive paper, and to blocks, pads, or tablets of the same, for photographic purposes. The following is the description given by the inventor:—

"In carrying the invention into practice I take superfine paper (preferably hand-made), as free as possible from grain or texture marks, and in order to eliminate all traces of lime or impurities of any kind, I pass it through a bath or solution of strong acid, preferably sulphuric acid and water, and thoroughly rinse. I then coat the paper with an emulsion of ground asbestos, talc, Chinese clay, or other substance of a similar nature in a solution of gelatine, starch, gum, and alum; when this is dry the paper is placed between highly polished steel or silvered plates and subjected to very heavy pressure by being passed between rollers. This paper is then again coated as before, but with a stronger emulsion of the same materials, and when dry is ready for glazing or enamelling; that is to say, for receiving a textureless glass-like surface so essential to the success of my process. This glazed or enamelled surface I obtain much in the same manner as lithographers obtain their transfer impressions from steel or copper engraved plates, that is to say, I damp the prepared paper on the back and carefully lay it with the prepared surface downwards on the polished metal or silvered plates previously made warm, and this paper is again submitted to very heavy pressure. The damp paper will adhere to the metal plate, but on again warming the latter, the paper may be easily stripped off. The paper is then stretched over a block by means of a frame similar to a linen stretcher, or by means of any other suitable apparatus; it is then carefully polished by being rubbed over the surface with paraffin-wax, bees-wax, or any material of a similar nature dissolved in highly rectified spirits; it is then coated by any of the well-known methods with a gelatine bromide of silver emulsion and when dry is ready for use. The paper may be used for a variety of photographic purposes: pictures can be produced upon it by means of photography, which pictures may be afterwards transferred to glass, canvas, opal, wood-blocks for engraving, or to any other substance to which it is possible to attach paper. It will be found most useful for decorative papers for windows, walls, panels, and the like, as any sized or shaped picture can be made. According to an important part of my invention, I arrange the paper in the following manner:—When the paper has been prepared in the manner above described, it is cut into suitable sizes, and any number of these pieces are superposed one upon another, the prepared side being upwards, and between each piece is placed a sheet of tin-foil or similar material. The papers so interleaved with metal sheets are then pressed into a shell or matrix of any suitable curvature by a die or pressing device of corresponding curvature which is subjected to heavy pressure, and forces the paper and tin-foil or other metal into a curve. The whole is then bound round the edges as is done with sketching or drawing-blocks or pads; the tin-foil assists the paper to retain its curve and also protects the rear sheet from light while the front one is being exposed in the camera. The paper and metal may also be made into flat blocks exactly similar to the ordinary drawing blocks. My object in bending or curving these tablets is that when they are placed in the camera in position for exposure they have the same centre as the curved surface of the lens, and by this means perfect equality of illumination is obtained over the whole surface. The lines are absolutely straight, the definition is more clearly defined, and many more technical advantages are secured, well known to the profession. The use of stops or diaphragms (if these are not entirely dispensed with) is considerably modified. The tablets are placed in the dark slide and exposed in the same manner as an ordinary sensitive plate. After exposure, the exposed sheet is detached from the block and developed in the usual manner. The surface to which the picture is to be transferred should be previously prepared by brushing over the same a solution of gelatine and alum, and allowed to dry. The picture while still wet is pressed in contact with the surface to which it firmly adheres, and when dry the paper may be stripped off, leaving the picture. The principle of curvature will also be found of great service in the process of enlarging where it is desirable to obtain absolutely straight lines. The picture having been produced on the paper can be transferred to a curved glass by the process above described, and the picture can be made to face either side by attaching it to the concave or convex surface. For magic-lantern slides or discs my invention is very advantageous, as pictures taken on the curved paper are transferred to curved glass, and when thrown on the screen will be found to cover the whole disc of light with perfect definition up to the edges."

T. H. G.

THE FOREGROUND IN SKETCHING—THE EXPANSION OF IRON — THE PERIODICITY OF STORMS—A CURIOUS WEATHER SUPERSTITION.

[20322.]—I FEAR that a "Country Sketcher," (letter 20291) will not arrive at pleasing results if he leaves out two of four fields between his eye and the distant object which he is drawing, under the belief that the eye will supply the omitted foreground. I suspect that the effect of that course will be merely to make the picture a representation of an object with two fields intervening, only drawn on a smaller scale.

Your correspondent, "J. W. W—s." is seemingly amused at my treatment of the Vienna Dome question; but he forgets that my remarks were made with immediate reference to the statements of Sir Edmund Beckett. I did not say that any part of the dome would undergo flexure, but only suggested that expansion might make itself evident in some other way than that mentioned in Sir Edmund Beckett's letter—a lateral movement of the pillars. Of course, when allowance is made in girders for local expansion, there can be no necessity for provision for expansion in their total dimensions. The whole point of Sir E. Beckett's letter, however, was that no such allowance had been made: and having no reason to doubt the statement, I was preparing to discuss the possible modes of expansion in structures so arranged. Your correspondent having called in question the truth of Sir Edmund Beckett's facts, I have no more to say.

I am sorry to see that Mr. Gardner (letter 20305) has left his 20 days' period theory of storms, and gone a hunting for celestial relations. As a matter of course, he has fixed upon the Moon, and will now probably spend the rest of his lifetime in the fruitless search for traces of lunar influence in our weather. Let him be warned in time, and give up the pursuit of the phantom. Many men have followed it before him, and all to no purpose.

It may be worth noting that on the 15th inst. (St. Swithin's Day) there was a new moon. That day being Saturday, we had the phenomenon of a "Saturday Moon," which ought to be followed by 20 days of wind and wet according to many proverbs. There are two curious circumstances connected with this superstition. The one is that it is unusually widely current. It is known among the farmers and peasantry in Scotland, Ireland, and the North of England. A correspondent of the *Athenæum* said he had heard it from American, French, and Spanish seamen, and even from a Chinese pilot. Whence this well-nigh universal belief? The other is that a gentleman actually deduced the rule from weather registers, without being aware of the existence of the popular superstition. He examined records covering a period of about 80 years, and as the result asserted that 19 times out of 20, a Saturday moon was followed by 20 days of wind and rain. He announced his discovery to the Royal Astronomical Society in 1848. Between the proverbs and the discovery, we are forced to conclude that there must have been some very striking coincidences to give rise to them.

J. A. Westwood Oliver.

Belle-vue Springburn, Glasgow, July 20.

STONEHENGE AND SUN-WORSHIP.

[20323.]—IT is the Clun stone circle I judge, from scant data possibly, but not altogether confined to flint implements, to have been constructed during the Neolithic Age. With respect to Stonehenge, I should be glad to know what evidence connecting it with either pre-historic era is forthcoming. That it is older than British times good authorities assert. Mr. Skertchley, speaking in these columns on ancient stone monuments has said: "We know that ages before the Druids worshipped here, these structures stood as hoary monuments of the zeal of long-forgotten races." He has also, anticipating the difficulty of supposing such massive blocks could be squared with only stone tools, said: "The Tahitians who, when first visited by Europeans, were quite ignorant of the use of metal, erected huge stone structures for the reception of the distinguished dead. One of these, described by Captain Cook, was no less than 267ft. long, 87ft. wide, and 44ft. high. The stones were 4ft. deep, and were neatly squared and polished. Similar instances might be cited from other places." Professor Ramsay says the standing masses of Avebury and Stonehenge have been set on end by a "vanished" race, and the same authority corrects Mr. Stooke with regard to the derivation of the material. He says the smaller stones only (believed to have been votive offerings) were brought from a distance. Most of the stones are simply the "grey wethers,"—fragments of denuded Eocene strata which orignally overlaid the chalk on that horizon. An eye-witness recently told me that similar blocks are seen sticking out of the soil all up and down in that neighbourhood. Any contribution of facts towards this discussion will be gladly accepted, I believe by others, besides Mr. Stooke and myself.

Neo.

COLOUR.

[20324.]—MR. SMITH (20307, p. 453) appears to misapprehend the bearing of Tyndall's experiment which he quotes. From a purely scientific point of view, the discussion about which colours are primary and which secondary or compound, is quite meaningless, because it is recognised that every tint and colour is both primary and secondary. Colour is, in fact, derived from two sources. First, it exists in the light itself, and every imaginable tint of pure colour exists as wave-length, or rate of vibration, in light. But it is also dependent upon sensation, and just as the sensation of white light is due to the combined effect either of the whole gamut of wave-lengths, or to the action of a variety of complementary colours or tones, so is each colour capable of being generated by several combined tones. The whole question has two aspects—the scientific and artistic, which have really no point of union, the one relating to cause and the other to effect; it is like the relation between the theories of acoustics and production of music from a violin. The effects of the spectrum, the decomposition, and recombination of the constituents of light, are entirely different from the relations of pigments and coloured materials, and science deals with one, and not with the other, for entirely different purposes.

Tyndall's experiment is perfectly simple and clear, when we understand that no agent adds to or produces colour at all: it only takes away a part of the light acted on. Once taken away, no subsequent combination can restore it. A blue glass simply absorbs all those rays of light which, when abstracted, leave blue; yellow and other glasses the same. The tone of each colour—that is, its purity, depends only on the residuary rays which pass. Now, taking the case illustrated, we have a so-called blue glass, which transmits blue and green, and a yellow glass, which transmits yellow and green. That is to say, we may consider the white light as consisting of blue, yellow, and green, because each of the two first glasses allows something to go through besides pure blue and yellow. But each of these glasses produces these colours, not by putting them into the light, but by taking out their complementaries. What happens when the glasses are superposed? The light first passes through the blue, which sifts out all the yellow, but permits green to pass with the blue; the yellow glass now sifts out all the blue, and, therefore, has nothing but green left to pass: that is to say, the green light is not produced by the union of blue and yellow lights; but is merely the residue. But blue and yellow pigments may produce a green effect with reflected light, notwithstanding, because these do send the two colours to produce a combined effect or harmony (which may be green) upon the eye.

In the second case, with two separate lights, the conditions are quite different. Here each glass sifts out only its own proper colour; but does send its residue on to produce its effect. Hence, the result is blue, green, and green-yellow, and the combined effect should be white, with an excess of green.

The explanation of the effect of white from a rotating compound disc, is that each colour producing in the eye its own rate of vibration, which is persistent, the whole of them combine to produce, in the eye, just the same result by their rapid succession as though they were acting synchronously, as in white light.

As I said at first, science recognises no three primary colours; for in fact we can produce the white light from various combinations.

Sigma.

[20325.]—IT is but a short time since Mr. Colton brought up this question before, and it is quite evident he has learned nothing in the interval, and that both he and Mr. Smith are only of the usual type of paradoxists, with whom argument is useless. When Mr. Smith quotes Tyndall, that by "judicious management one of these colours is rendered yellow and the other blue," he knows that he is only indulging in mere word quibbling. By judicious management, Tyndall means only judicious management of the stopping off screens so as to leave only the yellow and blue—*absolutely pure*—of the spectrum. It is only possible to misunderstand Prof. Tyndall's meaning intentionally. When Mr. S. goes on to say that, by Tyndall's own showing, what he here calls blue and yellow contain between them all the colours of the spectrum, I must ask him where Tyndall shows that? Tyndall tells him that he can obtain yellow and blue in the spectrum free from admixture of other colours, and that this pure blue and yellow light, when mixed produce white; but Prof. Tyndall nowhere says the white thus produced contains all the colours of the spectrum. On the contrary, it contains only the blue and yellow, as a prism would soon show. It is no use arguing, however, with paradoxists. I will, therefore, only propose a test experiment to Mr. Smith. Let him cut off from the solar spectrum all but the pure blue and yellow, and then recombine these. Let him test his blue and yellow before mixing by a prism, and after, and having done so, compare his resulting light with ordinary white light, and send you, Sir, the results of his experiment. If he is not satisfied of his error by that time, I am afraid he is past convincing. With regard to his assertion that an admixture of one-tenth white light to nine-tenths coloured would destroy all trace of colour to the eye, he says the thing that is not.

E. Holmes.

INDICATIVE SYMBOLS.

[20326.]—IF Mr. M. Jonson had been acquainted with the routine of a printing office, I believe he would not have recommended many of the indicative symbols contained in his letter (20248, p. 404). There can be no objection to Y, F, P, T, being used respectively to represent yards, feet, pounds, tons, though it looks remarkably like a change without an improvement; but there is an objection to Y^2, &c., and a very decided one to all signs with a line over them, or indeed to anything not usually to be found in the compositor's pair of cases. I believe if the mathematicians had consulted the printers when they adopted or developed the signs used in their formulæ, they would not have cause to complain of so many misprints. In writing, of course, there is no objection to any kind of symbols; but as written science nowadays is frequently printed, it is advisable to keep the symbols used within the ordinary type-range of a newspaper office. The saving in space by the use of these symbols is not a very large quantity; and seeing that mathematical formulæ, owing to the trouble and time occupied in setting, cost twice as much as ordinary matter, it requires considerable courage to introduce any new formulæ. In the ENGLISH MECHANIC I have noticed with satisfaction that the method of setting out sums suggested by Prof. Stokes has been adopted, instead of the antiquated and troublesome method of putting figures under one another with a line between, which line, being no multiple of the body-depth of the type, involves some trouble in justification, or making one column the same length as the other, besides keeping the lines square. It might be urged by Mr. M. Jonson that his suggested characters with the line over them might be cast in one, and so they might; but where are they to be kept? That is the gravamen of the whole business. The old-fashioned compositor is rapidly giving place to a race of mere type-setters, who take no pride in their work and no care of their employer's property. For this reason special characters, which have no appropriate boxes in the pair of cases, are frequently thrown on one side and lost—even Italic is not always restored to its proper place by these gentlemen, who are the loudest howlers when they cannot find the "sorts" they have themselves wasted. Apart from these considerations, it is not quite clear what is to be gained by representing "1 volt" as "Fu VIII.," but there is a decided gain in writing and also in printing "1 foot" as "1 F." The use of Greek letters to designate stars is, no doubt, convenient, and is well adapted to the purpose; but so far as the printer is concerned he is at this disadvantage—that the Greek letters are frequently mislaid, and often, thanks to the imperfect manner in which they are delineated by different writers, he has the credit of making a mistake—a printer, you know, being expected to be able to tell with "half an eye" whether the author meant Zeta or Xi Cancri, Nu or Upsilon Ceti. Those who wish to adopt symbo's have a fair supply in every pair of cases; they have, for instance, whole alphabets of capitals, small capitals, and lower-case; they have the three common accents on five vowels, and the diæresis ditto, parentheses, brackets, note marks (*, †, &c.), besides other signs which could readily be used, and, once understood, would be as effective as many of the troublesome signs now employed.

A Practical Printer.

THE PRESSURE OF WIND.

[20327.]—After reading Mr. Gardner's letter and the query of "Octurus" (47493) in your issue of the 21st inst., I am prompted to make a few remarks upon this subject.

In the first place, Mr. Gardner, in his letter on "Forecast and Periodicity of Storms," quotes the English Mechanic to the effect that in the gale of the 14th Oct., 1881, a wind pressure of 53lb. on the square inch—on the square foot, I think he means—was recorded at Greenwich. "Octurus," in his query asks, Which is correct? The "E.M." in stating the pressure of wind on the square foot at a velocity of 50 miles per hour, 49½lb., or "Molesworth's Pocket Book," which gives the pressure at that velocity as equal to 12·304lb. per square foot.

I would remark, with regard to the statement in Mr. Gardner's letter, that such a velocity as 53lb. on the square foot, not to mention on the square inch, is unknown in this country, except in anemometrical registers, and this I not long ago pointed out in *Nature*, curiously enough, citing this very instance. If your correspondent had wished for a still more astounding record of velocity, he might have stated the pressure registered, during the same storm, at the Bidstow Observatory, Birkenhead, which was 77lb. on the square foot, according to the newspapers.

The erroneousness in the registration of such high pressures as these, has been aptly pointed out by Mr. T. Hawksley, F.R S., in a paper read before the G. Section of the B.A. Meeting, York, 1881, in which he gives a formula, and a table compiled from it, by which the velocity and pressure of wind are connected, and which I will give here, if you can spare the room, as I think "Octurus," and others of your readers who take an interest in meteorological subjects will find it useful.

Let v = velocity of wind in feet per second; p = the pressure in pounds per square foot; ·0765 = weight in pounds of a cubic foot of the impinging air, 32 = coefficient of gravity. Then

$$p = \frac{\cdot 0765\, v^2}{32} = \left(\frac{v^2}{20}\right) \text{ very nearly.}$$

By means of this formula the following table of pressures is constructed.

Velocities in		Pressure in pounds per sq. foot.
Feet per second.	Miles per hour.	
10	6 8	0·25
20	13·6	1·00
30	20 4	2·25
40	27·2	4·00
50	34·0	6·25
60	40·8	9·00
70	47 6	12 25
80	54·4	16 00
90	61·2	20·25
100	68·0	25·00
110	74·8	30 25
120	81·6	36·00
130	88·4	42·25
140	95·2	49·00
150	102 0	56·25

When there is a diminished pressure, as in the case of the inclosed sail, roof of building, &c., we then have

$$p = \frac{v \text{ sin. } B^3}{20}$$

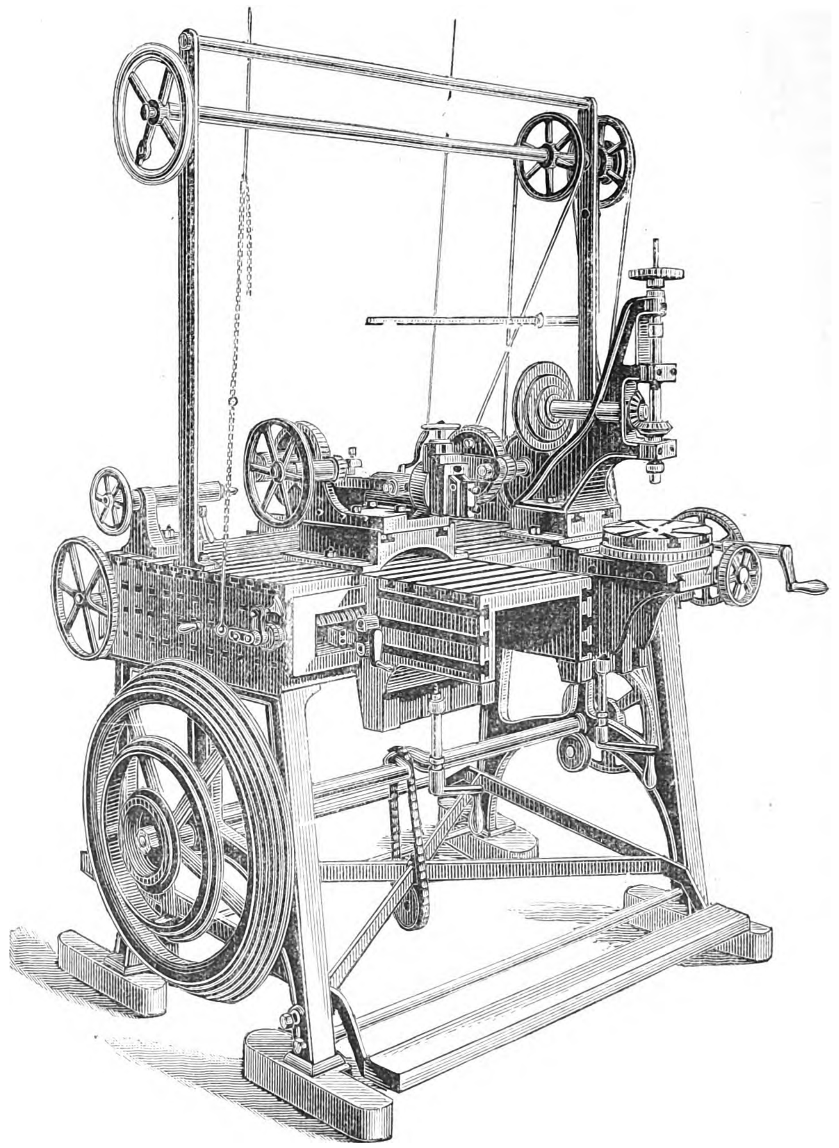
in which v = the absolute velocity with which the air strikes the receding plane, and s the internal angles between the obliquely-placed surface and the direction of the impinging wind.

By making use of the above table, "Octurus" will find that in the case he gives the pressure will be 14·81lb. per square foot. This, it will be seen, is greater than that given in Molesworth's Pocket-book, and considerably less than that stated in the "E.M." The formula and table given above, however, are more trustworthy, I think, than Molesworth, whose table of wind pressures, I find, on reference to an early edition, has remained unaltered for about 20 years. The figure in the "E.M." is evidently a mis-statement.

Worthing, July 24th. **C. H. Romanes.**

COMBINATION MACHINE.

[20328.]—I send two photographs of a new combination machine I have made. The bed is of cast iron, 4ft. long and 2ft. wide, with twelve T slots for bolting the different parts of the machine down, also thirty square holes on each end for same or fixing work. The standards are of cast iron, fitted with crank shaft running upon rollers, one end has balance flywheel, the other a driving-pulley. The treadle works on either side.



COMBINATION MACHINE.

The lathe side is fitted with Whitworth's 5½in. centre headstocks, traversing table is fitted with 1¼in. steel leading-screw, also rack and pinion. The leading-screw is fitted with quadrant for change-wheels for screw-cutting. The table is fitted with compound slide-rest, also with angle-plate to fix cylinders or other work. Work to be done on this side: Ordinary turning, screw-cutting, surfacing, cylinder boring—all self-acting.

The machine side is fitted with a drilling-machine and shaping-machine with two traversing tables. The one under drilling-machine is compound, having rotary, vertical, and parallel motions; it is fitted with eccentric to throw in and out gear of leading-screw for traversing the bed. The other under-shaping machine has T-slots on top, and each side it has vertical and parallel motions with eccentric, same as drilling-table. Work to be done on this side: Drilling, (shaping, either parallel or circular) wheel-cutting, tap fluting, nut shaping, milling, keyway cutting, boring, and many other things. The machine is driven from overhead shaft, fitted with clutch motion for starting and stopping.

The rotary table is fitted with mandril same as lathe-head for taking all chucks. A better explanation can be given upon seeing the machine.

Henry S. Frost.

(Engineer, Lathe and Tool Maker.)

45, Mortimer-street, Cavendish-square.

MEDICAL REPLIES.

[20329.]—Diabetes (47423).—The simplest test for sugar in the urine is its specific gravity, for estimating which a small hydrometer is sold. Healthy urine ranges from 1,010 to 1,030 at 60° Fahr. If the urine runs above 1,030, sugar is very probably present, and if so, the urine may range from 1,030 to 1,050. Put half an ounce of urine in a test tube, add a piece of sodic hydrate as large as a pea, and boil. If sugar be present, a dark brown colour is produced. Then there is the ordinary copper test, also that by fermentation, both of which will be found in textbooks. In diabetes a very large quantity of urine is passed of a high specific gravity, such as I have indicated. Great thirst and dryness of skin are induced by the elimination of so much water by the kidneys. As to diet in diabetes, the routine prescription is to exclude sugar and starch; but I believe that I have often seen life shortened by persistence in a rigidly non-saccharine diet.

Stammering.—In my note on this subject (47366) I see a printer's error. "Make the child read aloud, with extreme slowness and distinctness, for a quarter of an hour four *hours* a day" should be four *times* a day.

Billiousness (47239) is a hopelessly vague term which may mean anything. Querist must get personally examined.

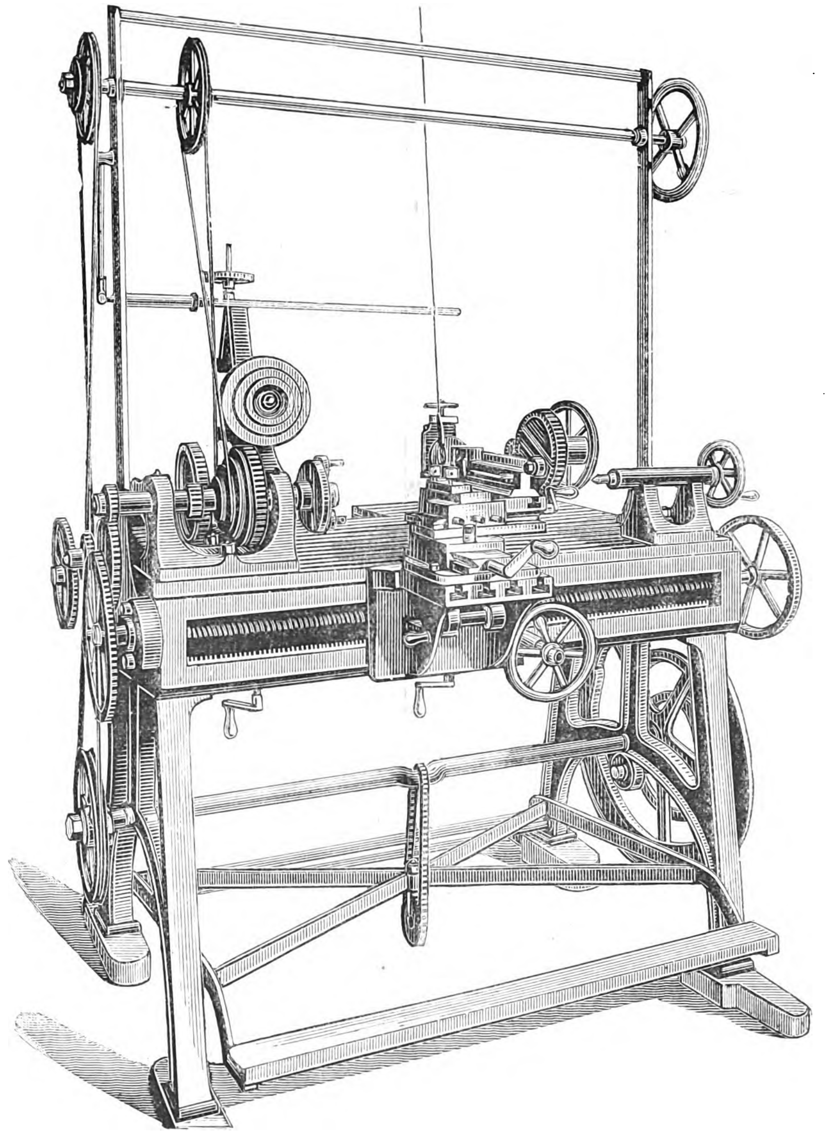
Pain in the Bowels (47436).—If "Printer" is suffering from lead colic, he will see a pale blue line round the edge of the gums on turning up the upper lip. For this refer back to a former full article by me upon "lead poisoning." If he has defective teeth, live on soft food, and do not swallow lumps of meat that have not been chewed. For this refer back to former articles on indigestion.

Dryness of Mouth (47488).—Not eligible for useful reply. **James Edmunds, M.D., &c.**

Grafton-street, Bond-street.

NOTES ON DYNAMO-MACHINES.—VI.

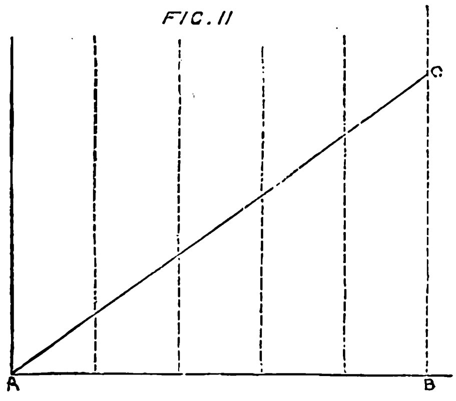
[20330.]—47. With reference to the characteristic curve for the ordinary dynamo-machine, we have said in a former note that for a short period at the beginning of the curve the strength of the magnetic field is proportional to the current. This, as has been explained, is due to the fact that the iron in the cores is as yet far from saturation, and it follows that this period, during which the strength of the field is proportional to the current, can be lengthened by increasing the amount of iron in the field magnets.



COMBINATION MACHINE.

48. For a machine having a comparatively large amount of iron in the field magnets, the rise of E.M.F. would be represented by a straight line A C, Fig. 11, taking, as in former notes, distances

FIG. 11



on the horizontal line A B to represent current in ampères, and vertical heights to represent E.M.F. in volts. This fact is important, as affording the basis of the solution to the problem indicated in Note 46.

49. We have a large number of incandescent lamps arranged in parallel circuit, and fed from a particular station. The problem is to arrange the generator so that fifty or a hundred, or, in fact, any number of lamps may be extinguished, while the current through the other lamps remains unaffected, the speed of the generator remaining constant. Let L represent the lamps (Fig. 12) and G the generator, then that every lamp may be perfectly independent of its neighbours, neglecting the resistance of the leading wires, it is only necessary that the difference of potentials between E and E′, the terminals of the generator, be kept constant.

50. The solution here given is due to M. Deprez

FIG. 12

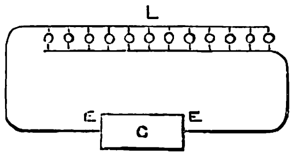


FIG. 13

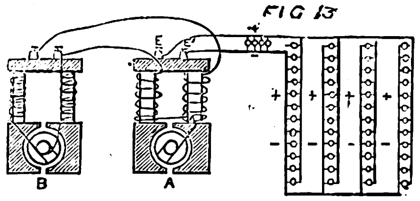
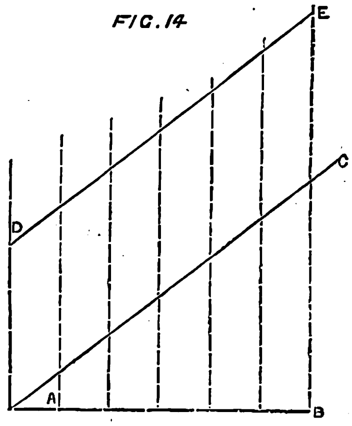


Let a dynamo-machine (A), Fig. 13, be constructed, having a large mass of iron in the cores of the field magnets, and having two coils wound on these cores: *a* wound as in the ordinary dynamo and in circuit with the armature and lamps; *b* fed by an auxiliary dynamo B. In this machine a part of the E.M.F. is due to the magnetism derived from the current in the self-excited coil *a*, and another part is due to the magnetism derived from the current in the coil *b*, which is fed from the auxiliary dynamo. The sum of these two E.M.F.'s gives the total E.M.F. of the machine. The characteristic curve for this dynamo when self-excited and when no current is being supplied by the auxiliary machine, will be represented by the line A C, Fig. 14. Let the auxiliary dynamo be started and

FIG. 14

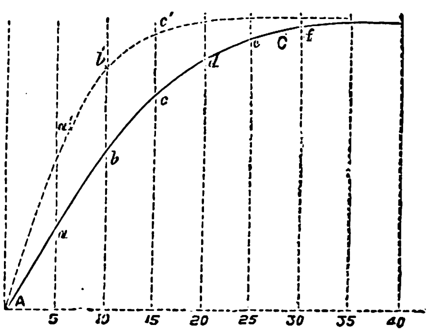


a current sent round *b*. A certain E.M.F., A D depending on the magnitude of this current, will be added to the first E.M.F., and D E will run parallel with A C (since the cores of field-magnets are very large), and will represent the total E.M.F. of the machine A. If the difference of potential between E and E′ is to remain constant, it is necessary to have the internal resistance of A such that if an angle be drawn with its tan. representing the resistance, that angle shall be equal to C A B; in other words, the tan. of C A B must equal the internal resistance of A—i.e., A must be driven at its critical speed. If this condition is fulfilled, it is obvious that whatever may be the total resistance in circuit or current flowing, the fraction of E.M.F. employed in sending the current through the external part of the circuit is constant, and is equal to A.D. This is only true for one speed of A, and if, during the process of lighting, the internal resistance of A increases, due to increased temperature, the speed must be increased a very little to make the characteristic curve coincide with the new internal resistance line. Increasing the speed of B does not alter the necessary condition of E.M.F. between E and E′ remaining constant, but merely increases the E.M.F.—that is to say, all the lamps are rendered brighter. The lamps can, consequently, be of any desired brilliancy.

51. The strength of field produced by an electro-magnet is proportional to $a\,N\,C\,\sqrt{L \times D}$, where a is a constant depending on material of which the core is made; N = No. of turns of wire; C = current; L = length of core, and D = diameter of core. This only holds good for very small currents, or so long as the strength of field produced is proportional to the current; but we can assume that the strength of field is constant for the same value of N C, and is independent within the limits with which we are concerned of the respective magnitudes which make up this product.

52. On this assumption, it is quite easy to say what effect will be produced by increasing the number of turns of wire on the field-magnets, since the E.M.F. is proportional to the strength of field. Let the line A C, Fig. 15, represent the

FIG. 15



characteristic curve for a particular dynamo having N turns of wire on the field-magnets. Let the turns on the field-magnets be increased to 2 N; then we know that with a current of 5 ampères 2 N turns will produce the same effect as N turns with 10 ampères. The first ordinate for the new curve is obtained by making $5\ a^1 = 10\ b$. Also with 10 ampères 2 N turns will give the same result as 20 ampères with N turns; consequently 10 b^1, the second ordinate of the new curve, must be made equal to 20 d; the third ordinate 15 $c^1 = 30 f$, and so on, the dotted line representing the new curve. It will be observed that the maximum E.M.F. is the same for few or many turns, since there is a point beyond which an additional current does not give an additional E.M.F. due to presence of iron. The effect of more turns is to saturate the magnets quicker.

53. Given the characteristic curve for any particular machine to find the new curve for increased No. of turns of wire on the armature, provided the space filled is about the same, we have simply to increase the vertical ordinates in the same proportion as we increase the number of turns of wire on the armature. It must be borne in mind that although we have taken considerable pains to explain the action of dynamo-machines geometrically, and have considered at some length how the characteristic curve is affected by modifying the construction of the machine, the results obtained are only to be taken as approximately true, for the complete theory of the dynamo has not yet been formulated. E.

FARADAY'S FIRST DYNAMO.

[20331.]—The following may interest some of ours:—"This instrument is of the horsehoe form, and is composed of twelve sheer (thin) steel plates, each 28in. in length from the poles to the centre edge. At the greatest width of the curve the horseshoe is 7in. across, and the extremities of the poles are 1½in. asunder. The keeper (armature), or lifter, which is made of the purest soft iron, is 5in. in length, 2½in. wide, and 1in. thick. Around the middle of the keeper, and occupying with its lower section the space between the poles, is a wooden winder, having about 100 yards of common threaded bonnet wire, from which the two ends, composed of four lengths of the wire twisted together, are carried out. One of the twisted ends passes beyond each end of the keeper, and rest upon the respective poles of the magnet. A short lever, placed in a frame, is so attached to the winder and keeper as to admit of their being forced up by the hand applied to the longer end of the lever. Every time this is effected a brilliant coruscation of light is produced at the end of the wire." Fiddler.

LEGAL REPLIES.

[20332.]—"Caveat Emptor" is a maxim of the English law, and it means "Let the buyer beware." Now it has been humorously translated, "Keep your eyes open." "F.W's." "impression" of what wonders the stove would do can clearly not avail him, and glowing statements in a circular or advertisement are, of course, mere puffery. There is thus no warranty, and without a warranty the buyer of an article of this kind can have no right of action, even though it fails to perform its promises. If the shopkeeper had, at the time of the sale, said that the stove would cook as advertised, and in a way that made his statement a warranty, then "F. W." would have been able to recover his money back again. But here there was nothing of the sort; and as there can be no legal obligation for the tradesman to change it for other goods, "F. W." must make the best of his bargain.

(47476.)—Without knowing exactly what were the terms of this agreement, I cannot answer for certain. But it is a clear rule of law that there can only be a distress for rent in arrear; and it is also decided that a distress after tender of the sum owing is illegal. In an ordinary way, therefore, the landlord could only distrain for the week actually in arrear, and if that were tendered him, a subsequent distress, even for that, would be illegal. But if, by the agreement, a power was given to distrain for the week's rent in advance, or to treat it as being in fact due, this would, of course, alter the whole question. The landlord, doubtless, refused the one week, in order that he might be able to distrain for the two, and, should he do so, the tenant can pay both under protest, and bring his action for damages in the county-court for illegal distress. Of course, the landlord could sue for the rent in advance; but, as far as I can see, he could not distrain, and, of course, the rent tendered must be paid.

(47479.)—As far as I can understand this confused question, what happened was this. The executors renounced probate; and, afterwards, when assets began to come in, the widow took out letters of administration with the will annexed—as she had a clear legal right, and, indeed, a duty so to do. The son's being under or over age has nothing to do with his position; and after the debts are paid, it is the widow's duty to divide the estate in manner directed by the will. The son will, therefore, get his appointed share, and, of course, the widow has no right whatever to will away the whole property, which she only holds as administratrix—though, to be sure, she can do as she likes with her own portion. The will remains perfectly valid. When there is a will there can be no such thing as a "sole heir," and, except as to land, a son has no more right than a daughter. "Adolescens" is very wrong in his law.

(47485.)—As I understand this question there was but one set of leaseholds, and but one sale by auction, and the share coming to the nieces from such single sale was over £200. Now, as the sale was the only source from which this property came, and as it took place upon one day, I am at a loss to see how the sum derived therefrom can be otherwise than succeeded to "at one and the same time and from the same source." To say that because the houses were sold in separate lots, therefore this one sale was divided into separate sources, is a refinement of casuistic argument that would find no support in any court of law nowadays. I therefore think that there is nothing in the point here put, and that it would not support an action, though it might lead its promoter into a very pretty bill of costs.

Fred. Wetherfield, Solicitor.
2, Gresham-buildings, Guildhall.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46744.]—**Marble.**—The streets in the city of Armagh, after rain, show that a good deal of native marble is used there. Finer slabs are made into chimneypieces, and polish up well. It is brown, prettily mottled. Sometimes a vein of pale-pink stone is found of the nature of madrepore, and of this small fancy articles are formed for sale as keepsakes.—H. O'B.

[46762.]—**Sick Child's Arm.**—This case will very likely be benefitted by a plaister made of mustard and common treacle, spread on brown paper, renewed daily, wrapping a cloth round it. This seems a queer remedy; but it is a good one. Steaming the arm over a pan of boiling-water, enveloped in a flannel cover, is most useful also.—H. O'B.

[46780.]—**Water Power.**—With 35ft. of fall and 473 cubic feet of water per minute, a Hercules or other good turbine will give 25 horse power; wheel 9in. diam., outlet for water 14in. diam. It would cost about £30. It would be waste and useless to put up any other than a turbine.—Quod Dixi Dixi.

[16792]—**Aquarium.**—Permit me to insert a caution on this subject. Select only pond creatures; the inhabitants of running streams will live but a few days (or hours) in the still water.—H. O'B.

[46859.]—**Indigo-Blue Dyeing.**—I fear J. Ormiston handles our friend S. J. Simpson rather ungenerously, and he by no means gives additional valuable practical information. "Blackwater" is much obliged to Mr. Simpson for his concise and explanatory answer. Mr. Ormiston says that "the writer displays ignorance of the two methods of indigo dyeing, or he would have given a fuller and more correct description than he has done." "Blackwater" simply asked for information as to Read, Holliday, and Son's process, and in what manner it differs from woad vats? This question remained unanswered a long time, and I have to thank S. J. Simpson for giving me all the information I required or expected. He rightly assumed that I had a knowledge of woad vats. In the woad vat indigo is reduced to a state fit for dyeing by the fermenting power of the woad, aided of course by bran and madder. Now, the successful management of woad vats requires special knowledge not to be acquired every day. Beside practical experience, powers of judgment, and observation, the "trade secret" is necessary. A dyer who is thoroughly master of woad vats should be able to dye, with eleven or twelve pounds of indigo in a woad vat, seven hundred (700) yards navy blue serge, ¾ yard wide. I should like to know what quantity of similar goods can be turned out of a Read-Holliday vat at same cost, taking the average value of good indigo at 6s. the pound. As a rule, good woad-dyers are few and far between, so that any process that simplifies indigo-blue dyeing is the greatest boon to woollen manufacturers. The more goods dyed by a certain quantity of indigo in the woad vat the more brilliant and faster the colour.—Blackwater.

[47023.]—**Sea-Sickness.**—A person who only feels bad really suffers more than one who is really sick. In this case the great suffering arises from the contraction of the stomach on nothing. A deal of suffering is spared by always eating, so that the stomach has something to act upon. Don't drink brandy, or you will suffer for it. In most cases, not always, the sickness goes off in a few days. Fight against it, but keep the stomach full.—Edward Thos. Scott.

[47039.]—**Clock Query.**—Pinch the spring of the fly so as to make it turn a little harder. You may make it strike as you like.—Edward Thomas Scott.

[47056.]—**Bacteria.**—I am truly obliged to Mr. Thoms for his lengthy reply to my query, and will endeavour to profit by his information. I forgot to mention that in mashing with water at 188° Fahr. a few gallons of cold water is invariably mixed with the mashing liquor to reduce the temp. to about 150, before the rye is added and mashing begun. I would gladly avail of brewery yeast for fermentations (as at home) were it obtainable at a reasonable price; but at two francs per kilog. this is out of the question, and in summer it is seldom fresh, having to come at least 800 miles by rail. I usually change the mother once a month, sometimes even less frequently. It may interest Mr. Thoms to know that, by means of the barm I before described, I have (during winter weather) fermented mash from sp. gr. 1050 to 1002 in forty-eight hours regularly; last winter, from month of December till middle of March, this was the invariable attenuation. The returns of spirit from maize mash (the maize being digested whole by means of light-pressure steam and saccharified with 9 per cent. to 10 per cent. green malt), being very little inferior to English work fermented with brewery barm.—Cygnet.

[47101.]—**Polypus.**—The tonic powder, Bayberry, used as snuff several times in the day, has cured one of long standing, and restored smell.—H. O'B.

[47140.]—**Ampere.**—The ampère, as I suspect Mr. Stooke knows, is the unit of current, and is the current-quantity passing through a circuit with E.M.F. of 1 volt, and resistance 1 ohm in one second. It is also that quantity of current which liberates ·000158 grain of hydrogen per second. It is the new name for weber, which properly means one weber per second. Coulomb is the new name for the unit of quantity, formerly known as "one weber."—S. P. T.

[47143.]—**Aluminium.**—I thank "Spaniard" for his reply on p. 431. I am sadly disappointed to find none who have written are wiser than myself on the subject. Had I guessed how very difficult my query was, I should have set to work, and not allowed beginners to lead me into such a mistake. In a desultory way I had tried all published processes; but all are expensive and unsatisfactory, considering the very low price at which I can obtain the alloy. I have no doubt ghanite would easily form an impure alloy. I do not use it. I can make my alloy with any metal. My first experiment was with lead, and I am not sure that does not answer best. My ardour is not damped. Having discovered a "new process" for obtaining crude aluminium, I may find a new process for purifying it; things hidden from the wise are sometimes revealed to a tyro in science.—Zelia Naien.

[47156.]—**Varnish.**—It is black japan, made quick-drying by the use of driers, gold-size, and turpentine.—T. P.

[47168.]—**Tinning Copper Sheets.**—From "Coppery's" original query, I understood that he only wanted to tin one side of the sheet, for which the method I gave is applicable. If he wishes to tin both sides, he must do them both at once, and if possible use a bath of tin. However, by spreading whiting, made into a paste with water, over one side, he may preserve it to a certain extent while tinning the other.—Mide.

[47170.]—**Blast Furnace.**—The usual arrangement is fuel, ore, and flux. What is meant by their "chemical order"?—S. M.

[47181.]—**Boiler.**—What sort of work is the engine to do, and how much room have you for boiler? It would be better to have a vertical, perhaps, and of those you will find many illustrated in back volumes.—Essar.

[47186.]—**Gum-Paste.**—Ordinary gum-paste is made of picked gum-arabic and white sugar, equal parts, and to each pound of gum one pint of water. Dissolve the gum, add the sugar, and evaporate until it is thick syrup. Then add the whites of eggs (about three to each pound of gum), previously beaten up with orange-flower water or other flavouring; strain through muslin, and continue the evaporation until it will set readily when cooled. I don't understand "treatment when made," or "preparation of moulds." Treat it how you like, and pour into any clean surface, such as a plate or saucer, and cut into what shapes you please.—C. D. P.

[47191.]—**Loco. Building Shops.**—I do not think there are any loco. shops at Liverpool; but there are numbers of traction, and pumping, and other engine works.—D. G.

[47194.]—**Organ Tremulant.**—There is an illustrated description of a very good organ tremulant in No. 528, p. 204; and several others in previous Nos. No doubt, all will be described in Mr.

Warman's papers; but, possibly, you will not care to wait for that time.—S. Mayer.

[47196.]—**Electricity v. Gas.**—Mr. Williams has not read the correspondence, or he would have seen who put the original query. Electricity may be a substance, or an element to be analysed, and as it can be stored, we may agree with Col. Shakespeare, and ask, Where is its source? Again, I did not mean Lewis's incandescent, but the hydrogen incandescent gas-lamp, with a light bright enough for spectrum analysis. This is a gas-lamp with one jar, while many jars are used for the electric incandescent light. Now, while our friends have been finding fault with me for writing letters, asking and answering questions, I find on p. 439 that two French electricians have been experimenting with the arc light, and have actually burnt a vapour or gas (sulphide of carbon) with or together with electricity, and with incomparable results. This is a great advance on my first idea, seeing that the combustion takes place in vacuo—a seeming miracle; but the effect is not continuous or self-contained. What we want, is to utilise the waste products, of which hydrogen gas is one, and a most energetic, agent. Could hydrogen gas be burnt in vacuo? Answer: As there are no elements of light, but only energy or heat, it would be useless. But as the electric light depends on a great expenditure of energy in the battery, and this large motive power escapes, how can it be utilised? Can it be suppressed in the battery by atmospheric compression? Would the electrical action go on, cease, or be increased? My reason for asking these questions is, that I know of no experiments tending in this direction—that of expressing or collecting the motive force by compression or leverage. I hope Mr. Patrick will explain his dynamo.—Fiddler.

[47197.]—**Stamping Brass Discs.**—A die-sinker would make the proper dies. The blanks will, I expect, have to be prepared a trifle thicker and smaller, and then the stamp will spread the metal, which will take up the letters on the edge. —T. P.

[47202.]—**Extraordinary v. Otto.**—This is much a matter of taste; but I should prefer the 'Xtraordinary, and the Facile to either.—T. P.

[47205.]—**Anemometer Indications.**—I believe you are correct; but I should like to know what the fact is supposed to indicate—a cyclone? —Ignoro.

[47216.]—**The Berliner Violin.**—With the new metallic resonator, the thin wooden strips may be left out. The triangular rib merely serves to prevent the strain of the screw bending in the back; and hence, in order to avoid opening the violin, a corresponding rib might be glued to the outside of the back with the same result; but this would not look well. Otherwise there is no reason why it is necessary to open the violin.—E. Berliner.

[47226.]—**Picture-Frame Making.**—Thanks to those who have kindly sent hints. Do I understand "J. A. A.," Liverpool, that it is necessary or desirable to shoot one of a pair of mitres with the face downwards, as I can hardly see how it is to be held true in this way. I have always understood that in shooting a set of mitres, keeping the set of the plane the same, an error in one direction was compensated by corresponding error in opposite mitre without turning the face of the moulding. —Beta.

[47239.]—**Deafness.**—It seems to me Mr. John Alex. Ollard is pottering away too much at his ears, and starving his body of proper food. If he is deaf and bilious to the extent that life is misery, why cannot he 'bout ship for a month or two, and infuse a little common-sense into his philosophy and the selection of his daily food? His stomach, I take it, is not built on the plan of the herbivoræ. Let him take one-half of his vegetables after their physiological conversion into beef or mutton, cooked properly, of course. He can please himself about a little wine for his stomach's sake, but I do think he should not neglect a regular and instant course of mineral waters. The vegetable food that he is groaning under is, without doubt, deficient in bile elements. The loss of eyesight is a greater loss than that of hearing. The writer has been totally deaf for twenty years, and has got so accustomed to the loss as hardly to feel it. If there is any hope of Mr. Ollard recovering his hearing, or retaining what he has, it really seems to me he must do two things: bring his body into a healthy state, by a complete change of food, and not to doctor his ears himself, but get skilled advice.—Another F.R.M.S.

[47239.]—**Biliousness.**—From what Mr. Ollard says, it is clear that to advise him to try rashers of toasted bacon, or rum and milk, would be out of the question; but he might try the effects of dandelion leaves eaten as a salad, or as he would water-cress between bread-and-butter (I presume he eats butter, though it is an animal food). The ordinary wild dandelion leaves are, I believe, the most active, but the large-leaved Taraxacum, sold by all the best seedsmen, is most palatable, and when grown quickly and bleached like endive is an excellent and tasty salad. A great deal, however, depends on what is meant by "biliousness," and it would certainly be wise for Mr. Ollard to consult a physician as to the cause of the effects he calls biliousness.—Nun. Dor.

[47279.]—**Spoiled Plate Glass.**—Do not be surprised if all your attempts at clearing this should fail. Ask a manufacturer, who can explain to you that damp affects the very ingredients of plate-glass, so that the clouding exists through the sheet, and not merely upon the surface.—H. O'B.

[47279.]—**Spoilt Glass Shelves.**—The sole cause of the spoiling is damp air. Had the shelves been perfectly dry no spoiling would have occurred; but plate-glass stood together, always has its surface spoilt by the ordinary moisture of the atmosphere. There is no cure except repolishing with rouge or putty-powder.—E. Holmes.

[47309.]—**Clarionet.**—I have one of Rudall and Carte's best B flat clarionets, and have great pleasure in giving the length of the several parts, the bore, and also the distance between the centres of the principal holes. I cannot give the size of the holes with sufficient accuracy in writing. Mouthpiece, 2·8in. long; reed, 2·5 × 0 5 full; tuning socket, 2·1in.; top joint, 7·4in., each measured outside when put together, so that the lengths of the portions which fit one into the other are extra. Lower joint, 8·85 to commencement of the portion which fits into the bell, thence to extreme end, 0·8, or 9·65 over all. Bell, 4in. long. The bore is 0·6 (6-10in.), from the top to 6·2in. from the upper end of the lower joint measured outside. From this point it enlarges in a curve to 0 9 at the extreme end of the lower joint. The bell enlarges in a curve from 0·9in. to 2·2in. The outside diameter of the instrument is 1·1in. at the centre of its length. The distances of the principal holes from the upper end of the socket into which the mouthpiece fits are:—Pipe-key, 3in. full; long side-key, 3·6in.; A key, 4·75in.: G sharp, 5·2in.; thumb-hole, 5·8in.; 1st finger-hole, 6·4in.; 2nd finger-hole, 7·5in.; 3rd finger-hole, 8·7in. In the lower joint the distances are measured from the top of the joint:—1st finger-hole, 0·8in.; 2nd finger-hole, 2·1in.; 3rd finger-hole, 3·3in.; G sharp key, 4·5in.; F natural key—for this there are two holes (patented) at 5·5in. and 6·6in.; F sharp, 6·8in.; E 8·1in.—Emeritus.

[47325.]—**Street Medical Coil.**—To Mr. Lancaster.—I want to make a street, medical coil the same as is seen in the streets, with bells and battery —a complete machine.—F. Rowe.

[47340.]—**Silvering Mirrors.**—"Prism" (page 412) is wrong in quoting 50oz.; it should be 50 grains to 2oz. of water. A 6in. mirror requires 8 fluid ounces to give about a half-inch depth of bath under the inverted face, and 12oz. will give about 1in. under. I have not tried a weaker bath than this proportion, and would not advise it. We are greatly indebted to Mr. Brashear for his process; it is economical, gives little trouble, and the result is certain and satisfactory.—J. C. L.

[47341.]—**Electric Locomotive Engine.**—You had best make a four-wheel locomotive, for which procure a piece of hard wood 12in. long, 4½in. wide, and 1in. thick. The leading wheels may be about 2in. diameter, and the driving-wheels 3¼in. Set the line of axles close together for a circle of 5ft. to 6ft. diameter, if you wish to make a circular railway. The best gauge is 3in. to 3½in., and you must use your own discretion in conveying the electricity from the rails, through the wheels, to the electro-motor engine. The Simplest form of motor engine would be a Siemens armature, 2in. diameter and 1½in.. wide, with field magnet of 1in. × ½in. wrought-iron, 2in. long in each leg, and 2in. space between the poles. You can use No. 20 cotton-covered wire, about 5oz. or 6oz. each for field magnet and armature; gear on to the driving-wheel by a small pinion.—J. Sutcliffe.

[47349.]—**Dry-plate Queries.**—The facts are as you state; but why they are so I really do not know, and do not think anyone can tell you. In order to explain the matter, one must understand what changes take place in gelatine emulsion during the process of cooking; but so far as I am aware no satisfactory explanation has ever been given.—W. Robinson, Jun.

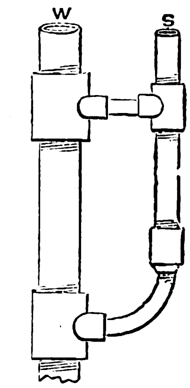
[47354.]—**Green Stains for Deal and Other White Woods.**—Acetic acid and copper filings. Turpentine and copper filings is another.—Jack of All Trades.

[47351.]—**Mathematical.**—I wish to contend that the assumption I made in my reply to query 47351 was not only legitimate, but true. As a case, take $(1 + x\ x^2)^3$. This equals $(1 - x^3)^3 (1 - x)^{-3}$, which equals $(1 - 3x^3 + 3x^6 - x^9)(1 + 3x + 6x^2 +$, &c). By multiplying each term of the first factor into each of the infinite number in the second, it will be found that all the terms involving powers of x higher than the sixth, destroy one another, leaving $(1 + 3x + 6x^2 + 7x^3 + 6x^4 + 3x^5 + x^6)$. This is the value of $(1 + x + x^2)^3$. "Hemisus'" reply shows that he has not considered the point very fully, or else I am sure he would have omitted the last five lines of his remarks.—An Engineer's Son, Sheffield, July 21st.

[47382.]—**Engine Query.**—For a condensing engine running at a speed of 264ft. per minute, with the boiler pressure at 75lb., I should give 1-16in. lead. To work with economy, the steam should be cut off at 1-10th of the stroke, or 4·8in. from the commencement of the stroke. Theoretically the terminal pressure should be 9lb.; in practice we should not have more than 4lb., the other 5lb. I should expect to lose from radiation and condensation. I am no advocate for expanding steam to 10 volumes, in particular when there is great variation in the load. Under such circumstances I should not expect to find steady running, however sensitive the governor might be. Calculations for the above given in full, if required.—J. Broadley, Bradford.

[47393.]—**Cocoanut Oil.**—If "Singapore" will send us an address, we can either suggest a very profitable manufacture, or introduce him to some City firm with whom he can open up communication with the same end in view.—Wynn and Co., 75, St. Peter-street, Islington, N., London.

[47399.]—**Condensing Exhaust Steam.**—For perfect condensation you would require 12 gallons per minute, which would be impracticable if water is so expensive as you say. There is a simple form of condenser that I have found useful, made of ordinary steam-pipe connections. S represents the exhaust steam-pipe in the figure, and W the water-pipe from tank. I don't think, however, that the return pipe to tank will reduce the back-pressure much, though it would heat the water for feed purposes. With a good supply of water the condenser will give a slight vacuum, sometimes 6in., and you may regulate your water supply in W to the extent of saving fuel by reducing back-pressure and heating feed-water, and not miss the expense of the water. Any water used for condensation will get too hot for second use, by reason of its obstructing the heat from the exhaust steam.—Fred. Walker.



[47400.]—**Electric Light for Workshop.**—If "P." would state how many gas-burners he has in his workshop, I should then be able to tell him exactly how many incandescent lamps he would require. If he has 15 ordinary gas-burners, he would require 15 incandescent lights. Those of the "Lane-Fox" type cost 7s. 6d. each, and if of 20-candle power, would require a "Brush" machine costing about £40. Of course, the capital outlay (about £300), would be rather great; but then, the many advantages which would accrue from the use of the electric light would soon reduce this to a minimum. I shall be glad to hear further from "P."—John Bull.

[47405.]—**Locomotive.**—As a practical boiler-maker, with eight years' experience as boiler inspector, I trust I shall be allowed space to give my opinion on the cause of wasting of plate at stay-holes as stated by "Hombre," who asks if there is a galvanic action formed between iron plates and copper stays. It is my opinion that the wasting of material is due to a mechanical action of the plates or the movements of the plates (bellows fashion) caused by expansion due to temperature and internal pressure tending to bulge out the plates which are rigidly held by screwed stays; this constant movement with every variation of temperature or pressure having a tendency to separate the atoms of the material in numerous very small fractures near all rigid bearings; these small fractures are filled with water or sediment, and on contraction of material so many very minute particles are wedged off, as it were, and thus an appearance of general wasting. This wasting, as described, is found more or less in all fireboxes, whether of iron with copper stays, iron and iron stays, copper and copper stays, or steel with iron or copper stays, sometimes on the outer casing of firebox or on the firebox itself, but always on the water side of the plate. When stays are of a large area and widely pitched, it is generally more severe than when light stays are used closely pitched; but this does not follow in all cases, as a strong firebox will sometimes cause wasting in the shell plate or casing, or a strong casing will set up wasting on the firebox whether of copper or iron. This wasting is best known among inspectors as "grooving" or "channelling," as it is generally local, and can clearly be traced to a mechanical action of the parts. It is found in all boilers more or less; in the locomotive it is found near the stays, as stated by "Hombre," and generally in the root of all the flanges forming the vertical corners of the firebox outer casing, particularly at the shoulders near where the firebox outer casing is secured to the barrel; here it is sometimes seen in a long groove ⅛in. wide, and from 1-32in. to ¼in. deep, and sometimes actually through, while in other cases (apparently under the same working conditions) it is found in the form of a fracture as fine as a line, scarcely visible when at rest, cold, as the fracture then closes. Perhaps "Hombre" had better look carefully for any traces of this grooving, for an outer casing with grooving in roots of flanges would not be worth even a new tube plate, as a new tube plate would have a tendency to excite such grooving, and cause it to set in more active than before. As a case in point, I may say a new fire-box was put in (against my advice) an old casing, and before it had been at work six months, the grooving came through at left shoulder, and in three months later, at the right shoulder. I did not see the casing with fire-box out; but surely the boiler-maker would not overlook it. Grooving is also often found on the plate along the edge or corner formed by the foundation ring when of the solid square section, particularly when the fire-bar level is low, or near the ring, which shows the advisability of keeping fire-bar level well up, clear of rigid joints or seams. In stationary boilers the grooving is very often found on end plates over furnace angle-iron rings, particularly when gusset stays are not properly applied; but in all cases "grooving" or "channelling" can clearly be traced to a mechanical action. Corrosion on boiler-plates is always understood to mean the defect due to impurities in the water, such as acids in different forms. It is therefore a chemical action. "Hombre" says the wasting is at taper holes, where stays pass through. Stay-holes should all be parallel, and the best means of putting in new stays will be to rimer out all the holes until a good thread can be had, and a larger stay applied. Has "Hombre" never seen a new tube plate put in without taking out the fire-box?—as I have; and I think it would come cheaper, if a good set of "loco." men were at it. Shall be glad to give further advice if necessary.—Boswell.

[47410.]—**Dry-Plate Intensifier.**—No change takes place in mercuric chloride on the addition of ammonia or other chloride, such salts being merely added to increase the solubility of the mercuric chloride. The addition of a soluble bromide or iodide changes the mercuric-chloride into bromide or iodide, as the case may be; but I am not aware of any special advantage in so doing. Whenever, in working with the wet collodion process, I had to resort to mercury, I always found a solution of chloride, followed by ammonia, hypo., or cyanide, to answer every purpose. With regard to the gelatine process, however, all attempts to intensify in that way have, in my hands, proved so unsatisfactory that should any negative be deficient in density I always prefer to take a fresh one, though I do not remember trying the particular process referred to.—W. Robinson, Jun.

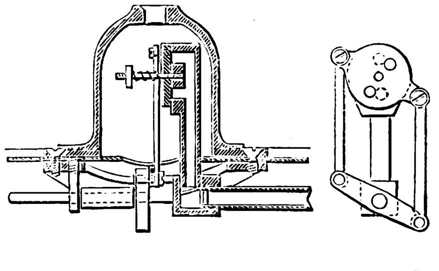
[47414.]—**Substitute for Leather Disc.**—Nothing like leather if managed properly. The fault lay in the shape of wheel and application of leather. Have no idea how applied, shape, for what purpose, &c., &c., and, therefore cannot advise. Are they both coned as bevel-wheels, or one. the driver, iron grooved, and driver leather or V?—Jack of All Trades.

[47415.]—**Organ Stop.**—If "L. G." will follow these few instructions carefully, I think he will have a fair quality of tone—no chiffing or quivering from his Clarabella stop:—1st. Lay all the pipes in their order—largest at left hand; then cut all the mouths open ¼in., nice and equal straight across, and the lips not too thin. 2nd. Cut the ears nearly level with the block (say, for mid C 1-16th of an inch, and top G 1-32in.); have them also equal from largest to smallest, and see that the caps fit square up to the ears, so as not to cause a hissing. 3rd. Nick them nice with a nicking-tool not too deep, and equal distances—say, mid. C 12 or 14 teeth to the inch, and gradually smaller to the top; then smooth the face of block with a smooth file, or a piece of fine sand-paper glued on a piece of wood, so as to leave no pieces of the grain for the wind to cut against; it is quite immaterial straight or cross-nicked. 4th. File away the cap at the thin edge for the wind to cut the lip—about 1-12th of an inch at C; also graduate to the top, but do not nick the cap at all, as that leaves the tone more crisp and pleasant (the caps want to be hollowed out and smooth). Now, one great fault with amateurs is that they want to do too much at once, and they spoil all by trying first one pipe, then another, with the mouth. Let me tell any one voicing wood-pipes: Don't blow them, as your breath swells up the wood, lessens the openings in the caps, and stops them speaking; but if they would only be patient, and try them on their own wind, they would find their labours rewarded with better success. P.S.—If "L. G." does not succeed, and he will advertise his address in the "Address Column," we will voice him one or two pipes, and send them back to him.—H. and S. B.

[47419.]—**Riveting China, &c.**—Should you not receive a satisfactory reply to your query, I will shortly give you such information, with sketches of tools, &c., as I can impart. I have never done such work; but have had frequent opportunities of seeing it done. For the reason given in my reply to 47470, I cannot do so just yet. —Alfojoe.

[47430.]—**Instantaneous Photography.**—The first defect referred to may be owing to your trying to cover too large a plate; to the lens not being well adapted for the purpose; or to a bad arrangement of shutter, which may possibly cut off some of the rays which should enter the camera. The second defect may probably be remedied by a little more care in development. Use a full dose of pyro. and bromide, but add the ammonia cautiously one or two drops at a time, and allow more time for it to act. At the same time, and if, as I presume, you want the cloud-negatives for printing in the skies of other negatives, you do not require any very great density, as the clouds should only be printed in very lightly. Choose a fine day with floating clouds, rather than one in which the sky is completely overcast.—W. Robinson, Jun.

[47432.]—**Locomotive Boiler.**—I don't know whether coppersmiths as a class understand model locomotive boiler-making, but before giving such a job to one I should make inquiries as to his ability. The starting-valve or regulator is sometimes put in the smoke-box, so that it can be easily got at, and generally consists of an ordinary plug-tap; but in a model I am making I have used a butterfly-valve, which is more easily made and less likely to get out of order. It is placed at the top of the supply-pipe in the dome, which latter I shall screw to the boiler so as to have access to the regulator. Cylinder 1¼in. long (but I suppose you mean 1¼in. stroke), if not more than 1in. bore, would hardly be large enough for a boiler 19in. long and 5in. diam.; they ought to be 1¼in. bore and 2in. stroke. If the engine is to be a coupled one, the driving and coupled-wheels should be about 6in. diam.; and if a single engine, then about 7in. diam. The inside firebox should be about 6in. long, 4in. broad, and 6in. deep; the boiler should have 22 tubes, ⅝in. diam. and 12½in. long, which, with the length of firebox and water space at back, would make up the 19in. I inclose sketch of the valve and method of fixing dome to boiler. If you should require any more information, I shall be glad to do what I can to help you.



Explanation of the Sketches.—The dome should have cast or soldered on an extra wide flange to hold the screws for fixing down; the lagging plates should be made to fit over this flange, close up to the curved flange of dome; a brass ring is riveted to the inside of boiler, to strengthen it and take the screws which hold down the dome. The valve and valve-face of the regulator should be ground perfectly flat. A small spring will keep it close until the steam is up; the dotted holes lead into steam-pipe, and the holes in valve are brought opposite by a slight turn of the handle at the other end of the spindle.—E. L. P.

[47433.]—**Portland Cement Floors.**—I must strongly advise "Melting Mechanic" not to adopt the plan suggested by "M.I.C.E."—viz., to put on the coarse bottom a ⅜ finish of one part cement and two parts sand, and then rubbing on the surface of this dry cement. It certainly makes a good finish when done, but is sure to scale off in time. I had two garden walks done last summer, one according to "M.I.C.E.'s" method, and the other as described by me. The former has now large patches of bare places where the cement has broken off; the latter is as good as the day it was finished. "M.I.C.E." suggests gravel, which might do, but must be well washed to remove all clayey matter; but is then not so good as broken stones or brick-bats, as the irregular surfaces of the latter bind together more firmly. The cost will vary according to price of labour, and whether the hard material is on the ground, or has to be bought. I think mine, buying everything, cost about 3s. a square yard 3in. thick.—E. H. Roe.

[47437.]—**Threads for Steam-Pipes.**—The Whitworth standard for gas threads, which is generally used for this purpose, is 11 threads per inch for sizes between 1in. and 3in.—T. W. Fillmore, Wimbledon.

[47441.]—**Minute Photography.**—I of course do not know for certain, but should suppose that ordinary photo. lenses of short focus and good defining power, would be used both for the reduction and subsequent enlargement of the despatches referred to; and for collodion, that which gave the most structureless film would naturally be selected by preference. Ordinary micro lenses, not being photographically achromatic, will not define properly unless allowance be made for the difference between the visual and actinic foci.—W. Robinson, Jun.

[47443.]—**Medical Coil.**—The dimensions given are quite correct, but 3in. means total height of bobbin, not between flanges. I have nine helices or layers, consequently three powers with the given quantity of wire; but you can make each separate helix a power, if you choose, by connecting the top and bottom of each one alternately to a corresponding pin in your power circle. I find three powers vary the strength sufficient for ordinary medical purposes, and the coil itself a useful and compact instrument. I have a couple of Daniell's cells connected to it, the cells standing in a cupboard, the wire coming to the coil through the skirting. Thus, standing upon the sideboard, it is always ready for use by screwing the contact breaker down, and forms an ornamental and useful adjunct to the sitting-room. I charge the cells once a week.—Fred. Walker.

[47444.]—**Boiler Corrosion.**—Does "E. M." mean to ask for a means of preventing "incrustation" or "corrosion"?—as from his query he speaks of corrosion, and appears to mean incrustation, which seems to be lime, which is very probable if well-water is used. By incrustation is meant the deposit on the boiler-plates, which, if lime as carbonate, is removable to some extent by the "Clark" process, so recently described in "ours," or by passing the water along a finely-perforated trough, and allowing it to fall in a great number of very fine streams, allowing the excess of carbonic acid gas to escape, and so precipitate the carbonate of lime; but even this will not thoroughly purify it. A little common soda used in solution daily (say, 1lb. a day) with the feed-water, will have a tendency to soften the incrust already formed, and keep new deposit from forming so hard; but constant careful cleaning is the best remedy. If "E. M." means "corrosion," wasting of plates (generally in fittings), due to the chemical impurities of the water, such as acids, the best plan is to get the water analysed, and so find out the best agent to neutralise the acids or other impurities which cause the corrosion. If corrosion is meant, a filter will be of little use. As a rule (with its exceptions, of course), where there is much deposit, there is little corrosion; and where there is much corrosion, there is little deposit, except what is loose and quite easy to remove, as incrust cannot firmly adhere to a plate which is constantly wasting at its surface, and the corrosive agents will not, as a rule, eat their way through a coating of hard deposit, particularly if of lime, from which it will be seen that a thin coating of incrust (say, 1-16in. of lime deposit) is a protection rather than otherwise.—Boswell.

[47446.]—**Photographic Enlarging.**—Formerly, enlargements were generally made on iodised paper, and developed with either gallic acid or pyro; but latterly, gelatino-bromide paper, developed with ferrous oxalate, has been largely used.—W. Robinson, Jun.

[47447.]—**Redipping Brasswork.**—Rub the articles with muriatic acid on a piece of soft rag.—T. W. Fillmore, Wimbledon.

[47447.]—**Repolishing or Re-dipping Sheet Brass for Labels on Tinwork.**—Dip them in aquafortis and into clean water, into which put a little soda; wash in clean water and dry in clean sawdust. This is best done when cut up into the sizes required.—Jack of All Trades.

[47449.]—**Induction Coils.**—What I meant by short-circuiting the cell is, that the two layers of 16 do not offer sufficient resistance to the cell; a bichromate would polarise in less than ten minutes. I have never read in any work what resistance a coil should be to obtain the full effects of a cell without polarising. I always make the primary just four times what you state the resistance yours is. If there is not sufficient resistance, the addition of more cells will not increase the effects; it is like adding cells to the quantity coil on a galvanometer. Stronger the coil is magnetised, the greater the spark. Why don't you wind two layers on large electromagnets? I made a coil the other day five layers primary, resistance 1 ohm; shock from this alone I could not bear, and with ten layers of secondary, not one-fourth the strength could I endure; this coil would go in the waistcoat-pocket. Further information if required.—George Tolman.

[47452.]—**Pleurisy.**—The safest remedy that can be applied to relieve and cure pleurisy is olive oil and turpentine. Put the oil and turpentine in a bottle, and pour the mixture on a piece of flannel large enough to cover the place that feels sore. A bandage or tape can be used to fasten it in its place. The proportion is six of oil to one of turpentine, by measure. It will relieve the pain immediately on application. It may take as long as four days before the inflammation is brought to the surface.—F. Norman Campbell.

[47454.]—**Bleaching Old Willow Baskets.**—These may be readily bleached by washing them and immersing in a solution of chloride of lime, rinsing afterwards through water, made acid to the taste by the addition of a little oil of vitriol. Or, if the querist has an air-tight chamber he can readily bleach his baskets by subjecting them to the influence of vapour from burning sulphur.—Nun. Dor.

[47459.]—**Silvering Looking-Glasses**—I can assure "C. H." (p. 460) that Brashear's silvering process is quite suitable, if not too expensive. A 6in. mirror costs for silvering from 6d. to 1s., according to price you pay for chemicals; but these must be pure and best quality. For method of application see Nos. 794 and 863, and Vol. XXXIV. generally; but "C. H." should have stated sizes of plates. If "C. H." requires it, I could put him in the way of buying the chemicals in fair quantities at wholesale prices, if he advertises his address.—J. C. L.

[47460.]—**Weight of Dynamite**.—The explosive effect of nitro-glycerine is given as equal to ten times its weight of powder. How far this holds for dynamite, of which 75 per cent. is nitro-glycerine, I am not prepared to say.—Ll.B.A.

[47461.]—**Black Transfer Paper.**—Get some unglazed paper, and rub it well with a paste made of gas black or black from a paraffin lamp and olive oil with a piece of sponge.—Jack of All Trades.

[47461.]—**Black Transfer-Paper.**—"J. C.," Pera, does not state for what purpose he requires the transfer-paper; if it be for the purpose of transferring plans on tracing-paper to drawing-paper, let him take a clean smooth sheet of tissue-paper, perfectly free from cracks or wrinkles, and sprinkle it with black-lead out of a packet of the "Servant's Friend," then rub in the lead with a pad made up of clean dry flannel until he gets a uniform surface, both as regards colour and quantity of lead. Lines made with this paper on drawing-paper can be easily removed with indiarubber after the drawing has been inked in.—Epura.

[47463.]—**Change-Wheels for Screw-Cutting.**—"Try Again" should get a book called "The Engineer's, Millwright's, and Machinist's Practical Assistant," by William Templeton, published by Crosby Lockwood and Co., in which he will find, among many other things, what he desires. Engineers generally have a table for the same.—T. W. Fillmore, Wimbledon.

[47464.]—**Wood Shrinking.**—Wood will shrink $\frac{1}{4}$in. in diameter,—i.e., soft woods have a cast-iron die, bell-mouthed; turn them $\frac{1}{4}$in. larger than required, and force them through, the one pushing the other out.—Jack of All Trades.

[47465.]—**Faded Daguerreotype.**—Cyanide of potassium (which can be obtained at any photographic establishment) will restore faded dagurreotypes. Make up a solution of about 6gr. to the oz. of water. Hold the plate, in the left hand, by one corner, and pour the solution over it. Keep it on till it has done its work; then drain off, and wash well under the tap. I was told this some years ago by a professional acquaintance, but have not tried it myself. If you prefer, you can get it done by any respectable photographer. I should advise the latter.—Camera.

[47465.]—**Faded Daguerreotype.**—According to Mr. England, a "faded" daguerreotype is a thing unknown; but the tarnish which causes the faded appearance can be removed as follows:—Pour on its surface a sufficient quantity of good alcohol (not methylated) to well cover the plate, and allow it to remain a couple of minutes to remove any grease; rinse well with plenty of water, and then immerse in a solution of cyanide of potassium 1oz., water 1 pint. It must now be closely watched, and the moment the tarnished film disappears, and the surface becomes bright, remove the picture, and place it in clean water, to stop the action of the cyanide. It can now be held at one corner by a pair of pliers, and copiously washed with distilled water, and a gentle heat applied by a spirit-lamp at the back, blowing gently with the breath on the face, without ceasing, till the last drop of water has reached the bottom corner. Any check in the drying will cause a line, and in such case the plate must be re-wetted, and another attempt made.—W. Robinson, Jun.

[47467.]—**Observatory on House.**—Americans travel a good deal, and if "American" could travel here before August 1 or after November 1 I should be happy to show him my observatory. Nothing can be structurally more convenient or successful. It is 50ft. above the ground and substantially free from injurious tremors. The pier is built on two iron girders, bolted together and bedded on felt and lead in recesses in opposite walls, the girders being clear of the brickwork in all respects, except where they lie by their own weight on their beds.—G. F. Chambers, Northfield Grange, Eastbourne, Sussex.

[47469.]—**Galvanising.**—You can use either lead-lined cisterns or stoneware. Pickle the articles in sulphuric acid 2 parts, hydrochloric acid 1 part, to 5 or 6 parts of water, and well scratch-brush with wire and sand. There is a good deal of difference in the quality of iron; some clean very readily in a weaker solution, as 10 parts of water. A piece of Malacca cane, hammered at the end, for a brush is very handy for cleaning with sand where you cannot get the outer shell of cocoanuts. When well-cleansed and dry, dip them into some killed acid and dredge with powdered sal-ammoniac, and put into a bath of molten zinc. Stoneware will stand fire to a certain extent, because it has stood fire before; but from the moisture it has absorbed from the atmosphere, which it will not very readily part with, the heat wants applying very cautiously.—Jack of All Trades.

[47470-1.]—**Watch Repairing.**—I regret that I am unable to give more than a very brief reply to "X. Y. Z.," owing to heavy demands upon my time just now. The desired information may possibly be given more fully by other correspondents. To hold or place the cylinder in position for inserting the plug, take an old watch-barrel, of good depth and size, a verge preferably, and (if it has a *bushing* in remove it) bring up the bottom part of the cylinder through the hole, letting the barrel rest upon the bench, and the cylinder-notch rest upon the barrel-bottom. This will form a convenient stake to drive the plug home upon. A small hollow punch is required to do the job. Certainly you could get a plug to fit if you purchase a gross of them in assorted sizes. You must be very careful in driving-in that the plug is not too large, or you will split the cylinder; it should be accommodated with very little force. The body of the cylinder must be made rigid with beeswax or shellac while turning the pivot up. You will not succeed in fitting jewels unless you have special tools. Such appliances are generally used in conjunction with the mandrel, which is rather an expensive tool. In any case jewel-holes require very accurate fitting, as, unlike brass holes, the depths, when once struck and drilled, cannot be altered. A countersink is formed in the plates or bars, by appropriately-formed cutters, into which the jewels, closely fitted, are placed. The edge of the metal is then turned over by a special-shaped burnisher, and the job is complete. Minute and hour-wheels may be bought finished, or in the rough, as may be desired. In some cases the socket and the wheel are formed from one piece; but by no means is it the rule.—Alfojoe.

[47475.]—**Sidereal Indicator.**—If "D. Mc." (page 461) means "sidereal *time* indicator," he will find engraving and description on page 116 of Vol. XVI. It is too long to quote here, but I will lend him my copy for a week if he advertises his address.—J. C. L.

[47477.]—**Waves.**—Chap. IV. of Rankine's "Civil Engineering" will give you some information on this subject in a condensed form. For further information you are referred to Airy's treatise on "Tides and Tidal Waves" in the "Encyclopædia Metropolitana." Haughton's little manual on tides might help you.—C. H. Romanes.

[47479.]—**Legal.**—The executors having renounced their right to prove the will and given up their legacies, and the widow having taken upon herself the administration of the estate, she is bound to divide the net assets, after the payment of debts and duties, in the proportions indicated in the will; or, if the bequests to the widow and the children are of specific sums, and the assets are insufficient to pay them in full, each legacy must be proportionally abated. The executors, of course, take nothing. The widow is only absolutely entitled to her own legacy or proportion, and the son can claim his legacy, subject to abatement, having attained 21; he could only be sole heir if there were an intestacy, and the property were real estate.—G. J. M.

[47481.]—**Colouring Gold Jewellery.**—Jewellery to be coloured should be at least 15 carats fine, and the solder should be only a shade under that. There must be no pewter or silver solder on it. It should just be annealed, and pickled in water to which sufficient sulphuric acid has been added to render it sharply acid to the taste. The best vessel to use for colouring is an ordinary clay crucible, and the colouring mixture I use is composed of 2 parts best saltpetre, 1 part of alum, and 1 of common salt. These are placed in the crucible with sufficient water to moisten them, and when they are melted, place the gold articles in the mixture. The jewellery must be strung on a piece of wire; it is better to keep a piece of platinum wire for this purpose, which should be annealed each time before use; failing that, a piece of gold wire (15 carat). You may use silver wire, but nothing baser. The colouring composition dissolves the silver, so you will require a fresh piece occasionally. You must move them about occasionally in the crucible, and as the composition gets thick, add a very little hot water from time to time. It must not be made too thin, but just sufficiently liquid to boil. The goods require to be in almost continual motion, or they will stick to the bottom of the crucible. Should this untoward (and, in the hands of a novice, far from unlikely) event happen, don't attempt to pull them out by force, but boil them out with hot water. After they have been in the crucible for a few minutes, take them out and examine them; but whenever they are taken out they must be plunged at once into boiling water, or the composition will dry on them, and you will have some difficulty in removing it. They should now be scratch-brushed and returned to the crucible From 10 to 20 minutes will be sufficient. When they are coloured, take them out, scratch-brush, wash in clean hot water, and dry in boxwood sawdust. For method of scratch-brushing see my papers on electro-plating in, I think, last volume. This process acts by dissolving away the alloy, and leaving only the pure gold on the surface. If the goods are anything less than 15-carat gold, they must be electro-gilt. I must take this opportunity of saying that I cannot answer any more questions through the post, as on the last occasion of my doing so I became involved in correspondence extending over many months. This included matter which would have been instructive and interesting to "E. M." readers, and it occupies time which I can ill afford for the benefit of one correspondent only.—Os.

[47485.]—**Legal.**—The nephews and nieces all "succeed at one and the same time, and from the same source," namely, on the death of the testator, the court deciding apparently that the leaseholds did not pass under his will. The fact that the property is not sold at the same time does not affect the case, each nephew and niece is entitled to an equal share of the whole, and in the case of the married nieces, if that share is of greater value than £200, it must go to their trustees under the covenant in the settlements.—G. J. M.

[47493.]—**Velocity of the Wind.**—The note in question states that on April 29 a pressure of $49\frac{1}{2}$lb. was recorded at a time when the hourly velocity was 50 miles. That is very different to saying that the pressure of the wind at 50 miles an hour is $49\frac{1}{2}$lb. The fact is mentioned as an exception, and was probably due to one of those sudden gusts, the cause of which is unknown.—F. M. S.

[47495.]—**Gun-Barrels.**—When brown enough to please, wash off well with carbonate of soda and hot water and then with clean; afterwards polish with a piece of black cloth and equal parts of raw linseed oil and turps, in which a piece of camphor is dissolved, or lacquer with plate laquer. I prefer the oil.—Jack of All Trades.

Whitworth Scholarships, 1882.—The following are the successful competitors in the order of merit:—£200: Charles Webster, Crewe. £150: J. H. Tomlinson, Newcastle-on-Tyne; J. H. Beaman, Woolwich; Thomas Turner, Sheffield; S. D. Codrington, Bristol; C. B. Outon, Stratford; G. H. Bannister, Woolwich; Frederick Lane, Woolwich; W. D. Laird, Woolwich. £100: Joseph Parry, Manchester; A. F. Ravenshear, London; C. W. Carter, Liverpool; A. Barrow, London; H. C. King, Swindon; M. Douglas, Crewe; Thomas H. Gardner, Manchester; E. E. Haine, London; George Halliday, Glasgow; G. W. Buckwell, Brighton; L. H. Cochrane, Liverpool; W. Duncanson, Stratford; H. Brown, Dudley; W. T. Hatch, Liverpool; T. Carlyle, Woolwich; A. J. Hill, Stratford.

The FitzGerald incandescent lamp has been exhibited as a street lamp in Westminster Bridge-road by the Phœnix Electric Light Company.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[47497.]—**Perspiring and Tender Feet.**—To Dr. Edmunds.—From childhood to middle-age, I have been a constant sufferer from perspiring feet, with attendant soreness and annoyance. In addition to this, for a year or two I have had soreness and tenderness of the soles of the feet of a different kind, mostly felt when awaking in the morning, and which, I am told, proceeds from the liver. Will Dr. Edmunds kindly favour with his advice, and oblige?—Rural.

[47498.]—**Indigestion.**—To Dr. Edmunds.—I watch with keen interest the answers to medical inquiries, hoping to meet with some that would prove valuable to myself. I suffer from what the doctors say is indigestion and sluggish liver. My attack commenced five years since, and after much suffering I tried homœopathy without success, and also allopathy with some relief, but not permanent. I led such a wretched life, that I would willingly have given up food altogether, were it possible. I gave up butchers' meat, which I have not touched for 3½ years, and I have lived during this period in such a way that many of your readers would think life under such circumstances not worth having. Here is my daily diet (each week being a repetition of the last): breakfast—dry bread and tea; dinner—crushed groats (cooked in water and salt) only; tea—same as breakfast; supper—lentils only (cooked same as the groats); this, with a fish dinner on Sunday (eaten with fear), is how I live, which I would not mind were it a perfect cure. My symptoms are: after food, a kind of heat in the spine, more especially that part opposite the stomach, and with it shortness of breath and great weakness, and altogether poorly. When I first commenced, I had an oppressive weight on my shoulders, which, at the present, I experience but slightly. About two hours or so after meals, I begin to feel a little better, until the pain is brought on again by the next meal. I do not feel any pain at the stomach. My work is neither laborious nor sedentary. With my present knowledge, I find a cold sponge bath my best friend, which I take in the morning. Were it not for its benefit, I do not know what I should do. My life has been remarkably temperate: so I have nothing to reproach myself with. I would indulge in half a pint of beer or porter with my supper, but cannot, because of the above consequences, and I dread anything with alcohol in it.—Indigestion.

[47499.]—**Model Electric Railway.**—Will some reader of "ours" kindly give me information and diagrams for making the above, and oblige?—A Subscriber.

[47500.]—**Bichromate Battery.**—To "Beetle-Crushers."—With reference to your bichromate battery (letter 20240), would you kindly say how often the battery would have to be taken to pieces and cleaned? Also, how many plates of zinc and carbon are necessary? And please explain how the wires would be attached to the wires of a small electric lamp?—Semper Fidelis.

[47501.]—**Clock - Wheel Cutting Engine.**—Would any of your kind contributors skilled in watch and clockwork favour us with a drawing and description of a clock-wheel cutting engine with straight cutter—not a circular one, as I want to finish one tooth at one cut, without having to file up afterwards? A circular cutter will not do that properly.—Ten Years' Subscriber.

[47502.]—**Transparent Photographs.**—I have been trying, with but indifferent success, to make those beautiful transparent photos resembling coloured ivories which have recently been introduced. They are rendered transparent, coloured from the back, and mounted on concave glasses. A professional wants 5gs. for the "secret," which I cannot afford. Can any one with practical knowledge tell me of what ingredients to make the transparent varnish, and how to attach the picture to the glass, so as to exclude air-bells, and avoid injuring the transparency? I manage the colouring nicely.—Beenhorn.

[47503.]—**Intestate.** — To Mr. Wetherfield.—I should be very much obliged if you would give me your advice as to the following:—My father and mother both died without leaving any will—leaving only household furniture, &c. I have four brothers and two sisters: my eldest brother was married before their death, and living away from them. My two other brothers, who are unmarried, my sisters, and I, live in the house in which our parents lived, and which we have carried on since. Can the one who is married claim any of the furniture, &c., or can my elder brother claim it all, seeing that the house is in his name, and has been since July 1876—or how? Also, what proportion each is entitled to?—S. Swindells, Manchester.

[47504.]—**Bottling-Wax.**—Could any reader oblige with a recipe for making above? Also, the proper proportions of ingredients and their treatment—how melted, and in what sort of vessel? I have tried sulphate of baryta, rosin and oil, but they have not the desired effect, as the wax remains sticky and liable to bend. This is, of course, for a cheap quality, which sells at about £1 per cwt. or less.—J. B. H.

[47505.]—**Hot-Air Engine.**—Would any reader give working drawings of a model engine to be worked by hot-air? I want one to work a blowpipe?—Albert Smith.

[47506.]—**Cement for Knives in Handles.**—Wanted a good recipe for a cement for fastening table-knives which have come out of their handles?—Mater.

[47507.]—**Sulphate of Potash.**—To Mr. Allen.—I wish to know the quickest way of determining the per cent. of sulphate of potash, and the per cent. of soda salts in some commercial sulphate of potash, and shall be glad of your advice. I have tried a sample by adding HCl and BaCl$_2$; boil and filter, neutralise filtrate, add lime-water, boil, filter, add AmHO, Am$_2$CO$_3$, AmOx; boil and filter, evap. to a small bulk, add excess HNO$_3$; evap. to dryness; dissolve and filter, evap. twice to dryness with HCl. Dissolve in water, transfer to a pt. dish, evap. to dryness, then weigh the mixed chlorides; then separate the potassium as K$_2$PtCl$_6$ by Teschemacher and Smith's plan (see Crooke's "Sel. Methods," pp. 1 and 2). This mode of procedure, it seems to me, is liable to error on account of the large amount of filtering and manipulation. Could not many of the above reagents be added in succession, and so make one filtration serve for a number of precipitates?—thus saving time and probable errors. Any information as to the best mode of proceedure for sulphate of potash will be gratefully esteemed by—A Young Works Chemist.

[47508.]—**Weight of Girder.**—I have to thank "Ditton" for the answer to above, and can see I have put my query wrongly. What I want is, to experiment with a box girder of the ordinary shape, and one of another shape. In view of the expense, it must be a model. I therefore wanted some idea of the proportion of one to carry a given weight, so as to have some data to compare the one of a different shape with. Could I make one of stout tin-plate soldered? If so, could you give me dimensions for one? Should feel obliged for any information.—E. P.

[47509.]—**The Modern Harp.**—Will any one of the numerous contributors to the "E.M." on musical instrument construction kindly give some information as to the above, or refer me to the back Vol. or Vols. in which I can find full particulars if ever before published in the "E. M."? I have not got earlier Vols. than XVIII., and in looking through the indexes cannot see what I want—viz., a full detailed description of the modern double-action instrument (with measurements), and is it an instrument that an amateur (who has built an organ) is likely to be able to manufacture?—R. Cecil Clifton, Perth West, Australia.

[47510.]—**Cistern.**—I want to save all the rain falling on the roof of a house in South Devon, the walls of which measure horizontally 70ft. × 23ft. What should be the capacity of a cistern in cubic feet to receive the same, supposing the quantity of water drawn off from it daily was 1/365th part of the total quantity of rain falling throughout the whole year?—J. W. B.

[47511.]—**Coffer-Dam.**—I wish to make a coffer-dam about 30ft. long, to keep out 4ft. deep of running water. Will some practical man kindly advise me the best way? I only want it to remain about a month.—Quod Dixi Dixi.

[47512.]—**To Mr. Lancaster.**—Thanks for your information concerning the Grenet cells the other week. Will you tell me the difference between Grenet and Leclanché batteries? I was under the impression that mine were Leclanché, although the word Grenet was on the outer glass cell. Will you also tell me why the canvas bags are used instead of porous pots, and if the Grenet are equally suitable for bells as the Leclanché?—J. W. B.

[47513.]—**Water-Filter.**—Will some reader kindly instruct me how to make a charcoal filter capable of filtering one thousand gallons of water an hour?—the matter to be removed being chiefly precipitated lime and iron. The filter ought to be made so that it can be easily cleaned and the charcoal renewed when necessary. Full instructions will be much valued.—Engineer.

[47514.]—**Tennis-Balls.**—Can any of your correspondents tell me any means whereby tennis-balls which have been slightly broken can be mended?—O.

[47515.]—**Dry Collodion.**—Will Mr. Lancaster, or some other correspondent, kindly give me directions for making dry collodion plates (not emulsion)?—Camera.

[47516.]—**Splitting Stone.**—Can any of "ours" give me any information about a mode of splitting stone by laying a line of some explosive on the unbed for line of division, and firing it? I have read or heard of some such process being successfully used, and am anxious for information, as it seems to me it would be a great advance on our present method with wedges, which, though effective, is tedious, and costs a deal in labour to "pick" out the crannies for the row of wedges. What explosive should be used, and what thickness will it split? Also, can it be relied on to produce a straight break vertically?—Treadle.

[47517.]—**Pumping Engine.**—I have a force-pump ½in. bore, 1½in. stroke, and I wish it to work by a steam-engine at about 1 stroke per second. The supply-pipe is 2ft. in length, and the pipe up through which water is forced is 6ft. in length. The inside measurement of both pipes is ½in. Would a double-action oscillating cylinder 1in. bore and 2in. stroke, having a vertical boiler 3½in. in dia., and 1ft. long, of ordinary thickness, with 4 inside tubes, drive the pump? Also, would an iron flywheel 8in. in dia., and weighing 2½lb., or thereabouts, be too heavy? Will the boiler keep up steam at a pressure of 15lb. to the sq. in.? The pump is not to be connected direct with the engine-shaft, but as it is—separate by a band. I can shorten the stroke of the pump.—Edmund Ashcroft.

[47518.]—**Balance-Wheel Cutting.**—Will "A Fellow-Workman" or "Alfojoe" be kind enough to give me an illustrated description of the balance-wheel cutting tool? Also, a few hints how to cut an escape-wheel?—T. F. A.

[47519.]—**Legal.**—To Mr. Wetherfield.—A husband some years ago made a will in favour of his wife as follows:—"I give devise and bequeath all my real and personal estate, whatsoever and wheresoever, and whether in possession, reversion, remainder, or expectancy, unto my wife (A. B.), for her sole and absolute use and benefit; and I appoint my said wife (A. B.) sole executrix, &c." The wife is doubtful if this secures to her freeholds acquired by the husband, subsequently to the making of the will, and a policy of assurance recently effected on his life. Will Mr. W. kindly say if the wife's fears are goundless, and whether the will is sufficiently comprehensive to secure to her property of every description to be left by the husband at death? They have no children.—Audior.

[47520.]—**Inspecting Weights and Measures.**—Can any reader give me any wrinkles useful to an inspector of weights and measures?—the tools required, manner of testing, &c.—X. Y. Z.

[47521.]—**Monochord.**—I am about making a first-class monochord, and will feel thankful for replies to the following:—Best kind of wood, length, width, and height of body, length between bridges, thickness of top, bottom, sides and ends, number and size of holes, and whether better in top or sides? Is it more convenient to have scale for length of strings marked on top, or to have a movable scale? Should it have legs of wood or metal, and if so, what height, and should they be fixed to body or not? Must the top have bearers fastened to underside for the purpose of strengthening it, and if so, how many? For how many wires should provision be made, and what distance should they be apart? Should the wires be stretched by a weight or screw? I think an article on the above, illustrated with a detailed drawing, would be acceptable to many other readers of ours besides—Phosphorus.

[47522.]—**Koenig's Adjustable Resonators.**—Will some reader of "ours" kindly give instructions for making these, and also reply to the following?—What are the tubes made of, thickness of the tubes, lengths and diameters of tubes, must the sliding tubes be a very good fit, what are the sizes of the holes in tubes?—Phosphorus.

[47523.]—**Cubical Revolving Mirror.**—What are the dimensions of each side—will common looking-glass do?—Phosphorus.

[47524.]—**Acetic Acid.**—Will some reader kindly give a table of strength of acetic acid with corresponding sp. grs., and also say what is the best method for estimating the amount of real acid in solutions of different strengths?—Phosphorous.

[47525.]—**Hay Barn.**—Would any kind contributor who knows give dimensions and instructions for the building of a hay barn, with a roof that can be lowered when the barn is empty—one of sufficient capacity to hold about 20 tons of hay, to be supported on wooden posts, and with either corrugated galvanised iron or wooden roof, and the probable cost?—Old Hay.

[47526.]—**Quickest Railway Run.**—Can any reader give further particulars of the train mentioned in the "E.M." of July 14, which ran from Leeds to London in three hours? Also, the number of the engine?—Experimenter.

[47527.]—**Microphone.**—Will some reader tell me if the following performance of my microphone is out of the common?—When it is placed on a small wooden loud-ticking clock, and connected with a Bell telephone, the sound can be heard anywhere in the room in which the telephone is placed.—Experimenter.

[47528.]—**Sowing "Con-Acre."**—What is the meaning of "sowing con-acre"? I see the expression in debates on Irish agricultural questions, &c. Will some Irish fellow-reader oblige?—Kappa.

[47529.]—**Electric Lamp.**—How is the carbon thread in an incandescent lamp guarded against accident by too much current? I have made a dynamo, but am afraid of volatilising or ruining the filament by too strong a current. Will some reader help me to guard against this?—H. W.

[47530.]—**Softening Hard Water.**—I have some water springing from limestone, having a total hardness of 82·15, or about four times as hard as New River water. What is the best means of softening it?—Dandie Dinmont.

[47531.]—**Ventilation.**—I wish to ventilate a chapel by means of a tube with burners inside in the roof, and air admitted by vertical tubes at the floor. How shall I proceed? What area should the tubes be, and where should they be placed? Size of building 80ft. × 40ft.—Dandie Dinmont.

[47532.]—**Coil.**—To Mr. F. Walker.—In the "E.M." of June 9th, p. 313, you gave instructions to make a medical coil. I want to make one with an 8in. magnet, ½in. thick, composed of fine iron wire. Should the bundle of iron wires be insulated from the copper wire, or should the wire be wound direct on the core? Also, would No. 16 gauge c.c. copper wire do for the same in the place of the No. 22 which you used? What quantity of wire should I require? Also, how thick should coil be when finished?—W. Wright.

[47533.]—**Secondary Batteries.**—To Mr. Lancaster.—Would it be advisable to use as a positive element a lead or copper box closed at the top, with small holes round sides, and filled with small pieces of lead, such as coarse raspings? Would hydrogen be absorbed, or would it adhere to such a box better than it would to a simple lead plate?—H. L. Donkin.

[47534.]—**Dutch-Rhenish Ry. Locomotives.**—Can Mr. Gobert, Mr. Clements, or other correspondent, give me sketches, with details, of the engines and tenders on this and other Dutch railways? There was a query in the "E. M." some weeks ago about S. American and other locomotives: does Mr. Gobert know anything of them?—E. E. R. Tratman.

[47535.]—**L.B. & S.C.Ry.**—Can "Carstairs," or other reader of the "E. M.," give me sketches of the two engines, Stephenson (single driver) and Belgravia (coupled), of the above line? I should be glad of details and sketches of the tenders? Who are the builders of the small engines which work the East London Ry.? They are the smallest I have ever seen on ordinary railways. What is their power?—E. E. R. TRATMAN.

[47536.]—**Legal.**—To MR. WETHERFIELD.—Is the accompanied form a legal acknowledgment of a debt due for rent? Does it require stamping, and if so, how much, and how soon after date?—

I, A. B., of No. ——————, promise to pay to Mr. C.D. £10 in ten monthly instalments of £1 each, the first instalment to be due and payable at No. ————, on the —— day of ————, 1882.—

(Signed) A. B.
—M. I. S.

[47537.]—**Musical Box.**—Can you tell me a good plan for repinning the barrel of a French musical box? Several pins in mine are bent down, and when I try to straighten them they break off, or else break off the next time they meet a tooth.—BROCKLEY.

[47538.]—**Lunar Measurements.**—Would "F.R.A.S." tell me the modus operandi of measuring the height of mountains in the moon?—A TEN YEARS' SUBSCRIBER.

[47539.]—**Wear of Brake-blocks.**—Could "North Star," or any other reader, tell me how long the blocks used by the Westinghouse Co. last when used on local trains; how long it takes to wear off the first 8th when used?—CONTINUOUS BRAKE.

[47540.]—**Measuring Flow of Water.**—I wish to know a simple arithmetical rule to find the number of gallons of water that will flow over a tumbling bay, say, 6in. wide, at various heights?—PITCH LINE.

[47541.]—**Coil.**—To MR. LANCASTER.—I have a medical coil which lately has given very indifferent results. I thought the fault was a short-circuiting of the secondary coil, so I unwound it and insulated each layer, but still very little, if any, improvement. The contact-breaker also seems to act all-right. By inserting a small condenser in the primary coil, would it give me a stronger induced current? If so, what would be the best way to make the condenser?—TELEGRAPHS.

[47542.]—**Insects.**—I inhabit quite a new house in a country village, which, since the warm weather has set in, has been infested with a small white insect which does not fly, but runs quickly. It is not a parasite, but is found in all the rooms, running about the furniture. Can anyone tell me what it is, where it comes from, and what is the best means of getting rid of it?—LOUISA GEORGE.

[47543.]—**Hardening Hammer Faces.**—Will "Jack of All Trades" tell me the best way to harden hammer faces?—salt will not do. The hammers are faced with steel, and to drive steel wedges into rocks.—W. H. G.

[47544.]—**Electrical Measurement.**—To "LL.B.A."—In your kind reply you say that if E be different, then R will be different; and if we know E to be the same, then R will be the same. Now, by this law, we know the resistance of a circuit in ohms, we know the current flowing through it in ampères, and we know the electromotive force in volts. Now if we insert our galvanometer in this circuit, we know that it alters the resistance of the circuit, and also the E.M.F. in proportion; but, however, it deflects our galvanometer, say, 10in. Now if we place our galvanometer in another circuit through which a current is flowing, and it deflects the needle 10in., as before, will not the current, the E.M.F., and the resistance, be the same in this circuit as the previous one?—STUDENT.

[47545.]—**Daniell Battery.**—Would some one describe an easy method (but accurate) of measuring the intensity and resistance of a Daniell battery, and greatly oblige?—EWANDALE.

[47546.]—**Crystallisation on Metals.**—In some of the tobacco shops I have noticed tin boxes, the surfaces being crystallised and lacquered over. Will any brother-reader kindly inform me how to produce the same result on sheet brass, and oblige?—SCIENCE.

[47547.]—**Legal.**—Mr. Wetherfield will greatly oblige by giving an opinion upon the following?—Is an agreement worded as hereunder sufficiently technical and binding as between employer and employé to prevent the latter at any time from entering upon the same class of business carried on by the former in the districts specified?—

"Agreement between A. and B., dated ————
B. agrees not to encroach upon the districts of the said A. as seller of ————, the said districts being C. D. E. F. The engagement of B. can be terminated on either side by one month's notice being given."

—DOUBTFUL.

[47548.]—**Industrial Company's Accounts.**—I should feel much obliged for the following information:—Are there any books on industrial organisation, &c., which explain how the accounts of factories and workshops are kept, how the cost of production and consequent selling price of articles is arrived at, how supervision and designing is charged for in the cost of production, &c., &c., and also how the work done by each workman is checked—e.g., a workshop producing machinery, tools, &c., and also doing repairs to same;—how, in this case, is the price of each article and job arrived at so as to find the lowest prices remunerative—the work being done by hand and steam? The problem is evidently a complicated one. Will any well-informed reader explain the general principles and practice in England and America, if there is no good work on the subject.—BOSS.

[47549.]—**Bloater-Paste.**—Will any of your numerous readers kindly inform me the best way to prepare or make bloater paste (as genuine as possible) from the Yarmouth bloaters,—how to extract the bones, &c., and what time of year is the most suitable?—BLOATER.

[47550.]—**Dynamo.**—To MR. LANCASTER.—Being about to make a small dynamo of the Bürgin pattern, I would feel obliged if you could give me any information upon the following points:—Sizes and quantity of wire upon field-magnets and upon armature for best results, winding of wire upon field-magnets for self-exciting machine. I wish to use the machine in conjunction with accumulators to feed incandescent lamps, and should like one arc lamp at times for a short time occasionally. The size of machine is 19½in. long, 8in. high, and 9in. through cylinder for armature; size of opening of cylinder is 5¼in.; size of space for wire on field-magnets is 9in. × 5in., cores 7 × 5 × 1½. Does it matter what size iron wire is used for the rings of the armature?—I intended to use eight rings. I would be very glad to have any hints from you regarding the making and charging accumulators, as you say you have been trying them for time. I have abundance of steam-power, and could keep some on the machine all day if desired. How many lamps might I expect to light with it from a day's supply?—T. F. H.

[47551.]—**Coil.**—To MR. LANCASTER.—I am going to make an induction coil with 8 or 10lb. of secondary, No. 32. Would you kindly say length and diam. of core, number of layers and size of primary, and size of condenser, with any other information you may consider of advantage?—ONTARIO, Canada.

[46552.]—**Japan.**—Could any correspondent give us a recipe for a good Japan that will dry hard by steam-heat and not shell off, and present a good appearance with one coat?—would prefer it without asphaltum.—ONTARIO, Canada.

[47553.]—**Problem in Dynamics.**—A weightless rope passes over a smooth pulley, having a monkey at one end, and a ball equal in weight to the monkey at the other. The monkey suddenly begins to climb up the rope with uniform velocity v. How does this affect the ball? Does it remain at rest, or does it also acquire an initial velocity $= \frac{1}{2} v$?—A. J. SMITH.

[47554.]—**Legal.**—To MR. WETHERFIELD.—Some months since, in consequence of my wife's misconduct, I refused to live with or maintain her; she then applied to the parish, and the magistrate made an order for me to pay 6/- per week. This has been paid till last week, when I stopped it, having obtained further proof of her miconduct. How can I protect myself against her again appealing to the parish or magistrate, perhaps months to come, and when my witnesses may be scattered I know not where? I applied to the Court, and was told by an official the magistrates had nothing to do with it. She has written me that she has left London, and requests me to forward her money to the address given in North Wales. I am a working man, and have but little money to spare.—J. WELG.

[47555.]—**Incubator.**—Will any one give directions for making an incubator to be heated by kerosene lamp?—AN AMERICAN.

[47556.]—**Calulating Sizes and Powers of Boilers.**—To "J. H."—Referring to letter 20117, by "J. H.," on calculating the power and size of boilers, in No. 897, and on p. 287, will he, or any reader who understands his formula, kindly explain a little more fully how the number 474 is obtained, which is used as a divisor to get at the amount of water that is evaporated per hour?—A LEARNER.

[47557.]—**Statute of Limitations for Property Law.**—A neighbour of mine some 14 years ago inclosed some of my ground by mistake, but refuses to give it up or pay anything for it. By the new Statute is it already his, or when will it be his, if I don't get some acknowledgment from him? From what date does that Statute intend the 12 years to be counted from, or does his 14 years' possession make my chance bad in a lawsuit?—LOSER.

[47558.]—**Water-closet Seats.**—Will any of your correspondents give me a correct or standard method for striking out the holes in closet seats (both for adults and children), the sizes they should be, and also the proper distance to round them back from under edge of hole? I should like the method and sizes used in first-class work, also the usual height from floor to top of seat.—UN FALAGNAME.

[47559.]—**Legal.**—To MR. WETHERFIELD.—Would you kindly advise me on the following matter?—My mother bought a business, which was paid for, carried on, and the rent paid in her name. She had two sons only, my brother, younger than me, assisting her for some years, during which three leasehold houses were bought in my brother's name, but proof can be had that money was borrowed in my mother's name to help pay for the houses. About four years ago, just before having two of the houses made over to her name, my mother died, leaving no will, and from then until now my brother has held possession of everything, and as misfortune assails and he don't assist me, I should be pleased to know if I can claim any and what portion of the property, and how to enforce the claim if required.—J. KING.

[47560.]—**Self-Acting Vertical and Angular Feed to Planing machine.**—I have a planing machine by Messrs. Buck and Watkin, of Halifax, who are now out of business. The self-acting vertical and angular feed motion has been removed before it came into my possession, and I am anxious to replace the same. Can any of your numerous subscribers help me with a sketch and description of the above motions?—CADMUS.

[47561.]—**Pot-Pourri.**—Will any reader kindly tell me the ingredients and quantities for making the above? I am drying a quantity of rose-leaves.—J. CHAMBERLAIN.

[47562.]—**Meat-Safe.**—Will any of your readers kindly give particulars for making a small meat-safe—say, 3ft. 6in. to 4ft. in length, about same height (including, say, 1ft. for height from ground), stating materials to be used, &c.? A small sketch would be of great assistance.—FRITZ.

[47563.]—**'Xtraordinary Challenge.**—Can any rider of this machine oblige me with an opinion of its merits? Is it inferior in speed to an ordinary bicycle?—UNDERGRADUATE.

[47564.]—**Photographic Lens.**—Can "Orderic Vital," "Prismatique," or any other obliging reader supply me with the elements necessary for working a photo lens of the rapid rectilinear or wide angle symmetrical class, and oblige?—JIM.

[47565.]—**Valve motion.**—Would some one kindly describe how the valve in the Hathorn rock drill is actuated? It appears to be a very ingenious arrangement.—E. S.

[47566.]—**Spectacles.**—For engineers finding it necessary to use spectacles at their work, what kind would be the most serviceable (there are the usual and several patent kinds) and be least injurious in the end for constant use? Several makers claim that theirs improves the sight.—ENGINEER.

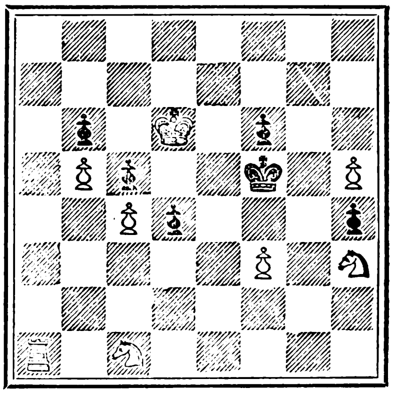
[47567.]—**Slide-Rule.**—Will any experienced reader please give an opinion as to the best forms of slide-rule or similar instrument of English make? I wish rather accuracy than variety of applications; a good, cheap, logarithmic rule without trigonometrical functions, say 18in. long, would be about what I require; but I believe there are improved forms in which the tables are arranged on discs or cylinders, and I remember having heard of one equal to an ordinary rule 7ft. long. I should like particulars of some of the improved forms. Are they easier to read, and do they (e g.) read to four figures?—MECHANICUS.

CHESS.

ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLXVII.—By H. F. L. MEYER.

Black.

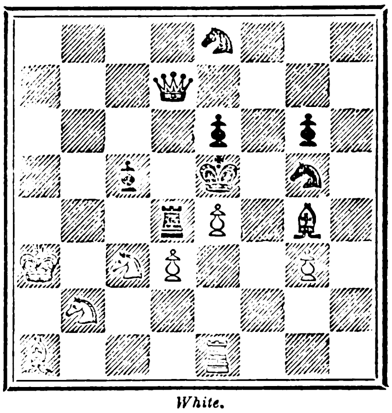


White.

White to play and mate in four moves.

PROBLEM DCCLXVIII.—By T. B. ROWLAND.

Black.



White.

White to play and mate in two moves.

SOLUTION TO 763.

White.	*Black.*
1. Q to R sq	1. R takes Q (a)
2. R to Q 7 (ch)	2. Kt covers
3. R takes Kt mate	
	(a) 1. B moves (b)
2. Q to Q 4 (ch)	2. K takes Q
3. R mates	
	(b) 1. R takes R
2. Q takes 4 (ch), &c.	

SOLUTION TO 764.

White.	*Black.*
1. B to R sq	1. Kt to K B 4 (a)
2. Q to K 4 (ch)	2. Kt to Q 5
3. Q to Q B 6 (ch)	3. Kt takes Q mates
	(a) 1. Kt to Kt 5 (b)

3. Kt to Q R 3 (ch)	3. R takes Kt mates
	(c) 1. B to B 3 (d)
2. Kt takes P (ch)	2. B takes Kt
3. R to B 7 (ch)	3. B takes R mate
	(d) 1. Any other
2. Kt to K 3 (ch)	2. B takes Kt
3. Kt to Kt 6 (ch)	3. Mates

If 1. $\frac{\quad}{\text{B-K 6}}$. 2. $\frac{\text{Kt to Kt 6 (ch)}}{\text{Mates.}}$.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 763 and 764 by Celsus; to 764 by G. Hume and Schmucke.

SCHMUCKE.—You will have seen the notice respecting 762 in our last.

WITH reference to Mr. W. T. Pierce's article on the A 1 Notation in the Chess Club Directory this year, Mr. Meyer calls our attention to the fact that the term "International Notation" was first used by Prof. O. A. Brownson, in 1874.

PROBLEMS received with thanks from F. F. Beechy and G. Hume.

THE *Jamaica Family Journal* has just started its second problem tourney. The prizes are: 1st, £2; 2nd, £1; 3rd, 10s.; 4th, 5s. There are also special prizes (1) for the best problem giving the black king most liberty, 10s.; (2) for the best, by a West Indian composer, 10s.; (3) for the best and most appropriate motto, a copy of Bland's Chess Annual: (1) and (3) are offered by Miss F. F. Beechey. The problems are to be two-movers; not less than two, and not more than four, must be sent by each composer. No competitor can take more than one of the regular prizes. Two problems at least must be posted on or before September 10th by other than Jamaica composers, and one month more will be allowed for making up the complement of four if so desired. The usual rules respecting motto and envelopes. Address: Mephisto, 96, Harbour-street, Kingston, Jamaica.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, July 26, and unacknowledged elsewhere:—

REV. E. S.—W. H. Smith and Son, Dublin.—Royal Cornwall Polytechnic Society.—C. Birchall.—T. Schobbeus.—J. Shanks.—W. H. Barwell.—Crossley Bros.—J. R. Cheshire.—Young Photo.—B. M.—J. P.—London River.—W. Bradshaw.—A Casual Sketcher.—Met l.—Orderic Vital.—Fellow Workman.—Jack of All Trades.—N. S. Heincken.

J. EDMONDSON. (A cubic yard of rubble masonry will, as a rule, require 1-5 cubic yard of mortar and 1 1-5 cubic yard of stone. The difference you speak of is due to the adoption of different local standards of measurements. The Irish "square perch" is 21ft. super., while the "square perch" used in the West of England is only 18ft. super.)—JOINER. (You can render ordinary glue insoluble in water by adding to the water with which it is mixed about a fiftieth part of the amount of glue used of bichromate of potash.)—EMIGRANT FARMER. (In this country, the following quantities of seed are sown per acre—viz.: Wheat, from 1½ to 2½ bush.; barley, 1½ to 3½ bush.; oats, 2 to 5 bush.; turnips, 2 to 6lb.; potatoes, 10cwt.; peas, 3 bush. in drills; beans, 4 bush.; carrots or parsnips, 6lb.; rape or cole, 2 to 4 quarts; rye, 4 bush.; 1 bush. of rye or oats and three bush. of vetches; 1 bush. of peas and three of beans; sainfoin, 4 bush. of rough seed with 8lb. of trefoil; white clover, 14lb.; red clover and cow grass, 15lb.; mixture of ½ bush. of rye grass, 6lb. trefoil, and 6lb. of white clover. Seeds, 2 pecks of mixed perennial and Italian rye grass, 3lb. white clover, 7lb. red clover, 1½lb. alsike, and 1½lb. trefoil; or 3 pecks Italian rye grass, 6lb. each of red and white Dutch clover and alsike, 3lb. trefoil, and 2lb. each of plantain and parsley. For crop of hay alone, 1 bush. each of perennial and Italian rye grass with 9lb. of red clover; for one year's hay crop and one or two years' pasture, 1 bush. of perennial rye grass, and ½ bush each of Italian rye grass and rough cocksfoot, 5lb. of red clover, with ¼ stone each of white clover and Timothy. Average yield per acre: Wheat, 4qrs.; barley, 5qrs.; oats, 6qrs.; turnips, 20 tons; mangold, 25 tons; beans or peas, 30 bush.; clover, 2 or 3 tons; hay, 2 tons.)—INCANDESCENT. (The question was answered by the contributor named on p. 457, last week.)—ELECTRICIAN. (It is usually taken at 1,000 hours, but some have been in use for much longer periods than that. Others fail after a few hours. After a time the glass becomes clouded by a deposit of carbon, so that if you get one to last 1,000 hours you may be satisfied.)—S. CROSSE. (See recent back numbers and articles on the Pacinotti ring and dynamo machines.)—ENGINEER. (The book you require is Nicholl's "Theoretical and Practical Boiler-Maker," which is published by the author at Yorkshire-street, Blackpool. The second edition has just been issued.)—R. L. JONES. (Full directions for making secondary batteries have been given many times. See p. 273, 293, Vol. XXXIV., and the index of that volume; also pp. 180, 200, 244, 247, 281, 291 this volume.)—GAMMA. (It is done by fitting the winding apparatus with ratchet work, but the maintaining power lasts only a limited time. See No. 852, p. 469, for full description.)—YOUNG POLISHER (Use Stephens' stains, or consult the indices. Copal, oak, spirit, or French polish.)—R. BARRACLOUGH. (For what purpose is it required? Generally speaking, a mercurial barometer verified at Kew is the best. To be obtained of any philosophical instrument seller.)—T. HENDERSON. (Have you tried your flying machine? We see nothing very new or likely to be successful in it.)—VITAL JACK. (Gamboge is a resin which oozes from the broken branches, or incisions made in the trunks of various trees which grow in Siam, Ceylon, and Cambodia. The substance is dried and exported in cylindrical cakes.)—T. GRAHAM. (We hardly know where you are likely to meet with a copy. We have one in an old volume of poetical extracts published many years ago without imprint. The subject was a favourite one with our old English ballad makers, and there are extant, besides the "King and the Miller," "King Henry and the Soldier," "King James and the Tinker," "King Alfred and the Shepherd," "King Edward and the Tanner," and probably others. "The King and the Miller" is, at least, as old as the reign of Edward IV.)—CHAIN SHOT. (We cannot undertake to value engravings. If you had mentioned the subject we might have told you something about it. Albert Dürer was born at Nürnberg in 1471. You will find a review of a good and recently-published "life" of him, and a reproduction of one of his latest plates—"Samson and the Lion"—in to-day's *Building News*.)—BROSCENICUS. (See No. 865, p. 167. Moulds of proper moulders' sand, thoroughly dry. Plumbago crucible. Have you a furnace? If not, see p. 76, Vol. XXX.)—F. S. (Cannot you see what you want in almost any optician's window? There is no necessity for a bulb. The tube need only dip into a little cistern of mercury, which may be of any material not attacked by that element.)—L. NEWTON. (You must not apply electricity for the cure of headache except on the advice of a competent physician.)—H. W. (If you refer to pp. 87, 111 of this volume, you will find illustrations of the method of applying electric bells in telephone circuits. If you want to make a bell, see back volumes.)—LUNETTES. (It is a question to be answered only by skilled examination of the eyes. You should wear your spectacles always, that is, when using the eyes, as their object is to relieve the strain on certain muscles. As a rule, in short sight, if suitable spectacles are used when the patient is young, they can be laid aside when maturity or middle life is reached.)—YOUNG MICROSCOPIST. (You mean the "eels in paste," we suppose. Make a moderately thick paste of flour and water, and keep in a warm place, stirring every day to prevent the growth of fungus. At the end of a few days examine the paste by putting a little bit diluted with a drop of water on the slide. You should procure one of the cheap manuals on the subject, or look through a series of articles in Vol. XXI.)—AN AMERICAN. (You will find description of such a machine in Nos. 773, 793.)

Watches and Jewellery.—Messrs. Woodward and Co., of Liverpool, have sent us a copy of their illustrated catalogue of watches and jewellery, which comprises goods likely to suit all tastes and pockets. The catalogue seems free from the ridiculous guarantees, offered in similar publications we have seen, of value and efficiency at impossible prices, and there is, therefore, the more probability that purchasers will put themselves into Messrs. Woodward's hands with satisfaction—especially as they undertake to take back all goods not approved of if returned within a week after sale.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Ointment may be relied upon in cases of inflammation or irritation of the internal mucous membrane. When it is diligently rubbed upon the back and chest, it relieves shortness of breath, fluttering of the heart, stitch in the side, cures colds, asthma, bronchitis, and protects the delicate against consumption.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Wanted, portable **Dry-plate Camera**, background, and Camera suitable for copying, &c. Many useful offers, or part cash.—BETA, Belbroughton, Stourbridge.

Hickory **Fishing Rod**, Winch and Lines, Acme Skates, Wood Skates, Daniell Battery, Porous Cells, Zincs, Leather Leggings, small Taps, Standard Screw Plate, Screw Chasers, Wire Netting for Poultry, Sulphate of Copper for Battery, brass Bottle Jack, quantity of Maps (suit school), botanical specimens, about 250 mounted on paper. Sell cheap or exchange. Want Fruit, Drapery, Dentist's Tools and materials, Plants. Would make artificial teeth for exchange.—DENTIST, 27, High-street, Rochester, Kent.

Binocular Popular **Microscope** (Smith and Beck), bought within last six months; ⅛, ¼, ½, 1, 2in. glasses, compound achromatic condenser with stops, polariscope, paraboloid, dark well, &c., first-class instrument, good as new; leaving country; every examination allowed; catalogue price over £30. Offers.—Y. R. S., Britannia Brewery, Allan-street, Kensington.

Wanted, set of **Tricycle Wheels**, or parts of same. Good exchange or cash.—WM. POATE, Havant, Hants.

Clarionet, 13 keys, E flat. Good exchange for large size Accordion, Magic Lantern, or offers.—WM. POATE, Havant, Hants.

32ft. **Reeds**, one bottom octave (CCCC to CCC), for harmonium. Offers wanted.—HAVARD and STEVENSON, 103, Bordsley Park-road, Birmingham.

What offers for 7½in. back-geared **Lathe and Tools**? Also Vertical Drilling Machine.—For full particulars apply to F. UNDERWOOD, Beverley.

Wanted, all the back numbers of the "**Electro-**METALLURGIST AND ELECTRIC LIGHT JOURNAL." Exchange.—G. C. T. CARTER, 3, Castle-street, Reading.

Type, chiefly new, several founts, press, &c. Offers requested in exchange.—L., 16, Addington-street, Ramsgate.

Telescope, 3in. O.G., well mounted, defines well, shows Jupiter's moons. Offers.—MILLER, P. O., Ramsgate.

I would like to exchange my collection of **Foreign** STAMPS, about 1,400, in Stanley Gibbon's 11s. album, for Coins or Britannia Company's Lathe.—J. C., 11, Calverley Park-gardens, Tunbridge Wells.

Boiler (slow-combustion), Hot Water Pipes, &c., wanted, for Heating Coil and cash.—Mr. S. HEWETT, South Norwood, London.

Bicycle, 52in., Bown's Æolus Ball Bearings both wheels, saddle, brake, bag, light splendid machine, nearly new, condition perfect, value £8. Exchange good Telescope or Microscope.—DAVIES, GILES, and Co., Sedgley, Dudley.

128 odd numbers from the 10 first volumes of the "**Eng-**LISH MECHANIC," in exchange for any useful book or numbers of the *Builder*, or send offers.—JAS. LEVESQUE, St. Helier's, Jersey.

Watch Mandrel, with compound slide-rest, £4 10s. Wheel-stretching and hole-closing Tool, £1 10s. Watch Depth Tool, 5s. Uprighting Tool, 10s. Box of Watch Punches, 6s. Watch Turns, with centres, 6s. Offers requested. Rare chance for amateur watchmakers.—J. WILLIAMS, 36, Mount Ash-road, Sydenham.

I have six, each ½in. and ¾in., **Bib Cocks**, low pressure; 6 each ½in. and ¾in. Ball, ditto; 1 dozen ¾in. Stop Cocks, ditto. What offers?—E. M., 4, Oxford-terrace, Windsor.

Organ Bellows and Windchests (new and second-hand), in good condition, ready for wind and pipes.—Address, WILLIAM JOHNSON, No. 12, Moxley near Wednesbury.

A good **Lathe** wanted. Exchange a splendid 50in. Bicycle, S.H.F. and double ball bearings.—Offers to HODGKINSON, High-street, Shanklin, I.W.

Electric Boat, fitted with paddle wheels, electric engine, paddle boxes, imitation boiler, funnel, rudder, battery; runs for two or three hours. What offers?—GEORGE TOLMAN, Wolverhampton.

Fine collection of **Minerals and Fossils**. Wanted, letter copying press, aneroid barometer, or violin case.—WORTH, Sheldmont House, Brondesbury, Kilburn.

Concertina wanted, Anglo, 30 or more keys, metal tops preferred. Exchange violin, bow, and case, value £5, cash.—HEWSON, 12, Great Crown-court, Haymarket, W.C.

My excellent solo **Violoncello**, worth £7 10s., in part exchange for really good Tricycle or Screw-cutting Lathe.—Address, T. REDMAN, Crossflatts, Bingley.

"**Cassell's Popular Educator,**" in 16 2s. parts, quite new and uncut. Offers in Quart Bunsen Cells.—C. W. BERDOE, 16, Broadway, London Fields.

Two **Lathe Heads**, 6½in. centre, 4 chucks, socket and rests. Wanted, Bed and Fly-wheel.—C. BLANCHARD, 4a, Little Church-street, Edgware-road, London.

Old **Gold or Silver** taken in exchange for any article on FRANCOIS' list. Highest value allowed.

A **Drilling Machine**. Exchange for a good 6in. slide-rest, or offers in cash.—GOULD, 3, Keen-street, Warrington.

Half horse-power Horizontal **Engine**, in the rough or finished. Exchange anything useful.—GOULD, 3, Keen-street, Warrington.

AND
WORLD OF SCIENCE AND ART.

FRIDAY, AUGUST 4, 1882.

SPECIMEN OF ORNAMENTAL TURNING.

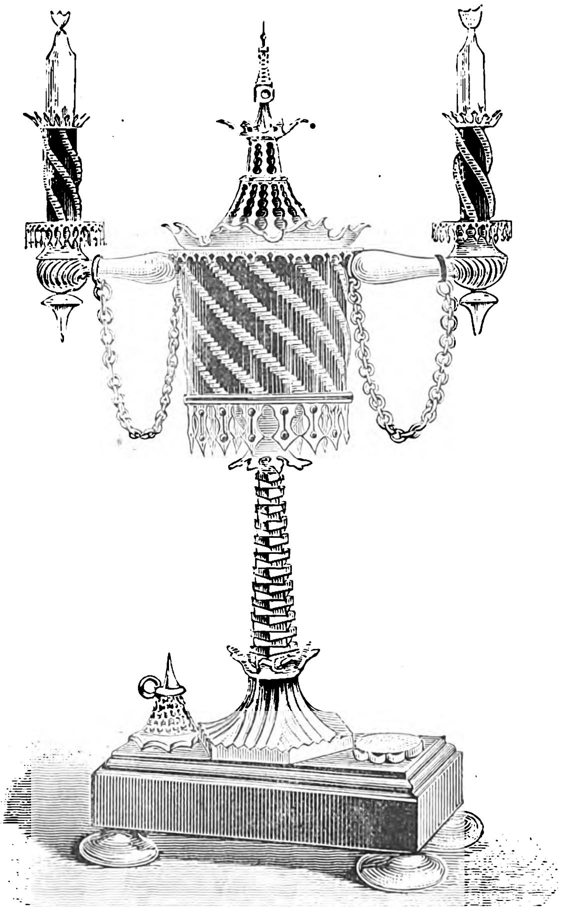
By J. H. Evans.

IN fulfilment of promise, and at the desire of a number of those interested in ornamental turning, I illustrate and describe in this number an ornament which contains a great variety of patterns, and although nothing out of the way in the form of apparatus will be required to do it, it will require a certain amount of experience in the use of those tools, cutters, &c., required to be used, and also a very considerable amount of patience.

It would be seen at once, could the original be viewed by all, that it is composed of African black-wood and ivory, the contrast being extremely effective. As in all cases I should advise beginning at the base, therefore the four feet will be the first thing to do. These are simply plain, without the slightest ornament or cutting about them. Having made them all exactly alike, which will require a deal of care, the stand, which is oblong, will be the next part to proceed with. This is four inches and a quarter long, by two and a quarter wide, and one inch deep. Although such a piece of wood does not seem much to look at, or appear difficult to produce, it is not at all an easy matter to do it. It will be seen that on the top edge a moulding is cut, all the mitres of which are brought up perfectly sharp, and I may mention that, unless all the edges of such a piece of work are made so, the beauty of the work is entirely gone.

Having now explained what it is, I will set about explaining the best way of doing it. In the first place it is better to rough out the piece of wood somewhat near the shape required, leaving, of course, enough material to finish it up. This done, hold it in a universal chuck, and, in the under side, screw it to fit the nose of the mandrel, and then place it upon the dome chuck. If necessary to be raised further from the wheel, a nose chuck may intervene between the work and chuck. With regard to the dome-chuck, I am now making them somewhat differently, inasmuch as the arm which carries the wheel is lengthened, to allow of larger work being cut in it. There is no reason why it should not be so made, and it is quite clear that the extra length does not in any way interfere with the working of it, except that it adds to its capabilities, which must be an advantage. The work being chucked, the slide-rest must be set quite true to the surface, and with the eccentric cutter, having the tool extended to cut a circle of about 1$\frac{1}{4}$in., the first side may be cut. This is a case in which the segment apparatus previously described will be found of very great advantage, as it holds the work perfectly rigid, which is a very important matter. Having cut one side, it is better to take one half-turn of the tangent-wheel of the dome-chuck, and cut the opposite side. This done, the slide-rest must be moved back, and, by moving the wheel one quarter, the position for the next face will be obtained; and, when cut, the half-turn again taken to bring the corresponding side to its place. The wheel having now been moved, and a face cut at each fourth, with care and a sharp tool in the eccentric cutter, about No. 20 wide, these faces may be cut perfectly smooth. We now come to the moulding round the top edge. To cut this, place in the tool-box of the slide-rest a universal cutter with a moulding-tool fixed. The precise radius is of no moment, as it cuts clean through. It will now be obvious that the cutter would cut the moulding exactly in the centre of the face of the wood, and, in order to bring the edge of the wood to its proper place, where the moulding is required, the screw of the dome-chuck must be moved, to lower the arm which carries the work. The dome-chuck should be fixed in a vertical position, which can be very easily done, especially by aid of the segment apparatus. When the work is set in position, and the tool to the centre, the two sides and ends may be cut, great care being taken when passing over the corners to avoid chipping—in the event of which happening the whole thing, so far, is at an end, and must, of necessity, be gone over again. We will assume, however, that, so far, all has been successful, and will proceed with the lower piece of the ivory pillar. This, it will be seen, is also cut in the form of a hexagon at the base, and to such a size that across the flat it is exactly the same as the top of the black wood upon which it rests. In cutting the semicircular flutes seen on each of the curves, there are two or three different ways to accomplish the same. First of all, the bare form must be cut, and this may be done with a long circular cutter about $\frac{5}{8}$in. in diameter, running in a universal or horizontal cutting-frame in the spherical slide-rest. Or another way to get over it, if the spherical slide-rest is not at hand, will be to have a horizontal cutter with a vertical movement. With this little difficulty will arise; in fact, it was with such a tool that the present specimen was done. Having set the tool to the centre, also to the radius of the curve, the six plain facets should be cut, the cutter being driven at a high speed, the vertical movement being taken each side of the centre till the corners are all cut up sharp. This done, set the vertical slide, for such it really is, to the centre with a round-nose tool, and cut the first flute. Take this round to each side by shifting the under peg, and then raise the tool by means of the slide, and cut three cuts each side. The tool should be kept with a very keen cutting edge, and then each cut will have a high polish when finished: this is one of the most important things in ornamental turning. The six sides to form the hexagon can be cut by simply setting the radius of the eccentric to cut sufficiently large to bring up the corners, and move the slide-rest the length desired to complete the form.

On the top of the curve will be seen another thin piece turned to a curve. This being turned, is fitted on to a box-wood chuck, and then cut into the shape seen by the aid of the eccentric cutter and drill, the eight points being brought up by cutting a corresponding number of circles, and adjusting the radius of eccentric cutter to bring the points up sharp. This done, the smaller hole is pierced through with a drill. Following this is the pillar, which is turned taper and cut with a basket pattern. The present was cut of a coarse pattern to give effect, and has in it 104 consecutive cuts. The tool being No. 10 ten-hundredth wide, it was, of course, equal to one turn of the slide-rest screw; and if the rest is set at zero when starting, particular attention being paid that there is no loss of time in the slide-rest, or, at all events, that it is taken up, which is easily done by moving the rest either always in the same direction, or, if not, move it either way sufficiently to be sure that the tool-box is moved, and not the screw only. To cut the pattern as seen, set the radius of cutter; see, as I say, that the reader on slide-rest screw is at zero, and cut, dividing the division-plate into four only, 96, 24, 48, 72. This is, of course, for the 96; any other may be used. The first cut will be according to these settings. This done, move the slide-rest one turn, and set the index-peg so that the next cut begins at 12, 36, 60, 84. These different divisions must be used alternately, which will bring each series of four cuts, with their points, in the centre of those previously cut; and when cut clear with a sharp tool it is one of the most effective patterns. There are a number of different ways of cutting what is termed the basket pattern. By altering the number of divisions between each series of cuts a spiral line of points will be the result, all equally effective in appearance. On the top of this pillar a corresponding piece to that on the top of the lower curve is cut and executed in exactly the same way.



CANDELABRA IN BLACK-WOOD AND IVORY.

We now come to the body, which is made of African black-wood, and, as will be seen, covered with ivory cut very thin. This entire part forms a box to hold stamps, &c. Having turned it to the form required, a thin coating of ivory must be accurately fitted to it, and the latter then transferred to a boxwood form of exactly the same shape, and well fitted, and then held to the boxwood chuck by some very thin glue, and, when dry, proceed to turn, keeping, of course, the slide-rest set to the same angle as when turning the black-wood; and here, in cutting the ivory we come to a basket pattern as before described, forming, as seen, a spiral line, only cut through in order to show the black-wood. This cutting through could not, as a matter of course, be done unless the boxwood fitted the ivory well all over, so as to support the latter, as it will be seen there is very little substance left. The ivory being turned, there will be no necessity to go to the trouble of highly polishing the outer surface, as it is cut up sharp all over; but it may be cut without. Place the vertical cutter, or the universal, whichever is to be used, in the slide-rest, and in it a cutter, No. 8. Set the division-plate at the 96 division, and cut round. Bring up the point sharp, taking eight divisions at each cut, leaving twelve points. Now take one division forward, and cut round at each succeeding eighth hole. Advance one hole again, and proceed as before, advancing one hole for each succeeding series of cuts, all being cut at every eighth. After the one hole has been taken for each adjustment, there are 35 consecutive series of 12, making 500 cuts in this one piece alone, every one of which must be very carefully done, simply because if one is hastily done and allowed to break away, the whole piece will be valueless, and this, I need scarcely say, is exceedingly annoying, more especially if it happens when the work is nearly finished. When cut, the boxwood must be placed in warm water, not boiling, in order to soften the glue and allow the ivory to come off. The chuck being taper, little difficulty will be found in removing it.

We now pass on to the pointed fringe, we may call it, that hangs down from the bottom of the body: this is made from a circular piece of ivory turned to fit the bottom of the black-wood; it is $\frac{5}{8}$ deep, and is cut out with the eccentric cutter and drill. First turn the ivory inside and then place it on boxwood, the same as in the previous case, and glue it on; then turn the outer surface, and if, when the part is turned that fits on to the chuck, the slide-rest is set to the stop, and the tool then set back to whatever thickness is required—for this a full 32nd—there will be no fear of turning it through, which is done in many cases in the endeavour to get it too thin. This piece, when turned, should be highly polished, as some parts of the surface are left uncut. To begin cutting out this pattern, it is always better to cut the largest hole first—that which forms the points. In this case there are 16, consequently 16 holes have to be made, and the eccentric cutter may be used in place of large drill, the radius being adjusted to the required size. Having cut the first row of holes, the slide-rest must be moved sufficiently to allow the next cut to pass into the hole previously made; the same number being cut, the drilling instrument must now take the place of the eccentric cutter, and a drill placed in it the size 24, and the rest again moved, so that nearly half the hole is cut into the second one, leaving only the full half. This completes the first part; it will now be observed that in the centre of each part left another hole, No. 12, is drilled, and then with a smaller drill a groove is cut through the ivory from one hole to the other, and so completes this part.

On the top of the body a ring of ivory is fitted, with a very thin projection, which is cut out in the first place with a drill, No. 20, which having been inserted 30 times leaves sufficient space for a small drill. No. 6 is used at the extremity of each part so left; at the top of this another hole is drilled, which finishes off the effect given to it. I may mention, as a matter of fact, that it is almost impossible to convey the exact appearance of the original by engraving, unless very great time and expense are devoted to it. We will proceed to the top or cover of the body, which is made of black-wood, the same as the bottom. Having fitted it, it should be chucked by the latter fitting, and turned to the curve desired; a piece of ivory must then be fitted accurately; the ivory then transferred to a counterpart of box-wood, and treated as all other such work—viz., glued. And here again I will call attention to the necessity of seeing that all parts of the ivory touch the boxwood-chuck, as it will be seen the ivory that is left after it has been cut is extremely delicate. In cutting such a piece as this, it would look like requiring a spherical slide-rest; but not so. The curve can be turned carefully by hand, and the surface highly polished; then the slide-rest can be set to an angle, and the centre of the drill brought as near that of the part to be drilled. The first cuts will be those that form the points, 15 in number; and follow on with a series of six drills, all gradually decreasing in size, which necessitates 90 cuts in this piece; following this is the ivory slip which goes above it, containing 32 holes in all, 8 in circumference and 4 in length; on the top of this is a very delicate kind of star, curved both sides, and cut out to 8 points. This is a very delicate piece of work, and will require more care in chucking really than in cutting. The extreme top is turned by hand, and then cut with a drill; and in the centre of the ball a small bead drill is inserted four times. On the bottom of the lid a somewhat deep piece of ivory is made to fit and curved over, being then cut into eight different points in the first instance, the centre of each remaining portion being again cut out, forming in reality 16 points in all. This lightens the appearance very much.

So far, then, the base, stem, and box are completed, and we must now go on to fit up the arm which carries the candle-sockets. In order to get them exactly opposite each other, place the black-wood on a chuck, and with the drilling instrument, drill a hole each side. If the drill is adjusted to the exact length of the lathe-centres, as it should be, the holes must be perfectly true, the arms extended are, as will be at once seen, quite plain. On the end of each a socket is fitted, being first turned in plain form precisely alike, the points turning downwards being separate pieces. When bored out to receive the candles, they should be chucked by that hole, each one on a separate boxwood chuck, identical in length, and to cut the pattern seen on the bottom, the eccentric cutter is the instrument with a left side cutter single angle of 45°, thirty cuts, the slide-rest being set about 3-16ths below the centre of the lathe; having cut one, place the other on the nose of the mandrel, and the chuck being the same length, and the same settings used, they must both be precisely alike. I may say that this is really the only way that I can recommend to facilitate making any number of things alike, as the same setting can be used without any readjustment of the slide-rest.

In cutting the fringes, so to speak, for the top of these sockets, extreme care must be used, as they are the most delicate parts about it: two pieces of ivory must be turned out, 1 1-16th diameter, to fit over the top of the socket, and, as will be seen, a very thin projection left to rest upon the top of the same, the two pieces being turned to the same size; place the same upon two separate boxwood chucks and glue them; when set, turn them each as thin as possible, and slightly taper off the extreme edge, so that the points left will be quite sharp. This done, set the slide-rest quite true to the cylinder, and with a No. 12 bead tool the first series of 24 holes may be drilled. The reason why I say use a bead tool is that it has less to cut out, and renders less chance of breaking away; when this row of holes is completed, shift the slide-rest, or rather the drill, so that when the next hole is drilled a kind of square is formed at the part left uncut; the division-plate must now be set to the centre of the part left, and another hole drilled at the top. When both these pieces are finished and are exactly alike, which they must be, the slide-rest must be set round to the surface, and with a small drill, No. 8, 48 holes are again cut, leaving the same number of points. This will be found exceedingly delicate; but as it is only to keep it resting on the top of the socket it is quite strong enough for the purpose; these two pieces will be found perhaps the most difficult part of this specimen; when accomplished, however, it is a most elegant finish. We now come to the stems in which the candles actually go. It will be seen that they are made of black-wood, with ivory over them, 1½in. long and ½in. in diameter, and highly polished. The ivory is turned in the form of a cylinder, and then fitted to a counterpart of boxwood in a similar manner to the other parts turned to the thickness required, and then cut with the vertical cutter in the same way as the body, only a lesser number—viz., 4 strands (we may call them) cut with a tool not so wide as the larger pattern. To complete its length 25 cuts are taken; thus the division plate divided into four, cut round, move one hole forward, adjust slide-rest exact width of tool, cut round again at every quarter of the pulley; proceed in the same way till the length required is cut. When finished it will be found a somewhat difficult matter to get the ivory off the chuck, for two reasons: first, the ivory that is left is so extremely delicate, and secondly, the wood upon which it fits being a cylinder, the wood swells with the immersion in hot water, and so fixes. In doing this specimen I broke several before getting two perfect ones. At the top of this part it will be seen there are two more pieces turned to a curve fixed in the same way, and cut out with a drill, which, being used in the same way as before described, forms a kind of star pattern, 12 points in the first, and eight in that piece which fits on to the bottom of the candle.

The chains are composed of separate links, each alternate one being split. This done, those that are split may be either put in the mouth or warm water; they will then open freely without splitting. The quickest way to make a chain of this kind is to hold a piece of ivory in a die-chuck, and bore it up the size required; then turn it into a long cylinder and cut off the rings with a sharp narrow parting-tool.

THE TRANSIT INSTRUMENT.[*]

WHEN the immortal Cap'en Cuttle presented Walter Gay with the celebrated "silver watch, which was so big and so tight in his pocket, that it came out like a bung," he accompanied it by the injunction to "put it back half an hour every morning, and about another quarter towards the afternoon, and it's a watch that'll do you credit." In these days, however, when millions travel daily by railway trains, running in no small proportion of cases, almost with the punctuality of the Sun itself; and when Greenwich Mean Time is automatically flashed daily at 10 a.m. to every Chief Post Office in the Kingdom, the kind of time kept by the watch of the honest old master-mariner must of necessity fail to find acceptance even in the most out-of-the-way Village. Hence, anything which will enable the dweller in country places unerringly to obtain the exact hour, minute, and second at his station (therefore at Greenwich), must possess the greatest practical value, and must be welcomed by all who have a train to catch, a phenomenon to note, or an appointment to keep. To explain, then, the method of deriving the time originally from observations of the heavenly bodies is the object of Mr. Clark's excellent little book, which we should be glad to see in the hands of all country gentlemen—and for the matter of that, town gentlemen too—throughout the kingdom. Our author commences by a description of the (seeming) diurnal rotation of the heavens, and shows how the passage of a star over a wire stretched by a weight, may furnish a means of roughly obtaining the time. He then goes on to describe the Transit Instrument, the method of using it, and its adjustments; shows how it may be brought approximately into the Meridian, gives examples of Transits of the Sun and Stars, whence, the local (and, of course, from the local, the Greenwich) Mean Time is deduced; tells the beginner how to find the meridian altitudes of the Stars he has to observe, and furnishes instruction on counting time by ear, on an ordinary watch, erecting a meridian mark, &c., &c. So far the work is thoroughly apprehensible to, and may be used by, any one familiar with the first two rules of arithmetic. In the second part of his work, Mr. Clark goes into the theory of the subject, explains the difference between Mean and Sidereal Time; shows how to calculate the times of Transits from the Nautical Almanac, and gives in detail the various corrections to be applied to observed Transits to render the resulting observations as rigidly accurate as the size of the observer's instrument will permit. To follow the whole of this intelligently, some rudimentary trigonometry and familiarity with the use of tables of logarithms will be needed. The work concludes with a copious series of "Transit Tables," which may be described as a large extension of the lists of Greenwich Mean Times of Southing of the Principal Fixed Stars, which conclude our own monthly "Astronomical Notes." The language employed throughout is plain and perspicuous, but the Student will do well to note example 5 on p. 57, as it seems to us that elsewhere it is not always made quite so clear as it might be, that it is really always *local* time that is obtained by a Transit Instrument, from which Greenwich Time is derived by the application of a constant quantity dependent on the Longitude. We have said above how desirable we deem it that the work under review should be widely diffused. Very notably would we commend it to the attention of churchwardens, authorities of town halls, and others having public clocks under their control. As the same time shown by a parish-church clock has more than once been decided to be the legal time, it is imperatively necessary that the indications of such a clock shall be rigidly correct. Mr. Clark expresses an opinion (which we regard as perfectly well founded) that any gardener or coachman might easily be taught the use of such an instrument as he advocates. There is no possible excuse, then, for the horological vagaries to be not infrequently observed in the clocks of country churches. The cost of such a Transit instrument as our author describes would form an absolutely insensible addition to the rates in almost every village in the Kingdom. We are, however, tempted to think that many a squire would cheerfully set up a Transit *impensa sua* for the enduring benefit of his own neighbourhood, when he once learned how cheaply it might be bought and how easily used. And this brings us to say, in conclusion, that an advertisement at the end of Mr. Clark's little book has reference to a form of instrument which the author has induced some manufacturing opticians to make, for about one-fourth of the price that a small Transit now generally costs. It is, however, described as having "a 14″ telescope and 1⅛″ aperture." Turning back now to p. 30 of the work before us, we find it correctly stated in a foot-note that "minutes and seconds of arc are written thus 1′ 15″." What sort of an affair a telescope of 14 seconds of arc focus, and one second and an eighth of arc aperture can be, we rather fail to see. We should have imagined that such dimensions would have been dependent upon the linear ones of the telescope and its distance from the eye. If, though, the sign ″ is meant for inches, we must protest against a practical astronomer, such as Mr. Clark obviously is, so misusing a symbol, which has a perfectly definite and universally accepted signification. The best thing for the reader to do, however, is to buy the book forthwith, and correct this slip with his pen.

---

[*] A Treatise on the Transit Instrument, as Applied to the Determination of Time, for the use of Country Gentlemen. By LATIMER CLARK, M.I.C.E. London, 1882.

THE ACHROMATIC OBJECT-GLASS.—VII.

By W. Bradbury.

(*Continued from page* 441.)

PROBABLY no one has since possessed so comprehensive a knowledge of the theory of the object-glass as Sir John Herschel. His results represent the accumulated study of the greatest theorists on the matter; and however unsuitable for practice some of the numbers may seem, undoubtedly they are as nearly correct as it is possible for such to be. I regret my inability to give a more systematic account of the analysis upon which they are founded. Herschel's work is subject to the same shortcomings as all purely mathematical research must be—viz., that theory is only of use in so far as it can furnish a guide for practical work. However exact a rule may be, mechanical conditions may not permit it to be worked upon.

Leaving the investigations of Herschel, I come to those of Barlow.

It will be remembered that in speaking of Martin's work with lens combinations, it was said that no rule existed by which the particular aberration of a lens could be computed. Also, one formula only was known for finding the general aberration of a lens of any kind of glass. Barlow set himself to work to remove these difficulties and deficiencies.

Taking the mathematical expression, which had then been deduced, showing the approximate error in refraction by a spherical surface, he formulated an equation giving the aberration of a lens for any condition of the incident rays. This was, essentially, all that was requisite for determining what kind of lenses would, when united, destroy each other's errors. For if the rays traversing the second lens were united in a point, the error introduced by passing through the first must be counterbalanced by the second. Or, in other words, the aberration of the second lens for diverging rays must be equal to that of the first for parallel rays.

Introducing the condition of parallelism, Barlow confirmed the accuracy of Huyghen's rule, and also found the true value of the equation for any description of glass. The coefficients depended on the refraction only, and when it was 1·5, they were the simple numbers previously given. I append several values for common indices in crown glass. Denoting the co-efficients by letters, the equation stands thus—let us call its value p, then:

$$p = \frac{A \, . \, q^2 + B \, . \, q + C}{(q+1)^2}$$

If this equation be solved, we find the value of q to be:—

$$q = \frac{P - \frac{B}{2} \pm \sqrt{\left(p - \frac{B}{2}\right)^2 + (p - C)(A - p)}}{A - p}$$

$$\text{or } q = \frac{p - \frac{B}{2} \pm \sqrt{p\,(A - B + C) - AC + \frac{B^2}{4}}}{(A - p)}$$

The value of the co-efficients are:—

Index.	A	B	C
1· 5	4· 5	1·	1·166
1·51	4·47	1·06	1·146
1·52	4·44	1·12	1·127
1·53	4·41	1·16	1·110
1·54	4· 4	1·23	1·093

The quantity p is the coefficient of parallel aberration, whose real value, as before found, is $p \times T$, or its equivalent $p \times y^2 / 2\,(\mu - 1)\,F$. A useful table may be formed, by taking various equidistant numbers for the value of p; and then by the second of the above equations, finding the corresponding values of q for the four or five crown indices.

Aberration Table for Parallel Rays.

Value of p.	Ratio of surfaces or values of q for different indices.			
	1·50	1·51	1·52	1·53

1·65	·979	·975	·973	·972
1·70	1·042	1·037	1·034	1·034
1·75	1·103	1·098	1·096	1·095
1·80	1·166	1·161	1·159	1·159
1·85	1·230	1·226	1·223	1·223
1.90	1·296	1·292	1·289	1·290
1·95	1·360	1·356	1·357	1·359
2·00	1·434	1·431	1·429	1·430
2·05	1·506	1·503	1·503	1·504
2·10	1·581	1·578	1·579	1·590
2·15	1·658	1·657	1·658	1·659
2·20	1·738	1·738	1·738	1·742

This table may be continued to any desired length, but probably the numbers here given will be sufficient for all forms likely to occur in Barlow's combinations. The higher numbers are for convex lenses having a much flatter outer curve, such as is used in Herschel's plan. By this table we can select a suitable ratio for the crown radii, when the aberration of the flint is known; but it will serve also as a general aberration table; for by multiplying the number in the first column by the thickness of the lens, we get its actual aberration.

In computing the error of the second lens, Barlow was not able to obtain an equation so simple and convenient as the previous one. Even with the artifices for reduction, it is tedious and intricate, and does not appear capable of being expressed in a simple form. When multiplied by the factor 2 F (μ − 1) of the convex lens, the quantity p', or the spherical error of the flint lens for diverging rays, is given by the following equation:—

$$\left\{ \left(\frac{C + q'}{C\,(\mu' - 1) - q'}\right)^2 \times \frac{C + q'\,(\mu' + 1)}{C\,(c\,(\mu' - 1) + \mu')^2} + \left(\frac{c + 1}{b\,c + 1}\right)^2 \times \frac{q'\,(c + 2 - b)}{c} \right\} \left\{ \frac{\delta\,(\mu - 1)}{q' + 1} \right\} = p'$$

The quantities b, C and c are introduced to simplify the calculations. Their values are $\delta = (\mu' - 1) / \mu'$; ($\mu'$ being the refractive index of flint lens): $C = \delta \, . \, q' \, . \, / \, (1 - \delta)\,(\mu' - 1)\,(1 + q')$: $c = \delta \, . \, q' \, . \, / \, b\,(1 + q' - \delta\,q')$. q' is the ratio of the back surface of the flint to its inner one.

The value of p' so found, must be looked for in the first column of the preceding table; and the corresponding value of q in its proper column may be determined by simple proportion.

In calculating the curves of a combination by these rules, it is always necessary to assume a ratio for the curves of the flint lens, and thus find the value of p'. They are not adapted to the inverse process of assuming the curves of the crown lens. The general nature of the operations may be thus indicated:—

1. From the given dispersive ratio, ascertain the crown and flint foci required to satisfy the compound focus.
2. Assume a value for q' the ratio of the flint surfaces, and from the focus and refractive power, find the curves requisite.
3. Determine the values of C, c and b, and thus obtain p', the flint aberration.
4. By reference to the table, or by substitution of p in the proper equation, find the corresponding value of q for the crown lens.
5. From q and the crown focus and refractive power the radius of each surface may be determined.

It will be noticed that Barlow's equation for computing the vergent aberration consists of two parts—the first represents the effect due to the incident surface; the second that of the emergent surface. The first part is by far the most complicated, and its value is very small compared with that of the second. Hence, in most cases, it may be neglected, and the value of p', found from the second part alone, will give a slight over-corrective power to the convex lens.

But if this method be used to compute the curves of an Herschellian combination, the whole expression must be taken into account; as, owing to the change in the character of the curve, the omission of the first part would entail serious errors.

For ordinary cases we may draw up a table, which will enable approximately correct results to be found, without much intricate calculation. Using only the second equational part, it may be expressed in terms of curve ratio, dispersive ratio, and refractive index. The intermediate quantities, b and c, are then unnecessary. Also since the values of q in the aberration table do not greatly vary, the mean may be taken as applicable to all the crown indices.

Approximate Rules for Finding the Curves of an Achromatic Object Glass.

Refractive index—crown = μ: – flint = μ'.
Ratio of dispersive powers = δ. Compound focus = ϕ.
Focus of crown lens = $F = \phi\,(1 - \delta)$.
Focus of flint lens = $f = \phi\left(\frac{1-\delta}{\delta}\right) = \frac{F}{\delta}$.

Assumed ratio of flint surfaces:—

$$r_3 : r_1 : 1 : q'$$

Then, inner flint radius $r_3 = f\,(\mu' - 1)\left(\frac{1+q'}{q'}\right)$.

Then, outer flint radius $r_1 = f\,(\mu' - 1)\,(1 + q')$.

Value of flint aberration:—

$$p = \left(\frac{\delta \cdot q'}{(\mu' - 1)\,(q + 1)} + 1\right)^2 \times \left\{1 - \frac{1}{\mu^2}\left(1 - \frac{\delta\, q'}{q' + 1}\right)\right\} \mu - 1).$$

Corresponding value of q:—

p	q	p	q	p	q
1·15	·374	1·45	·739	1·80	1·160
1·20	·446	1·50	·798	1·85	1·220
1.25	·506	1·55	·855	1·90	1·290
1·30	·568	1·60	·913	1·95	1.360
1·35	·625	1·65	·972	2·00	1·430
1·40	·683	1·70	1·030	2·05	1·500
1·43	·716	1·75	1·090	2·10	1·580

Then, front surface crown lens $r_1 = F\,.\,(\mu - 1)\,(q + 1)$.

inner surface crown lens $r_2 = F\,.\,(\mu - 1)\left(\frac{q+1}{q}\right)$.

We will illustrate the use of this table by finding the radii of an objective, made of the same glasses as used in illustration of Herschel's rules.

There are:—

Hard crown .... Index 1·51
Dense flint .... „ 1·62
Dispersive ratio = 0·6

Then, taking the standard focal length of 1,000in. = ϕ, we have:—

Focus crown = 1,000 × 0·4 = 400.
Focus flint = 400 ÷ 0·6 = 666·66.

Next, assume that the ratio of the flint surfaces is 10 = q';

Then—r_3 = 666·6 × ·62 × 1·1 = 454·66.
r_1 = 454·66 × 10 = 4546.6.

Substituting the requisite values in the equation of aberration, we find p = 1·487 and corresponding value of q = ·787.

Then—r_1 = 400 × ·51 × 1·787 = 364·5.
r_2 = 364·5 ÷ ·787 = 463·1.

Therefore, the radii giving a focal length of 1000in. are:—

Crown } 364·5 Flint } 454·6
lens } 463·1 lens } 4546·

Dividing by 20, we obtain those for 50 inches focus:—

Crown } 18·23 Flint } 22·73
lens } 23·16 lens } 227·3

Barlow gives several examples of the use of his formula.

No. 1.—Crown index, 1·515. Flint index, 1·6·

FIG. 1

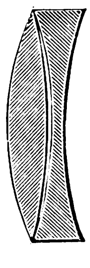

FIG. 2

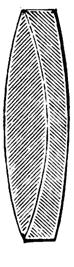

FIG. 3

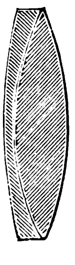

FIG. 4

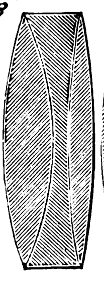

FIG. 5

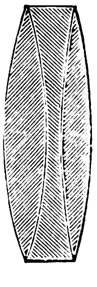

Dispersive ratio, 0·66. Object-glass, 5½in. Aperture focus, 80in.

Computed curves:—

Crown } 28·9 Flint } 27·19
lens } 27·2 lens } 271·9

Actual curves used:—

Crown } 28·4 Flint } 26·4
lens } 26·4 lens } 264·
Comp. focus = 77·9.

Spherical error perfectly balanced, although crown aberration = 1·738 instead of 1·730. Achromatism perfect, although δ = ·664 instead of ·66. Crown reversed—achromatism not altered, but spherical error not so well balanced: being 1·62 instead of 1·73.

No. 2.—An under-correct combination.

Crown } 30 Flint } 26·4
lens } 26·4 lens } 264.

These answer to value of δ = ·681. Blue colour at the focus too strong to allow any judgment on the spherical error.

No. 3.—An over-correct combination.

Crown } 26·4 Flint } 28·4
lens } 30· lens } 264

These answer to value of δ = ·638. Yellow colour at the focus preponderates.

No. 4.—Crown index, 1·515. Guinand's flint lens index, 1·63. Dispersive ratio, ·545. O.G. aperture, 5½. Focus, 77.

Computed crown curves, 31·57; 41·93. Flint, plano-concave.

Actual curves:—

Crown } 32·5 Flint } 40·4
lens } 40·4 lens } —

Corrections satisfactory in every respect.

No. 5.—Crown index, 1·515. Flint, 1·613. Dispersive ratio, ·637.

Computed radii of crown, 12·32 and 27·3.

Actual curves:—

Crown } 12·3 Flint } 22·2
lens } 27·7 lens } 56·4

Colour and spherical aberration both perfectly corrected.

No. 6.—An object-glass made on Herschel's plan:—

Crown index, 1·515. Flint, 1·587. Dispersive ratio, ·6775. Compound focus, 29·5.

Radii computed from Herschel's formula:—

Convex 19·91 } Concave – 6·66
lens 6·50 } lens + 34·49

Using Barlow's method to match the flint curves, those of the crown come out, 19·913 and 6·499.

To alter these so as to remove the central contact curves, the actual radii used were:—

Convex 19·0 } Flint – 6·58
lens 6·61 } lens + 32·5

These gave a very satisfactory result.

(*To be continued.*)

THE VARIATIONS OF GRAVITY.

THE idea has long since been expressed that it might be possible to measure the variations of gravity at different points of the globe by the height of the column of mercury which balances the pressure of a given mass of gas at constant temperature. M. Mascart has recently tried to carry out this method, and experience shows that it is susceptible of the greatest precision.

The apparatus (described in a note to the Paris Academy) consists of a sort of siphon-barometer, the short branch of which is closed, and contains a certain quantity of gas. To avoid oxidation of the mercury, and consequent loss of pressure, the author used carbonic acid; this gas was introduced at a pressure sufficient to balance a column of mercury of 1 metre when the tube was held vertical.

The chief difficulties encountered in the experiment consist in the determination of the temperature and in measurement of the level of the mercury by means of a divided scale. The instrument was placed in a metallic cylinder full of water, which was kept in agitation by an air-current from a syringe-bulb of caoutchouc. With a thermometer divided into 1-50th of a degree, the temperature could be estimated, at least in relative values, to less than 1-100 of a degree. The divided scale was fastened on the barometric tube itself; it was seen by reflection on a gilt surface which sent the virtual image into the axis of the tube, and the mercury was observed through the layer of gold, as in the prisms of M. Govi. One may thus, with a single microscope, observe at the same time the level of the mercury, and the corresponding division of the scale—all error of parallax being so eliminated. The scale was divided into tenths of a millimetre. When the illumination is properly managed with reflectors it is very easy to estimate the hundredth of a millimetre.

To submit the method to a decisive test, M. Mascart determined, by a series of observations at the College of France, the empirical relation between the apparent heights of mercury and the temperature. Then he carried the instrument to Plessis Piquet, to a tent at an altitude of about 180m. (600ft.); it was then brought back to the laboratory of the College. The mean difference of the readings was 0·027mm. Calculation shows, indeed, that between these two stations, with a difference of altitude not reaching 150m., the change of height in the mercury should be about 2-100th to 3-100th of a mm., i.e., a gravity hardly superior to the limit of exactness the experiment admits. No doubt, the instrument is somewhat inconvenient to transport, for it is necessary to avoid entrance of gas into the barometric chamber, but it is believed this difficulty is not insurmountable.

As regards sensibility, the method appears to be not inferior to the most careful observation of oscillations of pendulum. If the height of the mercury column be determined to nearly 1-100th millimetre (which the author believes realisable), the corresponding variation of the length of the pendulum would be also 1-100th mm., which would produce a change less than half a second per day, or 1-50th second during one hour. This is a degree of precision rarely attained in pendulum observations.

On the occasion of this communication from M. Mascart, M. Boussingault stated that during a stay in Ecuador he had attempted, by a somewhat similar method, to find whether, in the same locality, gravity did not undergo variations analogous to those of magnetism, observed first by de Chauvalon and confirmed by Hansteen.

In a spherical vessel of thick glass, having a capacity of 8 litres, was placed a barometer inserted in a small cup full of mercury. The graduated tube carried a runner with vernier, enabling one to appreciate a length of 1-20th mm. The glass vessel, having been filled with dry air, was closed. The upper part of the tube projecting out of the vessel was about 0·40m.

(16in.) The dry air was submitted to a pressure of about 640mm. The observations were made near the mines of Marmato (altitude 1,000m.).

The capital point in this research was to place the apparatus where the temperature would remain invariable. In the equinoctial region, the zone of invariable temperature is at less than 40in. depth. For greater security, the instrument was placed in the gallery of an abandoned silver-mine (the *Sachafruto*). A few days after, when equlibrium of temperature was thought to be established between the apparatus and the soil, observations were commenced. The air of the gallery was constantly 20·5° C.

The height of the barometric column did not vary. It was concluded that there had not been any perceptible change in the intensity of gravity during these experiments.

GIRDWOOD'S IMPROVEMENTS IN ENGINE-GOVERNORS.

In the well-known Allen governor (which was illustrated and described on p. 373, Vol. XV.) the inventor, Mr. R. K. Huntoon, made use of the resistance offered to the passage of the blades of a fan by oil contained in a small drum to regulate the speed of the engine. A novel departure on this principle has been recently patented by Mr. W. W. Girdwood, of Lea Cottages, Poplar, E., which will be sufficiently explained by the following description, and the accompanying engravings. Theoretically, governors of the type in which the containing vessel or the fan are made to revolve are not perfect; but Mr. Girdwood claims that he has succeeded in extruding inertia, centrifugal force, and impact from his governor. His invention consists of a hollow wheel containing liquid, which is mounted upon suitable bearings and has one of its journals extending through one of its bearings, to which journal is attached a disc having a pin fitted at right angles and eccentrically to it. A driving pulley is mounted upon suitable bearings, and in the same axial line as the hollow wheel. One of the journals of the driving pulley extends through its bearing nearest the hollow wheel, and has a disc attached to it. A spindle passes through the centre of the driving pulley and is free to move in any circular direction, and upon its extremity nearest the hollow wheel a small pinion is fixed; this small pinion and spindle must be imagined to remain stationary until an acceleration in the speed of the engine to be controlled occurs, when it has a slight rotary motion given to it. Upon the disc of the pulley is fitted a pin at right angles, and eccentrically to it and to the pin is attached the central portion of a volute spring, which is wound to a certain tension and is then enveloped with a metallic drum, which is capable of rotation upon its own axis. The circumference of this drum assumes the form of a cog wheel, which gears into and rotates round the central small pinion and spindle passing through the driving pulley. The crank disc of the hollow wheel is next attached to the periphery of the drum, either by a flexible chain, steel tape, or solid connecting rod. The pin upon which the spring drum is fixed passes through the disc of the driving pulley, and is connected to a ratchet and pawl arrangement for increasing the tension of the spring when the apparatus is at rest. If the driving pulley, which is driven by the engine to be controlled, be now put in motion, so long as that motion is uniform and steady, the spring drum with its cog-wheel will describe its orbit round the central small pinion and spindle without affecting it in any degree whatever, but should the pulley receive increments of speed, they are not transmitted directly to the hollow wheel, but impart, first, an epicycloidal motion to the spring drum and its cog-wheel, which in its turn rotates the central small pinion and spindle. Upon the other extremity of this central spindle is fixed a lever, from the angular motion of which action is obtained for either opening or closing the steam valve of the engine to be controlled. The angular motion of this lever is opposed by a spiral spring, which is capable of delicate adjustment. When the speed of the driving pulley increases, the epicycloidal movement of the spring drum causes a further convolution of the contained spring; but when the speed decreases an evolution of the spring occurs, and hence a reverse movement in the lever of the central spindle results, which is further assisted by the spiral spring. The hollow wheel containing liquid must be very light, and weight must be annihilated as far as possible. If the wheel is composed of iron, brass, or wood, it should contain oil or water; but if of glass, mercury. The weight of liquid should exceed that of the wheel and shaft, the object being to entirely obliterate any momentum that might be stored up in the revolving wheel. The level of the liquid must always be below the centre of the wheel, and the summit of the wave-line formed by its motion must not pass the centre line. In some cases the patentee puts a float inside the wheel, covering as near as possible the surface of the liquid in order to preserve its quiescence; above all, the wheel must not be full of liquid, because in that case the liquid would assume a circular motion by the rotation of the wheel, and its presence there would become nugatory as a means of offering resistance to the motion of the wheel. By using a light wheel in which the weight of liquid predominates, motion is weighed, and at various speeds the wheel offers various resistances, and it is the refusal of the hollow wheel to receive increments of speed that causes the epicycloidal movement of the spring drum.

In the drawings, Fig. 1 is a sectional longitudinal elevation, showing A, the hollow wheel; B, the driving pulley; C, the central spindle; the lever L being in connection with the steam valve and spiral spring, which is enveloped with a graduated scale for registering the pressure; D is the pinion fixed upon the extremity of shaft C, near the wheel; E is the spring drum with its cog-wheel gearing into D, and capable of rotating round it; F is the ratchet and pawl arrangement on the one side of the driving pulley's disc, with the volute spring fixed upon the ratchet spindle on the other side of the disc. The spring drum E is shown connected by a steel tape G to the crank disc H on the one extremity of the journal K, which is the shaft of the hollow wheel; L is the liquid, with the float M shown in section. Fig. 2 is transverse view of driving pulley's disc, showing ratchet and pawl arrangement for increasing the tension of the spring when the apparatus is at rest; the central portion of the volute spring is attached to the ratchet spindle upon the other side of the disc. Fig. 3 shows transverse view of the other side of the disc; E is the spring drum gearing into the pinion D of the central spindle C; G is the steel tape connecting the spring drum and crank disc H of the hollow wheel; the volute spring is represented by a number of concentric circles, and is attached to the ratchet spindle F. Now, immediately there is any attempt of the driving pulley, and hence of the spring drum, to travel faster than the hollow wheel, the distance between H and E would increase, causing E to revolve slightly, thus giving to the pinion D a rotary motion, also an angular motion to the lever L, acting on the parts operating the steam valve.

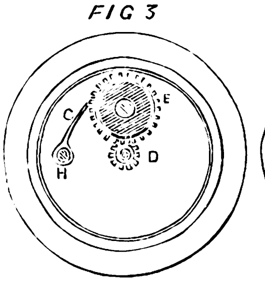

FIG. 2

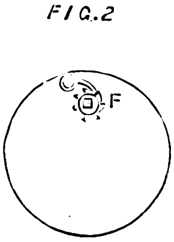


THE ARCTIC METEOROLOGICAL OBSERVATIONS.

By the time these lines come before our readers, the observing parties sent out to the Arctic regions will have commenced operations, and have begun that long list of observations which is to cover a period of twelve months' sojourn in the icy North. We need not recapitulate the story of the inception and gradual progress of the scheme; it must suffice to say that it originated with the late Lieut. Weyprecht, and took form in the shape of his programme presented to the International Meteorological Congress, held in Rome in 1879. Since then the scheme has been gradually growing, until we have arrived at the time when the observers are actually at their appointed stations, or on the road to them. The idea is to have a number of stations around the pole within or near the Arctic circle, at which observations are to be made throughout the year, commencing as nearly as possible on August 1, and ending as near as possible with the close of the following August, thus giving a period of thirteen months to those who are ready in time, and happen to be located at situations where there will be no haste in breaking up the establishment. With some such map of the Arctic regions as that given in No. 533, it will be easy to plot down the respective stations, and it will be then seen that one side of the meridian of 90° is occupied by only three expeditions, the other nine being, comparatively speaking, close together on what may be called the Greenwich side of the meridian of 90°. On that side, however, exploration has advanced further, and the places selected are better known and more easily reached than a corresponding number on the other side of that meridian could possibly be. As it is, the United States occupy Cape Barrow on the north coast of Alaska; the Russians are at the mouth of the Lena; and the English observatory is at Fort Rae, the latitude of which is only about 63°. The Germans are located at Cumberland Sound, about 66°, and the Danes at Godthaab, about 64°—the three last being outside the Arctic circle. The most northerly position is taken by the United States, who occupy Lady Franklin Bay, 81° 20' lat., 64° 58' W. long., in addition to Cape Barrow, which is between 71° and 72°. The Russians occupy the Lena mouth, 73°, and Karmakulé Bay, Novaya Zemlya, 72° 30', in addition to the station in Finland, at Sodankylä, 67° 24'. The Swedes occupy a position in one of the bays of Spitzbergen, in lat. 79° 53', long. 16° E; the Austrians will occupy Jan Mayen Island, 70° 58'; while the Dutch are located at the mouth of the Jenisei, in Dickson Harbour, 73° 30'. In addition, the Norwegians have an observatory at Bossekop, in 69° 56'. It will be seen that the majority of these places are readily accessible in the season—some, in fact, all the year round; but, although the Lady Franklin Bay party will be furthest away, it will be remembered that they have a supply of coal in the seams found by the *Discovery*; indeed, it is not unlikely that far north as it is, the station will become a permanent one, especially as during the season there seems to be little difficulty in reaching it. Cape Barrow is the most desolate post, speaking comparatively, and that too, is occupied by the Americans, who have thus a station at the two northern corners of their "continent." For the purpose of comparison certain days are indicated as term-days, on which all stations must make their magnetical observations at fixed intervals regulated by Göttingen mean time. That is, the readings are to be made every five minutes, and always at the exact minute, taking them in the following order:—Horizontal intensity, declination, vertical intensity. During one whole hour on term-days, observations are to be made of the declination every 20 seconds. On other than term-days, the magnetical observations will be made at the pleasure of those appointed for the duty, and each expedition will make the hourly meteorological observations according to any standard of time chosen. These latter observations will consist of careful notes of the temperature of the air, and also of the sea, where possible. Pressure of atmosphere must be specially observed, the barometer used being compared every week with the standard instrument. For humidity the psychrometer and the hair hygrometer will be used, but at low temperatures they will be frequently compared with other instruments for direct observations. For wind, Robinson's anemometer will be used, the direction being given for every 16 points, and according to true bearings. Clouds, weather, rainfall, &c., will be noted in the usual manner. The observations on terrestrial magnetism depend for much of their value on being made synchronously; and special attention will be taken of this branch, as also of auroral phenomena, on term days. Three classes of observations are expected to be made by each expedition, and the summaries are to be sent to the International Polar Commission, who will publish them as speedily as possible. Besides the observations specified in the programme as essential, there are many "optional" observations, as they are termed, which will, no doubt, be made as often as possible by some members of the expeditions, during certain seasons, at least, so that when happily the observers return to the more habitable parts of the earth, we may expect to receive from them information as to the physics of the Arctic regions which will, if followed up in future years, be of considerable value. It should be mentioned that the French will have a station in the South at Cape Horn, while Germany will observe at South Georgia, both about 55° S. lat. The Italian Antarctic Expedition is also expected to return with valuable data connected with the physics of the icy South, and as similar observations will be carried on in connection with the Arctic expeditions at a number of observatories in different parts of the globe, it is possible that at least our knowledge of terrestrial magnetism will be much enlarged.

RECENT IMPROVEMENTS IN VOLTAIC AND STORAGE BATTERIES.

THE recent development of electric lighting has apparently given an impulse to the invention of improvements in, or modifications of, voltaic batteries, some of which are undoubtedly of value; but, for obvious reasons, the attention of inventors seems mainly directed to the construction of storage cells. If we may judge from the claims put forward by the patentee, Mr. Ross, of Camberwell, a battery recently devised by him is better suited to working the electric light than the Bunsen or Grove, for it occupies but little space, is very economical, and at the same time is of great power and permanency. It is a carbon-zinc battery, composed of broken coke, graphite, charcoal or other varieties of carbon, either platinised or not, in the carbon cell, and small lumps of amalgamated zinc in the zinc cell, by which means the patentee is able to expose a larger amount of the surface of the elements to the chemical action of the fluids in which they are immersed, and give a larger amount of conducting power to the negative element. The zinc is prepared in a comminuted form by pouring it, when in a molten condition, into water, and afterwards amalgamating it. As regards the liquids in which the zinc and carbon elements are immersed, the patentee has found that it is advisable to modify the ordinary practice, and has proved by numerous experiments that some of the best known galvanic batteries, such as the Bunsen, Grove, Daniell and others, would neither be economical nor convenient for the purpose of domestic lighting, because they occasion a large consumption of zinc, and also because there are objections to the use in the carbon cell of nitric acid, as it gives off offensive vapours. With the view of obviating these objections he has obtained very advantageous results by putting in the carbon cell hydrochloric acid, either pure or diluted, with about one-fifth of its volume of water; but its action must be strengthened by the addition of a small quantity, usually not more than from 5 to 10 per cent., of some powerful oxidising agent such as nitrous or nitric acid, aqua regia, chlorate or permanganate of potash or others containing two or more atoms of oxygen.

In the zinc cell he uses sulphuric or hydrochloric acid diluted in the ordinary way, according to their strength, with from eight to twenty parts, or thereabouts, of water to one of acid; but when using hydrochloric acid in the carbon cell, he finds it advantageous to dissolve in the acidulated water of the zinc cell chlorides or sulphates of iron, soda, potash, or magnesia, using by preference, but not necessarily, saturated solutions of these salts.

Amongst recent improvements in storage or secondary batteries we note as containing a novel feature the invention of Mr. D. G. Fitz-Gerald, of Brixton (No. 5481, 1881) in which carbon is employed in conjunction with lead or compounds of lead. The carbon is in the form of fragments, which should be in direct contact with each other at one or more points, whilst the insterstices between the fragments are filled with lead in a state of division, or with an oxide of lead, such as red-lead or plumbic peroxide, or with an insoluble salt of lead, such as the sulphate. The carbon fragments may with advantage be in the first place impregnated or coated with lead by immersing them in a solution of a salt of that metal such as the acetate, and subsequently reducing the metal either by heating the prepared fragments without access of air or by electrolysis, the prepared fragments being in the latter case made the cathode in a suitable electrolyte—preferably a solution of the acetate or nitrate of lead with which a plate of lead is used as anode. In the construction of a cell or couple with the carbon fragments the latter are divided into two portions, each of which is in contact with a plate of carbon, to which a suitable terminal is attached by the use of a binding-screw or by casting on to the carbon plate a lug or piece of lead in which a connecting or terminal wire is imbedded. The two portions of carbon fragments are prevented from coming into contact by the use of a diaphragm of felt, of porous earthenware, of Paris plaster, or other suitable material.

Mr. Fitz-Gerald prefers to employ boxes or vessels of wood rendered waterproof by immersion in melted paraffin, the interior portions being further coated with a waterproofing substance such as marine glue. These boxes, or containing vessels, have two of their dimensions very large in comparison with the other dimensions, so that when one side of the box is removed the remaining portion has the form of a square tray. A plate or strip of gas carbon of smaller dimensions than the bottom of this tray is laid flat upon the latter, and is made to project through the side of the tray sufficient to establish a contact. A layer of carbon fragments of such thickness as nearly to half fill the tray is then laid upon the bottom, and lead in a state of fine division, or an oxide or insoluble salt of the metal is sifted on to the carbon and shaken down into its interstices, the layer being subsequently subjected to a pressure sufficient to bring the carbon fragments into good conductive contact with each other and with the carbon contact piece. A plate of porous earthenware, a sheet of felt or other suitable material to constitute a diaphragm, is then laid upon the compressed layer, the edges of the diaphragm being preferably cemented to the tray. Or a layer of Paris plaster may be run on to the layer of carbon fragments, the plaster being used in conjunction with the felt, or otherwise. Upon the diaphragm is then placed a second layer of carbon fragments with the interstitial spaces filled with lead or a compound of that metal, exactly as in the previous case. The side of the box constituting a lid or cover to the tray is then applied with sufficient pressure to bring the carbon fragments into conductive contact. To secure a watertight-joint strips of caoutchouc may be employed, and for the purpose of introducing the electrolyte a glass tube may be cemented into the upper portion of the box or containing vessel. The electrolyte may be dilute sulphuric acid in the proportion of one of acid to ten or twelve of water.

Mr. J. W. Swan, of Newcastle, has also patented further improvements in secondary batteries, in which, after corrugating the plates, as described on p. 414, Vol. XXXIV., he exposes them to the combined action of acetic acid, carbonic acid, and atmospheric air, which results in the production of a coat of carbonate of lead. The plates thus treated are paired with other lead plates and subjected to the action of electrolytic hydrogen by making them the cathode in an electric generator. They are then made up as in a Planté cell. This invention is simply the use of white-lead instead of red-lead.

Still another invention which compares curiously with Mr. Fitz-Gerald's, above noticed, is that patented by Messrs. Grant and Jones (No. 5521, 1881). The patentees combine lead or other metal with carbon in the following manner. Flour, starch, or meal is mixed with an oxide of lead into a plastic condition by the aid of syrup. The mixture is moulded into suitable shapes and carbonised, the organic matter being oxidised, and the salt of lead reduced to the metallic state. For some purposes the patentees mix red-lead with flour and syrup, and spread it over sheets of paper, which are then folded into suitable shape and carbonised, a solid lead core being used to form an attachment. This utilisation of flour enables the patentees to prepare moulded blocks of a very porous nature, for they ferment the mixture of lead, salt, and flour with yeast, and carbonise it when it has risen, just as if it were bread. The invention includes the use of plates of carbon covered with dusty or granular lead, which is prepared by adding powdered charcoal to molten lead and stirring the mass until cool.

PROPER MOTIONS OF THE STARS.*

By Prof. R. Grant, M.A. LL.D. F.R.S.

THE spectacle presented by the stellar heavens as viewed by ordinary observers is characterised by two remarable features: the absence of uniformity in the brightness, and the absence of uniformity in the distribution of the stars. Certain of the stars soon came to be recognisable by their superior lustre, and certain groups of stars became familiarly known as so many landmarks in the stellar firmament. The way was thus prepared for an important discovery. It was ascertained respecting a limited number of the stars that their places in the heavens relatively to the general multitude of the stars were continually changing. They consequently received the appellation of planets, or wandering stars, while, on the other hand, the stars in general, in consequence of their always maintaining the same relative position, were denominated *fixed* stars. Ptolemy, in his great work upon the astronomy of the ancients, places the earth in the centre of the universe, and assumes the sun, moon, and planets to be revolving in orbits around it, while beyond all was the sphere of the fixed stars, which revolved with a uniform motion around the earth, effecting a complete revolution once in twenty-four hours. No opinion is expressed respecting the nature of the stars, nor is any allusion made to the possibility of the stars being endued with a proper motion.

When Copernicus propounded the true system of the universe, he made the earth a planet revolving like the other planets round the sun, and he explained the phenomenon of the diurnal revolution of the starry sphere by the revolution of the earth upon a fixed axis in the opposite direction. No opinion was expressed by him respecting the physical nature of the celestial bodies, or their having any probable community with the earth in this respect. Indeed, it could hardly be said that any new light was thrown upon the physics of astronomy by the theory of Corpernicus. As a mathematical exposition of the movements of the celestial bodies it was eminently successful. Indeed, it wanted only the discoveries of Kepler respecting the elliptical movements of the planets to make it perfect in this respect. But it must be acknowledged that in the system propounded by Copernicus the earth was regarded as the body of paramount importance in the universe.

It was the invention of the telescope and its application to the purposes of astronomical observation which first revealed to the human mind the marvellous extent of the physical universe, and suggested the idea that the earth might be a mere atom in comparison with the vastness of the material system beyond. When it was discovered that the planets are round dark bodies like the earth, shining only by the reflected light of the sun, and that they presented apparant diameters of sensible magnitude when viewed through the telescope, no doubt was henceforward entertained that the planets are bodies comparable with the earth in magnitude, and that the earth is merely one of a family of similar bodies, which revolve in orbits of different magnitudes around the sun. It is worthy of remark that Galileo, to whom is due the telescopic discoveries which first disclosed the vast extent of the material universe, has nowhere expressed any opinion respecting the nature of the stars. His mind was probably too much occupied with the more immediate consequences of his discoveries to indulge in speculations leading to more remote conclusions; and a similar remark is generally applicable to his successors in the field of telescopic exploration, who flourished during the seventeenth century. It was reserved for Huyghens to propound the doctrine that the stars are suns. This he did in a work on Cosmical Astronomy, which was published in 1699, shortly after his death. Henceforward the stars have been regarded by astronomers as self-luminous bodies, comparable in magnitude and splendour with the sun.

---

* Abstract of lecture delivered at the Royal Institution.

While more correct ideas were being formed respecting the nature of the stars, the method for ascertaining the exact position of an object in the celestrial sphere underwent at the same time a complete revolution. The telescope in its original form was not suited for aiding the observer in fixing the precise position of a star in the heavens, but the subsequent form of the telescope, consisting of a combination of two convex lenses, suggested the admirable invention of telescopic sights, which may be said to constitute the foundation of all exact astronomy. The places of the stars were now determined with a vastly greater degree of precision, and the way was thus prepared for the consideration of the important question whether the epithet *fixed* is strictly applicable to those bodies, or whether they might be rather endued with a movement so extremely slow as to have hitherto eluded detection.

To Halley is due the discovery of the important fact that some of the stars have a proper motion. In 1717 he communicated a paper to the Royal Society, in which he showed that a comparison of the places of Sirius, Arcturus, and Aldebaran, as determined by Hipparchus about the year 130 B.C., with corresponding observations of the same stars made by himself, clearly indicated that during the intermediate interval the stars had sensibly moved southwards with respect to the ecliptic, and he obtained a further confirmation of this result by examining the account of an occultation of Aldebaran by the Moon, observed at Athens in the year 509 A.D.

A few years after Halley announced this important fact, Bradley made his famous discovery of the aberration of light, and its effect upon the apparent place of a star; and subsequently the same astronomer discovered the apparent sidereal movement depending on the nutation of the earth's axis. The astronomer could now ascertain the true place of a star in the heavens with a precision to which the results of previous efforts could offer no comparison, and it seemed probable that ere long the great problem of the proper motions of the stars might be attacked with some hope of success.

To ascertain the proper motion of a star it is necessary to have two well determined places of the star separated from each other by a sufficiently great interval of time. Down to the middle of the last century no such materials may be said to have existed, if we except a few isolated cases, such as those referred to by Halley, for the probable errors in the observed places of a star far exceed in magnitude the minute quantity which was the object of inquiry. To Bradley is due a great work of observational astronomy which has constituted the basis of the more extensive investigations of the present day relating to the proper motions of the stars. This consisted in a series of star observations executed by that astonomer at the Royal Observatory, Greenwich, from 1750 to 1762, but which it was reserved for Bessel, the great German astronomer, to reduce, and finally to publish in the year 1818. A comparison of those star places with the corresponding results obtained at Greenwich Observatory in the present century by Sir George Airy, the late Astronomer Royal, has conducted astronomers to important conclusions respecting the proper motions of the stars. Materials tending to elucidate the same great question have also been derived from the star observations of several other astronomers of the present century.

[The lecturer here exhibited a diagram containing the following illustrations of the proper motions of the stars:—

Star.	Magnitude.	Proper Motion in a Thousand Years. ″
Sirius	1	1360
Procyon	1	1210
Arcturus...	1	2230
α Centauri	1	3710
Capella	1	250
Rigel	1	20
Antares	1	30
Groombridge, 1830 ...	7	7106
61 Cygni	6	5200
O² Eridani	4	4100
Lalande, 27,744... ...	6	1681
Lalande, 30,044... ...	7	1607
Lalande, 30,694... ...	6	1789
Weisse's Bessel XVII.,322	7	1476]

The last four proper motions have been recently detected at the Glasgow Observatory, where a system of star-observing has been prosecuted since the year 1860.

It must strike every one who inspects the foregoing list that the proper motion of a star has no relation whatever to the apparent magnitude of the star. Thus Rigel, one of the most brilliant stars in the heavens, has a proper motion of only 20″ in a thousand years. On the other hand, the star 1830 Groombridge, which has a proper motion of 7106″ in a thousand years, is a star of only the seventh magnitude. The same remark obviously applies to the other stars in the list. And yet one would have thought that the brighter stars, being presumably nearer to us than the fainter stars, would for that reason have a larger proper motion. With respect to α Centauri and 61 Cygni, which we know, from the researches of astronomers on their parallax, to be the two nearest stars, it turns out comformubly to what one might expect, that they have also large proper motions; but what are we to think of 1830 Groombridge, which, although a star of only the seventh magnitude, and one which hardly indicates any sensible parallax, exhibits notwithstanding the largest proper motion of any star in the heavens? These anomalies are doubtless attributable to differences in the absolute magnitude and intrinsic splendour of the stars, and furthermore to the fact that the proper motions as revealed by the telescope are only the motions which are resolved at right angles to the line of sight.

Heretofore the proper motion of a star has been found to take place constantly in the same direction and as the angular amonnt of proper motion is in all cases exceedingly small, the same result will probably continue to manifest itself for ages to come. The mean apparent diameter of the sun amounts to 1944″, consequently Arcturus would require nearly a thousand years to describe, in virtue of his proper motion, an arc of a great circle of the celestrial sphere, equal to the mean apparent diameter of the sun.

HOW ANIMALS BECAME CARNIVOROUS.*

IN the scale of creation plants were developed first; they began as very low forms or may even all have sprung from one low form. As time went on they grew in number and variety. Some slight circumstance was sufficient to cause one to change its character, and it handed down its peculiar character to its offspring. In this way fresh varieties of plants were formed, and now we have an immense number of all sorts. Some are content to carpet the fields like the daisy, whilst others thrive best by shooting up into the air like buttercups, but each one has assumed its present shape by finding that it could so get on best. These changes were not made in a few years, but are the works of centuries, and if anyone could have watched them he could scarcely have been able to tell where a change began, so minute were the differences. After the plants had appeared—or almost at the same time—the lowest forms of animal life appeared and fed on the plants. These low forms of animal life had also to differentiate themselves by some stress of circumstance, and in time new kinds of animals were the result. Some insects were forced by stress of circumstances to feed on each other, they did this for some time; their organs changed in structure, and in time it became right for them to feed on carcases.

We see an everyday example of this in the midge; it sucks the blood of animals if it can get it, if not it feeds on the sweet juices of plants. The leech is also another example, it feeds on vegetable food in the pond in which it lives, but it will live on the blood of an animal if it can get it.

No doubt at one time animals were herbivorous, but some stress of circumstance made them feed on the bodies of one another until they developed certain peculiarities, and hereafter it was right for them to do so, and now they are called carnivorous animals. Let us instance many goats on an island, they increased in number until there were more goats than there was food for them—this is now a recognised law. Some died of starvation or in the fight for food; one was very hungry, and tearing off the skin it eat the flesh of its fallen kin. The flesh appeased its hunger, and when hungry it again returned to the carcase, and thus it went feeding on dead bodies. After a time it began to like flesh, and when it could not get dead bodies, then it killed its kind and fed on them. The offspring of this animal would tend to do the same, and since it has to fight for its living it has to grow new parts. Its teeth must change, its limbs must also change, and the character of its stomach must alter. After a few centuries we find a different animal from the original goat; in fact, we have now a carnivorous animal. From this instance you see how changes may occur. Some one may say that goats could not be taught to eat flesh, but experiment has shown that goats and sheep or any animal can be taught to eat flesh until it refuses its natural grass, hay, or corn.

A change of this nature has been lately seen in New Zealand. In the memory of man the kea or *Nestor notabilis* was a fruit-eating parrot. Sheep were introduced into New Zealand, some of them died, and the kea tearing off the skin eat some of the flesh. It liked it and began to feed on flesh only. Now, as dead sheep were not always to be had it attacked living sheep; killed them and fed on their bodies. The kea is now a carnivorous bird, and in consequence is killed wherever found. Man himself has tried to be carnivorous or partly so. His original dwelling-place was in a hot country where he had fruit all the year round. He increased rapidly, and to find food emigrated to places where fruit was only ripe once a year, so that he could only live on it for about six months. In winter he killed animals for food, and found that by eating their carcases he could live until the summer came round. He found hunting hard work, so he tamed the young of the cow and the sheep, and killed them when he wanted them. This has now gone on for ages, and man has begun to think that a mixed diet suits him best. But for all his carnivorous practices he has not changed his nature yet; his teeth, tongue, stomach, length of intestine, flat nails and perspiring skin all point to his frugivorous character. That such is his nature seems beyond dispute, and that men can live without flesh food is now an everyday experience. There are hundreds of men now living in England who never eat meat from year's end to year's end, and they are as strong as other men and remarkably free from disease. Let readers ponder over this, try and live without meat, and they will soon come to the conclusion that man has no carnivorous traits.

DRYING MOULDS.*

A WELL-DRIED loam or dry sand mould is a very essential point in making a casting that shall be free from scabs. Some irregularity may be admissible in the mixing of the loam or blacking; but it must be thoroughly dried. When the water in a damp mould is heated, it is converted into steam, and steam, when confined, creates pressure. Iron, when poured into a mould, heats up the surface and interior portions, and this heat generates steam if moisture is present, and the mould is very rarely strong enough or close enough to hold the pressure, which increases until it forces an opening through which it can escape. This may be towards the surface away from the iron; but it is more likely to be in a direction towards and through the iron. The outside of a mould is generally encased by an iron flask, or held by a curbing, between which and the brickwork sand is rammed hard and compact, and, with the exception of through a few vent-holes, it is almost impossible for steam to escape in this direction. Towards the face of mould the brickwork is open, or, if it is a dry sand mould, the surface is generally made porous by vent-holes, so that it may be seen why steam will escape through the surface of a mould before it will find its way through the outside. This is the reason why a damp mould will cause a casting to scab.

It may be asked, Why does not a green sand-mould scab, the sand being damp? True, the sand is damp; but there is a certain limit to this dampness, which, if overreached, will cause trouble. The surface of a loam or dry sand-mould is generally hard and close, while that of green sand mould is porous, thereby permitting the steam generated at the surface of the mould to escape through the sand until it is free; but should the green sand be rammed too hard then the steam cannot force its way through, and it will come up through the surface of the mould and pass up through the liquid iron, thereby making a scabby or bad casting. A green sand mould that is rammed too hard, and a loam or dry sand mould that is not dried, have very much the same effect on the casting. Whether a loam mould is dry or wet is very often guessed at. The moulder will say it looks dry, and that as it has been in the oven a long time it must be dry. It is not the length of time a mould has been in the oven nor the looks of its surface that can always be depended on to indicate its quality of dryness. A mould that should be dried in two or three nights is often only half-dried, as the oven may not work well, or there may have been some neglect on the part of the watchman. The fire may have been very hot for a short time, thereby scorching or burning the surface of the mould, while the interior is not half-dry.

There is a great deal to be done in the way of properly managing a fire so as to save fuel and dry a mould as it should be dried. The first fire should be a slow and easy one, so as not to blister or crack the surface of the mould, which is caused by the effects of the steam—quickly raised under the surface—to escape. This steam meeting the resistance of the half-dried blacking, which is very much like a sheet of rubber, stretches and blows it up into little hills, but has not sufficient pressure to burst through and escape. There are many who think that by keeping a slow fire all the time to dry a mould or cores they save fuel. In some cases this may be so, as when a mould has a little body, so that one night's firing will dry it; but when a mould has a large body, after the first easy firing, in my opinion, there will be more fuel saved by keeping a good steady fire than by keeping a slow one. A slow fire will drive the heat in for about 8in., after which the further drying will be very slow. With some moulds or cores this slow firing might be kept up for a week and yet the interior not be dry. Whereas if the fire had been hotter the heat would have been forced into the interior and the steam and dampness expelled with probably two-thirds less fuel. I have seen large cores put into an oven and orders given for a slow fire for fear of burning them, and after there had been fuel enough used to dry two sets of such cores, the boss would get disgusted because they were not dry, and give orders for a very hot fire, at the same time looking at the cores as if to say, "We will see who is to be boss." When the cores came out of the oven in a burnt condition, one could imagine them as saying, "Well, Mr. Boss, if you had used better judgment we would all have been well dried long ago." In the making of large body-moulds, or cores, there should, if possible, be openings made from the centre to the outside to assist the steam in escaping from the interior; and also, when possible, the centre portion should be filled up with coke or cinders as much as can be safely done. The more coke or cinders the less sand and firing will be needed. Plenty of venting in moulds or cores is also a great assistance in drying. It is generally easy to tell when a dry sand mould or core is dry; but with loam moulds it is not so easy. Very few loam moulds are made; but that the following plan could be adopted for determining if they are dry. Let the moulder, when building the bottom part of his mould, make an opening that will allow the inserting of a wet brick, or a lump of wet loam, and on the outside of this let the opening be closed with temporary brickwork and mud. When he thinks his mould is dry, he can pull out the temporary brickwork and see the condition of the inserted brick or lump of loam. If this part of the mould has been placed away from the fire, and this brick or loam, when broken, is dry, he can generally depend on the mould being dry.

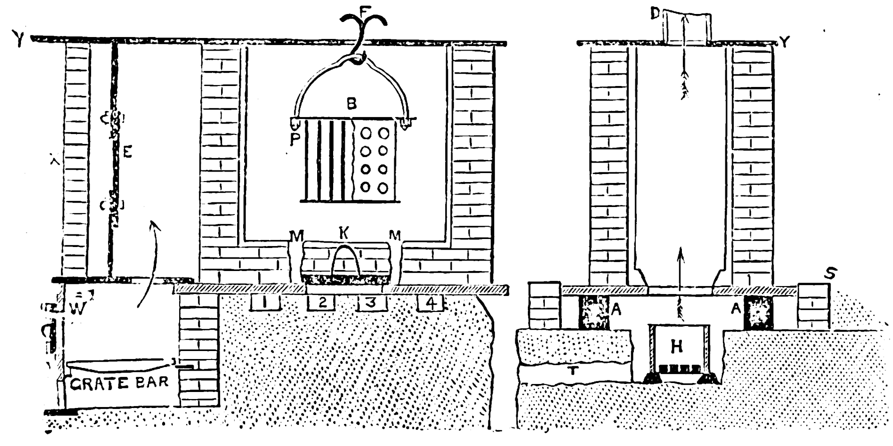
---

* By T. R. Allinson, L.R.C.P., &c., in the *Field Naturalist*.

* By Thos. D. West, in *American Machinist*.

The cuts shown are for illustrating some of the ways of drying loam moulds, that are too large to be dried in the ovens or too heavy for the crane to lift, making it necessary that they be dried in a pit or on the shop-floor. B is a fire basket, sometimes made in the form of an open grate-frame work all round the sides, as shown at P, and sometimes of boiler-iron, drilled full of holes, as shown. For bottom grate-bars in both styles, wrought-iron rods are generally used. The baskets are made round or square in form, according to the shape of moulds there are to be used in. The width and height will depend upon the dimensions of the mould. There should be at least 18in. of space between the surface of the mould and the fire-basket, to prevent burning the surface of the mould before it gets thoroughly dried. Sometimes, instead of using one large basket, three or four smaller one are used, in order to better distribute the heat.

When the mould has a bottom in it, like the one shown, the baskets are generally hung by having the hook F held up by a crane, or a strong bar. When a mould has no bottom in it, the basket can be let down so as to rest on bottom bearings. For moulds of this class, it is best, when possible, to have them hoisted up so as to have the bottom part of the mould about on a level with the top of the fire-basket, the better to dry the lower part. When the inside of a mould is too small to admit of a fire-basket being placed in it, a temporary fireplace is made adjacent to the bottom of the mould, and the heat made to pass up through the inside of the mould, by having the outer opening or space closed up with brickwork or sand, as shown at S. The fireplace shown at H can be made in the form of a basket, and placed directly under the mould or core. This basket can be pulled out to clean and renew the fire. Or there can be a temporary fireplace, as shown at W, built up outside of the core or mould, and the heat conducted through a channel to get to the inside of the mould. To confine the heat, the moulds are generally covered over with sheet or boiler-iron plates, as shown at Y Y. D is a stove-pipe, to carry off the smoke and create a draught. E is a sheet-iron curbing for retaining the heat. X is a brick wall for the same purpose. Either the wall or the curbing will answer the purpose. The combined fires are only needed when there is over an 8in. wall to be dried, in which case a fire in W, so as to heat up the outside of the mould, is combined with a fire on the inside of the mould, and also channels, as 1, 2, 3, and 4, connected with the fire W, to carry the heat underneath the bottom plate, which should have plenty of holes in it. The two fires thus combined will thoroughly dry a mould. These channels can be formed by using brick, or rough gutters can be made in the sand, either of which, if desired, can be filled up with sand after the mould is dried. The heat could be got under the bottom by having the plate raised on iron blocking, as shown at A A. It is always the bottom portions of such moulds that are the hardest to dry, especially so if the mould is built up in a pit. In such cases, it is a good plan to have, when possible, a large hole cast in the bottom plate, so that when the bottom is being bricked up there will be a part of the mould left open. Then below this opening in the mould let there be a small pit dug with channels T, to the outside of the mould, to admit air to the pit, creating a draft. Then, with a fire-basket lowered down through the mould into the pit, we would have a fire below the bottom of the mould the same as shown at H. After the mould is thoroughly dried by the combination of the fire-baskets H and B, the pit is filled up with sand, and a plate having built upon it bricks or core-sand and previously dried and still hot, is lowered down to fill up the opening, as shown at K. Between the two plates there should be a little soft loam to form a solid bearing. The open space M M, is then filled up with a dry mixture of loam, and should the top surface not be even with the original surface, it is made so by filing off or building on. A thin sheet-iron plate, having on it a charcoal fire, is laid over so as to assist in drying out dampness.



Sometimes when building the bottom of a loam-mould that is very thick, it is best to partially dry the bottom brickwork before the upright portions of the mould are made; which can be done by having the plate raised up and a wood fire underneath and a charcoal fire on top. After this the bottom can be permanently set where wanted. The best kind of fuel to use in the fire-baskets will depend on the draught. Charcoal requires the least air, gas-coke more, and soft and hard coal and coke the most. The moulder must use his own judgment as to the best plan to be adopted for drying any particular mould, as there are hardly two moulds that the same drying arrangements should be used for, but it is hoped that from some of the different plans given there can be found one that will answer his purpose.

ALLOY FOR SILVERING METALS.

A METHOD for silvering, or, more properly, whitening metals, has been recently devised by M. De Villiers. It is a modification of the tinning process, an alloy being used instead of the pure tin. This alloy consists of 80 parts tin, 18 parts lead, and 2 parts silver, or 90 parts tin, 9 parts lead, and 1 part silver. The tin is melted first, and when the bath is of a brilliant white the lead is added in grains, and the mixture stirred with a stick of pine-wood, the partially-melted silver is added, and the mixture stirred again. The fire is then increased for a little while, until the surface of the bath assumes a light yellow colour, when it is thoroughly stirred up and the alloy cast in bars. The operation is then carried out in the following manner:—The article, a knife blade for example, is dipped in a solution of hydrochloric or sulphuric acid, rinsed with clean water, dried and rubbed with a piece of soft leather or dry sponge, and finally exposed to a temperature of 70 deg. or 80 deg. Cent.—158 deg. to 176 deg. Fah.—for five minutes in a muffle, to prepare the iron or steel to receive the alloy, by making the surface porous. If the iron is not very good the holes are large, and frequently flaws and bad places are disclosed, which make the silvering more difficult. With steel the process goes on very regularly. The article, warmed to, say, 140 deg. Fah., is dipped in the bath, melted in a crucible over a gentle fire. The bath must be perfectly fluid, and is stirred with a stick of pine or poplar; the surface of the bath must have a fine white silver colour. For a knife-blade an immersion of one or two minutes is sufficient to cover it; larger articles require five minutes of immersion. After taking it out of the bath it is deeped in cold water, or treated so as to temper it, if necessary. If left too long in cold water it frequently becomes brittle. It is then only necessary to rub it off dry and polish without heating it. Articles treated in this manner look like silver, and ring like it too, and withstand the oxidising action of the air. To protect them from the effect of acid liquids like vinegar, they are dipped in a bath of amalgam, composed of 60 parts mercury, 39 parts of tin, and 1 part of silver: then dipped warm into melted silver, or electro-plated with silver to give them the silvery look. This kind of silvering is said to be very durable, and the cost comparatively small.

RECENT ADVANCES IN PHOTOGRAPHY.—III.*

By Capt. ABNEY, R.E., F.R.S.

THE next spectra are exceedingly interesting, to me at all events, and I should like them to interest you. They represent a new form of molecule. I believe very few people know anything about them. The peculiarities of the mixture were discovered by me, and a paper about them sent to the Royal Society a very short time ago. That molecule is this: it is not a combination between iodide and bromide in the ordinary acceptation of the word, that is to say, it is not $Ag_2 Br_2 + Ag_2 I_2$, or not simply one equivalent of each of bromide and iodide of silver added together, but an absolute combination, $Ag_2 Br I$, or a double molecule, which has been formed, and on which the spectrum has a totally different effect. You will see (No. 7) that, instead of having the maximum intensity at G, its maximum is far into the green, and it has a minimum about G. In the same way another molecule is formed by a combination of molecules of chloride of silver and iodide of silver, and that, too (No. 8), has no maximum about G, but has a minimum there, which is the place where the maximum sensitiveness is found in the ordinary iodide of silver.

I will try and explain how these last curves are produced. If you take iodide and bromide of silver together, and expose them to the spectrum, what happens is this: first of all, iodine and bromine are liberated. What becomes of the iodine and bromine? The bromine immediately attacks the sub-iodide of silver, and forms a new molecule, $Ag_2 Br I$; the bromine undoes the work of the iodide as fast as it is done, so that we have, in the place of maximum intensity of the iodide, the least work done. In the same way with the chloride. The chlorine liberated from the chloride undoes the word which is done by the iodine; the consequence is that, in the place of maximum intensity of the iodide, we have a diminution of intensity in the case of the double salt; in other words, the dry bromo-iodide of silver is less sensitive for the spectrum about the part G than any other part of the spectrum to which it is sensitive. In order to prove that, I tell will you a little experiment which was carried on by myself. Chloride of silver was absolutely blackened in the light, and sub-chloride was formed; then it was treated with iodine again, and it become a buff colour. When this new molecular form was placed in the spectrum, we got exactly the same result as we do here, showing that we have a new molecule of chloro-iodide of silver. I think this will very likely throw a great deal of light upon some of the phenomena which are met with in ordinary dry-plate work.

---

* Condensed from a series of Cantor Lectures delivered before the Society of Arts.

Now I crave your attention to one thing. You may ask if chlorine always undoes the work done on the iodide. The fact is, that it does not, if you have free nitrate of silver present: since this salt is able to take up the iodine and bromine, therefore the bromine cannot act on the sub-iodide of silver; it leaves it there, and you have the impressed spectrum totally different; in fact, the bromide and iodide spectrum are superposed one on the other. There are a great many facts I could show you to prove this. We come to the conclusion then, for sensitiveness, you must have a sensitiser present. In gelatine plates, you must say that gelatine is a sensitiser, but it certainly is a very feeble one; anyhow, if you want to get sensitiveness in a plate you must have a sensitiser present which will mop up, not only iodine, but bromine. When this is the case, bromine cannot go and destroy the work done on the iodide.

Before concluding this part of my lecture, I may also say that I have found that the printed image and the developed image have precisely the same characteristics. Thus, if you get pure iodide of silver, you get the termination of both the printed and developed spectrum close to G. A curious thing with regard to iodide is this: if you have the smallest trace of impurity in it, it is immediately shown in the spectrum by a prolongation below G, and you can go to the chemist and tax him with having given you iodide which is not pure.

Now there is one point that has exercised the minds of a great many photographers, and that is the illumination of their dark rooms; and I hope I may be excused if I go over what may be apparently well-trodden ground, but I believe that there are many here present who have no absolute certainty as to why they are using certain glasses to glaze their developing rooms. I want to show photographers the absolutely safest light they can use in developing their pictures. Here we have a spectrum, and beyond it you see the fluorescent rays. I will ask Mr. Woods to pass through the spectrum one or two glasses. First of all, we will take ruby glass (No. 2), and you will see that when it becomes very bright indeed, there is a certain amount of blue light comes through the glass; I can see a trace of yellow, and a trace of green. Now I will take the yellow glass: here is one which photographers are very fond of, but I dare say you will see that there is a great deal of blue light comes through that. That was the ordinary glass used for photographic dark rooms within the last half-dozen years, and people were perfectly content if they glazed their rooms with it. But there are yellows and yellows, and I will show you the difference between two. Now we will have a magenta (No. 4), which you see cuts off a great deal more light. The next (No. 6) is a stained red glass, which cuts off the green, too. Now, there is one combination which I wish to show you, because people often complain that their photographic studios are not safe as to light, and that they use ruby glass and get foggy plates. I have great doubt about fogging bromide plates with proper red glass, where ordinary precautions are taken, though not with the ruby glass which lets blue light through. If people would only use the spectroscope with a strong light, they would very soon see where their glazing is at fault. Now, I will throw on the screen the light through a piece of blue glass (No. 1), and I think you will see that there are bands in the red and yellow: there is plenty of blue coming through and some green. If photographers want to be absolutely safe, let them glaze their studios with cobalt glass and stained red, and they will get nothing but the light of that particular refrangibility which I will warrant is totally unable to affect any gelatine plate—of the ordinary type, at all events. You may glaze and glaze with ruby, but you will never get rid of blue light entirely. Of course it diminishes with every thickness you take. If you want to use ordinary plates, which are not so sensitive that you cannot look at them, my advice is to use a combination of stained red (No. 6) and ruby glass (No. 2), which will give you a comfortable light to work in, for it cuts off the blue, and leaves the red in a brilliant patch. Those that are using that combination ought to have nothing to fear; but if they still fear, let them use a combination of cobalt (No. 1) glass and stained red glass (No. 6), and then they will only get the colour of that narrow strip of light which you saw just now. I should like to show you the green glass in the spectrum (No. 7), that you may judge what kind of light gets into it. It was at one time seriously recommended as an admirable thing for not trying the eyes, and for being safe to use in the developing room. A combination of red and green is a fairly safe light for iodide plates or ordinary plates, but not for gelatine plates, which are extremely sensitive. Next we come to a series of pretty colours, which may be very useful to us. Here is the spectrum of magenta (No. 4); the yellow is cut out entirely, and the green, leaving the blue, violet, and orange. Now I will try aurine (No. 8) and chrysoidine (No. 3). Here you see the blue is gone entirely. Some have said that the ultra-violet rays go through aurine, but I will leave it to you to say whether they do or not. There is no trace here of the ultra-violet rays when I apply this card with the sulphate of quinine on it. They should appear if there were any. We have next a combination of magenta and aurine, which is a perfect red light, and is very good indeed for the photographic studio. I think I may say, without a breach of confidence, that I believe a certain "ruby medium" in the market is made according to the directions that I gave some time ago. You may ring the changes of combinations of these glasses; you may have scarlet and aurine, or mageta and aurine, and either one or the other will give you this red band only. If all other means fail, the photographer may use the ferrous oxalate developer. You will see that it cuts off the blue light at all events. I should not at all mind developing a plate in such a light as that. In fact, you may bring the most sensitive plate out into a white light, when developing in a dish, with a covering of ferrous oxalate over it.

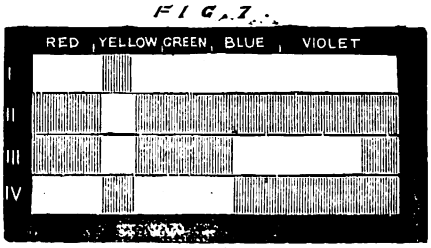
9. Quinine.

In 1874 we had a most astonishing discovery made, and that was, that by dyeing a film of sensitive collodion you were able to get an increased action by the spectrum. In common with others I took up that subject and investigated it, and I wish to draw your attention very briefly to it to-night, because I think it is one of the advances made in photography which ought not to be passed over. If you take one of these aniline dyes, such as a blue dye, and expose it to light behind a piece of black paper, with an aperture in it, such as I have here, you get an image on the dye, such as you see. What is the meaning of that? The meaning is that the dye is oxidised, for if you apply an oxidising agent you get the same result. Dr. Vogel found that if you dyed plates with some of these fugitive dyes—they were all fugitive to a great extent which he used—he was able to obtain an extension of the impressed spectrum exactly in those parts in which the dyes were absorbed, and he introduced the term optical sensitiser to describe the fact. Now, I am going to quarrel with that expression, because he explains it in this way; he says, in effect, that the sensitive aniline dye is able to take up a vibration, and to direct it to something else; in other words, that when light has done all it can in endeavouring to bleach a dye, that its period is transformed, and it does something else on the silver salt which is in contact with it. Well, that is not a philosophical way of looking at things, because if you could only arrive at that principle, you might just as easily arrive at the principle of perpetual motion, which is a thing which I am not prepared to admit. Now, I honestly say, that for a long time these experiments staggered me, and the arguments Dr. Vogel brought forward seemed fully to justify his term of optical sensitiser, as applied to the dye-stuff; but eventually I was able to come to a different conclusion, and that conclusion I wish to put before you. If you have a substance which is oxidised in the presence of a haloid salt of silver, what do you expect? You expect that the haloid salt of silver would be reduced. If you place pyrogallic acid in contact with the haloid salt of silver, and help it to be oxidised by ammonia, you expect that the haloid salt of silver will be reduced, and I lay the action of the dye to precisely the same principle as the pyrogallic acid, which helps to develop the image; in other words, the oxidation of the dye causes a reduction of the bromide of silver, or iodide of silver, as the case may be, and simply provides a nucleus on which development can take place. I wish, however, to point out that Dr. Vogel has an objection to my explanation. He says, "Oh, but you require time to bleach things; you require time to alter them." So you do; you require time to blacken the chloride of silver; nevertheless, the slightest exposure to light begins the change in it, and so the slightest exposure to light begins the change in the dye, and on this principle, of course, the action of dyes upon sensitive films can readily be explained.

I have got behind the screen three pieces of sensitive bromide paper, one dyed with a blue dye, another with eosine, the third, pure bromide of silver, without anything. I propose to develop those on the screen. I must give this a rather longer exposure than last time, because blue dye takes away the sensitiveness to a material extent. You can see the colour—it is somewhat of a lavender grey, which no doubt will show that it absorbs exactly in the same position where the extra length of the spectrum is developed. In the eosine, I dare say you notice a peculiar dimming of light about the green; this is a very fluorescent dye, and it is in that position where we shall expect the action to take place. I will, however, show you where the absorption takes place of these two dyes we have used. This is a spectrum of the dye: it lets the ultra-violet rays through; in the green we have a great cutting-off. Here we have the cyanine, which is a different colour altogether. It cuts off the yellow, and also the green; therefore, on the principle of work, we should expect that where absorption takes place in the dye, there dye would be oxidised, and the silver reduced in consequence. I now expose the three slips of paper above alluded to, and I will develop them before you. [The papers were developed in yellow light, as before.] The impression of the spectrum on the eosine-dyed paper flashes out, the part in the green comes out very strongly indeed. The blue-dyed paper shows, besides the ordinary spectrum of the bromide, a band in the yellow. Finally, we have the undyed paper. The above diagram shows the effect obtained on cyanine blue. Here you see the marked difference in the three cases.

FIG. 7.



USEFUL AND SCIENTIFIC NOTES.

The Tractrix Screw Propeller.—This propeller has some points of novelty which deserve attention. Its surface is generated by the tractrix curve, which is claimed to be the only natural form of least resistance to rotation. The resistance at the root of the screw is abolished, and a direct thrust astern is obtained, the propeller being the only one which forms a complete column of water astern at all speeds. The tractrix screw is said to apply its power in the same direction as that in which the water is moving at the time of entering the propeller; and amongst its advantages may be noted the same efficiency at all speeds, greater length and strength of blade, with smaller diameter, and the minimum of noise in working. The tractrix propeller is decidedly worth a trial, especially in steam launches, to which its comparatively small diameter admirably adapts it.

Paris as a Seaport.—While Manchester merchants are seriously discussing the project for making a waterway between that city and the sea, the French Society of Civil Engineers have recently had under consideration a project of M. Bouquet de la Grye, hydrographer to the Navy, for rendering Paris accessible to ships with a draught of six or seven metres (20—23ft.). He proposes to deepen the Seine bed by dredging, and to lower the water level between Rouen and Poissy, so forming a maritime basin about 103 miles long and 150ft. in width. The excavation would progressively reach a depth of 53ft. below the present bottom at Poissy, and the water level would be lowered about 40ft. The quantity of matter to be removed is estimated at 75,000,000 cubic metres. Only the sharper curves of the river would be avoided; bridges would be raised or rendered movable. At Poissy vessels would rise by a "cascade" of locks, about 110ft. in the forest of St. Germain, to an upper canal, fed with water from the Seine, by means of turbines driven by the fall of Seine water at the locks of Poissy. This canal would extend to Aubervilliers, passing above the Seine and the railways; its level would be nearly that of the canal of La Villette. There would be two harbours, a lower and an upper, at the borders of the forest of St. Germain, and ships going to the higher canal would not interfere with those at the lower port, whence Transatlantic merchandise would be sent straight to the Rhine Valley. The expense of th lower canal between Rouen and Poissy is estimated at about 150,000,000 francs, that of the upper about 100,000,000. The scheme has been vigorously discussed, and some eminent engineers have taken grave objection to it.

SCIENTIFIC NEWS.

ON the 23rd of the present month the annual general meeting of the British Association will be held at Southampton, when Dr. Siemens, the President-elect, will be inducted to the chair and read his address. The presidents of sections are:—A, Mathematical and Physical Science, Lord Rayleigh; B, Chemical, Prof. Liveing; C, Geology, Mr. R. Etheridge; D, Biology, Prof. A. Gamgee; department of Zoology, Prof. M. A. Lawson; department of Anthropology, Prof. W. Boyd Dawkins; E, Geography, Sir R. Temple, Bart.; F, Economic Science, Right Hon. Sclater-Booth, M.P.; G, Mechanics, Mr. John Fowler. The American and the French associations meet about the same time and last as long as the British, which, so far as the American Association is concerned, is unfortunate, as the meeting in Montreal was intended to have an international character, at all events so far as regards English-speaking races.

The following ephemeris of comet Wells may be useful. The time is Greenwich midnight:—

	h. m. s.		° ′
Aug. 6	12 4 51	N. Dec.	4 22·7
10	12 13 43	,,	3 48·2
14	12 21 56	,,	3 15·7

The volume of Greenwich Observations for 1880 has been published.

Mr. Tebbutt, of Windsor, N.S.W., who discovered the great Comet of 1881, has undertaken to organise a society of amateur comet-seekers in Australasia. The Boston Scientific Society is the prime mover in this enterprise, which it will be remembered Mr. Denning has endeavoured to promote in this country. The additions made to the list of comets in recent years are ample encouragement to those who will undertake to systematically sweep an allotted portion of the sky.

It is stated that Mr. A. Marth will have charge of the Transit of Venus station, at Aberdeen Road, Cape Colony, Mr. Burton, the observer previously appointed, having died suddenly.

The statue of Darwin, to be placed in the Natural History Museum at South Kensington, will be executed by Mr. Boehm.

The report of the City and Guilds Institute for the 1882 Technological Examinations, shows a considerable increase in the number of candidates, and also in the number of subjects, the former probably depending to a certain extent on the latter. Although some of the examiners are able to report favourably, and others hopefully, there is abundant evidence of the need of these examinations, or rather of the education which they are supposed to test. Taking all the subjects (37) together, the percentage of failures amongst all the candidates is 38, but amongst those candidates coming from classes affiliated to the Institute, it is 42·3 which compares favourably with the 50·6 in 1881. The proportion of candidates who have fully qualified by passing the examinations of the Science and Art Department is small—only 400 of the 1,222 successful candidates having obtained the requisite certificates of the Science and Art Department. That is nothing more than might have been expected, and the sooner the regulation is abolished the better for the success of the City and Guilds Institute examinations. The reports of some of the examiners are severe, but no doubt just, and call for serious investigation. For instance, Prof. Graham, the examiner in so simple and yet important an industry as breadmaking, says, "In the pass examination forty candidates entered; not one has passed. Those numbered 1343 to 1390 seem to be children who have been crammed by a person grossly ignorant of the subject, and whose sole idea has been to get the children to learn by rote various parts of my 'Cantor Lectures.' Parrot-like, they repeat my words, not only without knowing their meaning, but mixing them up so as in many cases to produce the most absurd nonsense." Capt. Abney says "some of the candidates who sat knew absolutely nothing either of the practice or theory of Photography." Mr. Holtzapffel (Tools), and Mr. Thrupp (Carriage Building), complain that the candidates are unable to draw, while Prof. Perry (Mechanical Engineering) reports an improvement in the "character of the sketches," although he finds that "good teaching" is still wanted.

One would have thought that scientific instruments employed in works of public utility were safe from the mischievous fingers of the British Tourist; but Mr. Clement L. Wragge writes that on July 23 it was discovered that malicious or wanton damage had been done to the intermediate station at Red Burn, on Ben Nevis. The thermometer box had been broken into and the wet bulb broken, while the compass points had been removed. The station is about 2,700ft. above the sea.

An ingenious patentee proposes to supply towns with the electric light free of cost. His "idea" is to attach the lamps to advertising columns, and the rent paid for displaying the notices is supposed to cover the cost, and leave a surplus sufficient to pay a good interest on the outlay.

Herren Nies and Winkelman are reported to have made a series of experiments on the changes in volume of metals on cooling from fusion. They find that tin, zinc, bismuth, antimony, iron, and copper, all expand at the moment of solidification, and they have reason to believe that the same holds good for lead and cadmium. They believe, in fact, that all metals expand on solidification, which, it should be noted, means the moment of solidification, as the majority contract on cooling. It is only at the moment of change from the fluid to the solid or semi-solid state, that the expansion takes place.

Mr. F. W. North's report on the coal-field of Natal estimates that the field in Klip River county covers about 1,350 square miles, and contains over 2,000 million tons of workable coal. The quality is good.

As an indication of the interest taken by the United States in fish culture, it may be mentioned that the Government has voted a sum of £10,000 for the International Fish Exhibition, at which America will be fully represented by a splendid collection of appliances and models.

M. Cailletet recommends vaseline as a lubricant wherever mercury is likely to be present.

While the instantaneous photography of objects in rapid motion is now practicable, that of objects at rest, while the apparatus is in rapid motion (of translation), is of course also practicable—*e.g.*, photography of landscapes from a railway train or a balloon. M. Candeze has lately described in the Belgian Academy some successful attempts to photograph from trains. He supported the camera with both his hands to avoid shaking as much as possible, and directed the objective to the landscapes passed. The objective was of special form. Instead of a longitudinal tube with the lenses screwed into its two ends, he used a tube placed transversely, carrying its lenses opposite each other in the curve. Within the tube was a light drum, moving under the action of a spring on release of a catch. This drum had two quadrangular apertures, and was at once shutter and diaphragm, producing on the sensitised plate a sort of flash, the duration of which could be made as short as a hundredth of a second The views obtained have not, of course, all the fineness of those taken under ordinary conditions, still they are regarded as very satisfactory. Their size is that of an album-carte. With regard to focussing, this, being impossible for each view, is done, once for all, in advance on an object distant about 100 metres. The distinctness is then general from that point to the horizon.

The natural caves at Roquefort (Aveyron) are an interesting formation, of which the following are some particulars from a recent account. From the north slope of the plateau of Lazac rises the mountain of Cambalou, with an abrupt escarpment on the north side. At some epoch undetermined, part of the oolite rocks of this hill slipped down, following the motion of the clay beds on which they rested. The strata tumbled about in great blocks, formed a new irregular ground, with numerous fissures. The air entering these forms currents in various directions, while the percolating water of rains affords abundant moisture. It was on this new ground that the village of Roqnefort was built, at an altitude of about 2,590ft. It is those faults or fissures and the fresh air circulating in them that have been utilised for the preparation of the cheese produced from the milk of the sheep in that region. The natural grottoes were the first caves, and at their mouths were afterwards formed larger spaces, which are the present caves with their accessories. The temperature of the caves varies between 4 and 8 degrees C. from day to day, and from one cave to another. The air coming through the faults is charged with moisture, showing, on an average, 60° in the hygrometer. It is these relations of temperature and moisture that give the caves their high value for the industry referred to.

The influence of snow on the temperature of the lower strata of air has been shown by Herr Billweiler from a comparison of the last two winters at Zurich. There were very much the same general conditions of weather, long prevailing barometric maxima with abnormal heating of the upper air and frost in the lower; but, whereas, in 1879-80, the temperature at Zurich sank to − 13 °C. early in December, and repeatedly reached −9·5° and − 10·5°, last winter the extreme colds were only − 3·5° and − 4·2°. (The extremes for Switzerland in the two winters were, −20° and −8·5° respectively.) Now, these winters were greatly in contrast (and especially in December), as regards snowfall in Central Europe. The influence of the snow cover consists in its breaking, as a bad conductor, the connection between the ground and the air. In December the ground is considerably warmer than the air, which is thus slowly heated from below if snow is absent, but the snow interrupts this transference of heat almost entirely. The surface of the snow cools greatly by radiation, and this cooling is shared directly by the air.

The sense of hearing in insects has been recently studied by Herr Gruber. Of air-insects he found the cockroach (*Blatta Germanica*) very sensitive. On sounding a violin-note when a cockroach was running across the floor, the creature always suddenly stopped. Again, a number of these cockroaches were enclosed in a glass vessel, and on making a strong sound, there was evident agitation and excitement; some would fall down from the glass, as if paralysed. A cockroach was hung by a thread from its hind leg; when it was quiet, a bow was drawn sharply over the violin-strings at the distance of about 4ft., whereupon the insect was greatly excited, and struggled round, getting its head uppermost. Beetles also were readily affected by sounds; but grubs and ants gave no certain indications. Of aquatic insects, various kinds of *Corixa* were tried. These would often remain quite quiet for several minutes, but on tapping the glass with a glass tube, they rushed about in much agitation. A disc at the end of a long rod, drawn to and fro in the water near a quiet Corixa produced no effect; but on conducting the sound of a struck bell into the liquid by the rod, there was lively reaction; similarly, when a glass bell, stroked with a bow, was brought to touch the water. These creatures were also sensitive to high violin notes in air, to the sound of a metal plate struck with a hammer, &c. Still more sensitive to sound were various aquatic beetles (*Laccophilus*, *Laccobius*, *Nepa cinerea*, &c.) On the other hand, various larvæ, especially of ephemerides, were unaffected; but these were sensitive to mechanical agitation of the water. Herr Gruber considers the response the insects made to sound an indication of true hearing, and not mere reflex action.

From experiments recently made on plants, Mr. F. C. Phillips concludes (1) that healthy plants, grown under favourable conditions, may absorb through their roots small quantities of lead, zinc, copper, and arsenic; (2) that lead and zinc may enter the tissues in this way without causing any disturbance in the growth, nutrition, and functions of the plant; (3), that the compounds of copper and arsenic exert a distinctly poisonous influence, tending, when present in large quantities, to check the formation of roots, and either killing the plant, or so far reducing its vitality as to interfere with nutrition and growth. Mr. Phillips' paper appears in the *Journal of the Franklin Institute* for July.

M. Alph. de Candolle has recently called attention to an interesting point (hitherto overlooked) regarding Batatas, one of the species of Convolvulus. The enlargements or tubercles belong, in it, to the lateral roots, whereas in the other species known it is the primary axis that becomes a tubercle. Now, this corresponds to a distinction of properties. The roots of Batatas are formed mainly of a cellular tissue filled with starch, and have a saccharine taste. Axile tubercles, on the other hand, have a remarkable complication of vessels and cells, which secrete resinous matters. The Batatas is good to eat, and serves as food in tropical countries. The other tubercles are eminently purgative (*e g.*, jalap and scammony). Generally, in the family, what belongs wholly or partly to the stem, is more or less purgative. The *Convolvulaceæ* seem to support the law that like parts in a family have properties of the same nature. M. de Candolle thinks a new monography of this family desirable, in which the underground parts should be more considered.

In the French Academy the other day, M. Carré, well known for the freezing apparatus he has invented, and which bears his name, gave a calculation of the cost at which the trichinæ in meat may be destroyed by cold. A machine of his system producing 300 kilogrammes an hour might cool to – 30 degrees 100 cubic metres of ham, that is to say, 60,000 kilogrammes of this meat, by means of 8,000 kilog. of coal, and 27 kilog. of ammonia. One man would suffice to conduct the operation, and the total expense would be less than 500 francs, or about 1 centime per kilogramme. The apparatus would cost 60,000 francs. M. Carré urged the application of this system to making raw meat wholesome (as that is so largely now given to invalids). M. Fremy, on this occasion, desired information as to the facility of assimilation of raw meat. M. Vulpian said the theory of the action was not complete. M. Bouley thought albumen coagulated by cooking more difficult to assimilate than the fluid albumen of raw meat. But M. Fremy considered that on entrance into the stomach, and contact with the acids of gastric juice, the fluid albumen must be coagulated.

Some interesting observations on snow and ice under pressure at temperatures below 32° Fahr. are described by Mr. Hungerford in a recent issue of the *American Journal of Science*. He finds that broken prisms of ice at temperatures far below 32° will firmly reunite if the faces of fracture are brought together and moderate pressure long applied. Snow is converted into ice under long-continued pressure not exceeding 2,000lb. per square inch, and probably much less, and at temperatures near zero Fahr. No satisfactory evidence was found of the presence of moisture in the snow thus treated, though great pains were taken to detect it; still, there may be a local development of it in centres of contracted pressure. The evidence is not inconsiderable in favour of time as a factor in production of continuity between ice-fragments and snow crystals; and this, so far as admitted, militates against the idea of liquefaction and regelation at those temperatures.

A Constant Battery.—Mechanical agitation has been adopted sometimes to render the current from certain voltaic batteries constant by disengaging the gases which collect on the negative plate. Heating has been recently applied by an Italian engineer, Signor Gaudini, with a like effect in the case of a cell consisting of a cast-iron pot or vessel containing a porous clay vase in which was placed a plate of carbon, while a zinc cylinder surrounded the vase as a positive electrode. The exciting liquid was a saturated solution of chloride of sodium, and the depolariser a super-saturated solution of bichromate of potash and sulphuric acid. When in a cool state this cell gives a strong but rapidly falling current on being worked continuously. If, however, it is placed over a small gas heater so as to raise its temperature to about 100° C., the current keeps very constant and is very powerful. Crystals of bichromate of potash dropped into the depolarising solution from time to time serve to keep up the strength of current. When cool, such a cell gave an electromotive force of 2·10 volts and an internal resistance of 0·82 ohms. When hot, the electromotive force rose to 2·44 volts with a resistance of 0·71 ohms. Heating, therefore, increases the electromotive force of the cell, and the conductivity of its solutions, while at the same time it lessens the polarisation of the electrodes.—*Engineering.*

Professor Loomis states that the heaviest rainfall is met with in the rain-belt which surrounds nearly the whole globe lying between the north-east and south-east trade winds.

LETTERS TO THE EDITOR.

FEATHERY MIST ON THE MOON.

[20334.]—Last evening (July 17) I again saw the "feathery mist or cloud on the moon," the same as written of in letter 20151, of May 20th, as then seen on May 19th. It lay, as then, on the terminator, just over the westerly edge of the Mare Crisium against the Promontorium Agarum, and seemed to extend itself longitudinally, parallel with the Promontory, of height apparently equal or greater than the mountain range, partially obscuring the mountains from view.

My notion now is that the cloud forms at that place during the lunar night of every lunation, and can only be seen on one particular evening about 60 hours (more or less) after conjunction (new Moon) just as the rays of the sun, rising over the mountains of the Promontory, become sufficient to illuminate the mist, and yet the increasing warmth of the lunar mountain has not had time to dispel it.

The fact that the moon is then but a slender crescent, necessarily low in the haze of the horizon, and seen but an hour or so before setting, must be the only reason why it has not been more frequently observed.

I missed it, on account of clouds in our own horizon, after the New Moon in June, and only caught it through the rifts last evening, but quite sufficiently to be sure of the presence of the phenomenon, as above described, and to be confirmed in the impressions formerly had of the extent and importance of the appearance as indicative of the present physical condition of the moon.

I marvel much, however, that it has not been noted elsewhere ere this, and am anxious for other observers to be giving their attention, since the magnitude of the cloud far surpasses anything of that character heretofore noted, and its importance must be acknowledged by all as soon as witnessed.

During the old age of last moon, I watched the same lunar region, with the terminator at the same place, as the sun was setting upon it; but no mist or cloud was seen. The Mare Crisium, however, with the setting sun shining horizontally across it, showed a different formation from what had previously appeared from the other side; for the bottom of the Mare did neither run in horizontally, abutting against the base of the Promontory, nor rise against it by what might be called "foot-hills;" but there seemed to be a roll of land in the Mare parallel with the Promontory, and between the two a deep dark gulf; from which conjecture might indicate comes volcanically the "misty cloud" under discussion.

Allow me to add, in conclusion, that the moon's orbit was less inclined southward in May than at this time; and the moon consequently remained much longer above the horizon than now, allowing of a much more perfect view in a better light. The appearance seemed so prominent then that, methinks, a skilful spectroscopist could have readily obtained a spectrum of it.

It will be very interesting, when observers get the matter in hand, to catch by observations encircling our globe the time of first visibility of the cloud, and the time of and phenomena attending its disappearance. **J. G. Jackson.**

Sunset Cottage, Hockessin, Delaware, U.S.A., July 18th.

P.S. of July 19th.—I caught view of the moon again last evening through rifts of cloud; but the Terminator had moved rapidly forward. The sun was shining full and clear over the "Promontorium Agarum" and the plain of the "Mare." *No vestige of the mist remained.*—J. G. J.

P.S. of July 21st.—Observations of the "Promontorium Agarum" continued, seem to show on the slope of the Promontory next the "Mare" what looks like long, narrow openings, not noticed a month ago, at which time it was carefully observed. I am much impressed with the idea that volcanic action is constantly going on in that vicinity of a very interesting character, and that the evanescent "cloud" is but one of its manifestations.—J. G. J.

THE JULY ANDROMEDES — REAPPEARANCE OF THE MARKINGS OF JUPITER.

[20335.]—On July 24th, 11h. 30m., I saw a small stationary meteor at R.A. 7°, Dec. 38° N. It evidently belonged to the shower of July *Andromedes*, which many observers have seen at this epoch. It appears to be a rich display of swift, streak-leaving meteors, and the radiant is one of long duration, as the following list of observations show:—

		α	δ	
1867-8	July 21—	11°	+ 38°	Schiaparelli and Zezioli.
1877	July 6—Aug. 16—	7	+ 36	37 meteors. D. No. 49, 1877.
1872	July 15—Sep. 14—	10	+ 33	45 meteors. D. from Italian obs. 1872.
	Aug. 1—Sep. 30—	11½	+ 34½	140 meteors. Heis.
1870	July 27—	7	+ 32	Tupman, No. 45.
	August 23—	0	+ 33	Tupman, No. 45.
	July 28—Sep. 3 (?)—	8	+ 36	Greg. and Herschel, No. 103.
1878	July 25-31 and Aug 10—	6	+ 37	23 meteors. D. No. 7, 1878.

The mean of the eight positions is at 7½° + 35°, which we may conclude is very close to the centre of the astronomical radiant of this prominent shower.

On July 29, at 14h., I turned my 10in. reflector on Jupiter for the first time this season. Definition was not good, the planet being very low, and his light much enfeebled by fog. I saw the middle of the red spot came to the central meridian at 14h. 18m. It was very faint and ill-defined. The following end of the spot was estimated central at 14h. 48m., but I cannot rely upon these times being accurate, owing to the great indistinctness with which the details were seen. I had computed that at this date the brilliant equatorial spot should follow the middle of the red spot about 1½h., and I soon detected the former object in the position assigned. I was surprised at its brilliancy as it came to the c.m. at 15h. 49m. Considering the very unfavourable position of Jupiter, this bright spot was certainly as conspicuous as I had ever seen it. It will come to conjunction with the red spot on the night of August 5, so that the extraordinarily rapid motion of this object relatively to the red spot has been well sustained during the last few months. for I had indicated last December (*Monthly Notices* R.A.S., Vol. XLII., p. 99), that the two markings referred to should come to conjunction on Aug. 4, 3h. 14m., a.m. The spots may be well observed on the morning of Aug. 6, at 3 a.m., when they will be nearly central on the planet.

While observing these features on July 29, I also noticed two very dark spots on the equatorial border of the great southern belt. They were to the E. of the bright spot, and very similar to markings seen in the same position during the last opposition. These should be watched, for they appear to drift rapidly westwards, and temporarily obscure the bright spot.

Bristol, Aug. 1. **W. F. Denning.**

SCIENCE AT SOUTH KENSINGTON.

[20336]—Will you kindly permit me to make a few remarks on the article which appeared under the above title in the English Mechanic for July 28? Let me say at the outset, that, regarding the amount of money spent by the Science and Art Department, I know nothing; but, as regards the other "facts" you give, I can say something, and I speak from experience.

You say that "artificers are extremely scarce among the competitors." If this is so now, things have changed very much of late years; for when I was at the school the number of working men—and by this I mean men who had been in the habit of earning their living in the workshop—was by no means small. I myself came under that head, and was selected direct from a workshop, and that, too, with the full knowledge of the Department. While at South Kensington I received instruction and gained information which has enabled me to take such a position as would have been impossible from private study only. And this was not peculiar to me. I know a number of men now holding important positions in both pure and applied science, who could not have hoped to have attained to such positions had they not have been fortunate enough to get to South Kensington. One is a teacher of science under a school-board, another is in a corporation surveyor's office, a third chemist in a large chemical works, a fourth science master in a grammar-school, and so on, to say nothing of the great number earning a living as science teachers under the Science and Art Department. I will venture to say that had it not been for this department, the majority of these men would have still been earning their living in a workshop; and I say this from my thorough knowledge of the men. I am the more anxious to correct your statements regarding the selection of artisans, as they are calculated to deter working men from competing, and so tend to bring about the state of things you profess to deplore. I am not prepared to deny that pupil-teachers were present, but I do say that the proportion was not unduly large. Indeed, it seemed to me that great care had been taken in the selection, both as regards the class and the districts from which they had been selected. The students seemed to be chosen from many trades and professions. Thus there were artisans, clerks, pupil-teachers, one from an actuary's office, one from a surgeon's laboratory, and another from a drawing office, and so on.

The remarks you make concerning the qualifications of teachers under the Department are not very complimentary to a large number of your own subscribers, for I know that many of the science teachers are subscribers to the English Mechanic. Ten years ago there would have been some truth in your remarks concerning their qualifications; but the Department was aware of this, and to meet the want of better-qualified teachers the Science School at South Kensington was instituted, and since it opened hundreds of competent teachers have left its walls, and been sent all over the country.

You give a number of absurd statements which were given as answers to questions in physiography. Surely, you know that a few such answers taken from the worked papers give no just idea of the quality of teaching given to the students. Not even the teachers themselves, much less the Department, can be held responsible for these answers. Granted that the answers show that cram has been resorted to, it by no means follows that the cram was the teacher's, but rather that the students had not paid attention to the lessons through the session, and then about a week before the examination he finds he must read hard if he is to make any show at the examination. That this is the case in many instances is too well known by all teachers, and if you can suggest a remedy you will be conferring a boon on them. I remember while at South Kensington one of the answers to a question in Physiology—viz., "What is the medulla oblongata?" was, that the spinal cord was fastened on to the brain with the medulla oblongata. Surely you would not lay the blame of that answer upon Prof. Huxley? That the teacher of the student who gave the answer was not responsible I know, for he was thoroughly competent and conscientious. In conclusion, allow me to ask is it honest and dignified to attack the department in the way you do? It is a little singular that no other paper finds it necessary to take up the attack. I by no means contend that the department is perfect, and where criticism is just by all means criticise. **Edward Jackson.**

Birmingham, July 29, 1882.

[20337.]—I am glad to see that you have taken in hand the misuse of the funds granted to the department at South Kensington, and hope you will follow the matter up. The following items from 1881 Blue-book may perhaps be of service to you. The cost of inspection and examination was £14,968. There were 70 officers employed, so each got about £200 for his work. The number of teachers was £1,700, and the grant £44,000, thus giving each teacher an average of £23, or little more than one-tenth of what was paid to inspectors; yet the teachers do the real work. Even in the prizes to students the jobbery creeps out, for the candidates are not allowed the benefit of the 2d. in the shilling discount allowed on books; it would be interesting to know where this goes to, or rather *whom* it goes to. Again, it is well known that the standard of examination is being raised most unfairly, rendering it more difficult to make anything satisfactory now than it was years ago, while the method of payment *merely* by results directly encourages cram, and yet the examiners have the impertinence—I can use no other word—to complain of *cram*.

Again the subdivision of the subjects is radically bad. Except mathematics, all the subjects are cut down or stretched out to the "three stages," regardless as to whether they are suitable or not.

A curious item appears in the Blue-book just mentioned.

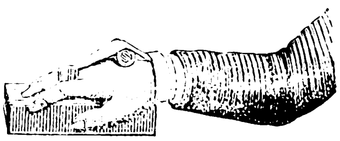
"Simkins' defalcations £6,233 3s. 3d." Who was Simkins? And was he caught and punished? Or was the deficiency made up by so many fewer passes?

I sincerely hope you will not let the matter rest, but continue to call attention to the jobbery prevailing.

Some time ago the department raised the number of lectures required from 25 to 28. Of course no increase in grant was made for the 12 per cent. extra work. **Science Teacher.**

AMATEUR SURGICAL APPLIANCES.

[20338.]—About 30 years ago I had the misfortune to tear asunder the patella of my right knee by the mere effort to save myself from a fall. The separation between the fragments was, and has remained, great—at least 1in. The rupture was very imperfectly amended by ligamentous tissue. However, for many years I suffered comparatively little inconvenience from the accident. The advance of age, and of late years, frequent attacks of serious illness, have wrought their usual effects upon me, and in consequence, I have felt much pain and trouble from my fractured patella. The imperfect union, and consequent inadequate strength, of the extensor muscles do not afford sufficient resisting power to that of the flexors. To meet this difficulty, I have tried various plans with little success. However, I hope I have now contrived an apparatus which is effective; possibly, the invention may be an old one, though my medical attendant, Dr. Pullin, who admires its simplicity, is not aware of any such appliance. In the hope, therefore, that it may be of service to some other sufferer, I forward a description of it to you for insertion, at your pleasure, in the English Mechanic. The apparatus consists of a long gaiter of *thick* cloth, buttoning *tight* to the leg from the upper part of the thigh to near the ankle. At the back of this a long pocket is made, which contains a spring of steel. I have used simply one, or if one is not strong enough, two ordinary steel "busks." When, therefore, the knee is bent by the too-powerful flexors, I have thus given them something more to do than to overcome the weakened extensors, and make them store up power to aid their enfeebled antagonists. I can now, I think, report favourably of the action of the apparatus, having for some time worn it daily. In connection with the foregoing, I may, perhaps, mention that when in bed (not then wearing the gaiter) I have found a sling of "list" attached to the foot, and of sufficient length to reach the hand, of the greatest service in enabling me to move the leg into different positions, with little consequent pain. To the above, I add that some 22 years ago I unfortunately nearly severed the extensor of the middle finger of my right hand. In consequence, the finger dropped, and I feared that all organ playing was at an end for me. However, I then contrived a somewhat similar plan to that adopted for my broken patella, and attached an artificial extensor to the finger made of ordinary "elastic." I found this most fully to answer the intended purpose, and I was at once enabled to play the organ. Of this contrivance I forward an account and photograph for the benefit of any of your readers who may have met with a similar accident. To a band of leather, which is buckled tight round the wrist, three pieces of "elastic"



3in. long by ½in. broad are sewed. These pieces of "elastic" are fastened to a large cork, cut about ½in. from the wrist. Underneath the cork is an oval pad of thick soft leather, which lies across the back of the hand and relieves it from pressure. The cork acts as a fulcrum, and gives upward tension to the "elastic." Again, the ends of the "elastic" are sewed to a piece of ½in. tape. This is passed under a ring of soft leather fitting tight to the lower part of the finger. Under this the tape is passed, and thus the "elastic" can be drawn to the necessary degree of tension and there fixed. **N. S. Heineken.**

COLOUR.

[20339.]—I agree with much that is in Mr. Smith's letter (20307, p. 453), and can confirm some of his experimental results; but I do not believe in any theory of *three* primaries. I do not think "Sigma's" letter (20324, p. 477) an adequate or correct reply to Mr. Smith's; and as to Mr. Holmes's letter (20325), I consider it to be rendered quite unworthy of reply, by its arrogant and discourteous tone.

It is quite impossible to give a complete or satisfactory explanation of colour-vision in the compass of a short letter; but I may refer present readers to some letters of mine on the subject in the "E. M.," beginning 24th April, 1874. Later study and observation have confirmed and developed the views I then held, and have enabled me to add to my experiments for elucidating the subject.

I am convinced that, whilst the wave-lengths concerned in producing colour sensations are innumerable in variety, the distinct or different simple colour sensations are limited; but I am equally convinced that no part, however small, of the spectrum, produces a pure or perfectly simple sensation of colour, excepting, possibly, parts at the extreme ends.

Two objective colours may seem to produce the same colour sensation, and yet be quite differently composed. The green tapes of green Venetian blinds are generally made as close a match as possible; but if they are looked at through glass which is commonly termed deep blue, but which is really violet-blue, the glass being coated with gelatine coloured with picric acid (all other light being carefully excluded from the eyes), the tapes will appear red, whilst the slats will appear of nearly the same green as before. A white cloud looked at through the same combination appears greenish-grey, and with another combination, consisting of special green and purple glasses, the cloud looks to be of nearly the same greenish-grey, whilst crimsons or reds, very slightly inclined to the pink side, appear violet-blue; and many pairs of objective colours which appear identical in ordinary light, are quite different when looked at through either of the combinations. Looked at through the combination first described, grass and green leaves appear to be scarlet.

The objective colours of a landscape are quite differently composed from the objective colours of the pigments used to represent the landscape. It is a remarkable fact, that whilst different persons must differ greatly as regards their vision of colours they do not see corresponding differences in the colours of pigments, owing, no doubt, to the circircumstance that the pigments in ordinary use have gone through a process of natural selection add survival of the fittest for average eyes. Great differences are, however, seen in landscape (and some other) colours; and, consequently, artists unsciously show us (but, of course, only approximately) in what respects their several visions of colour differ from the average; one artist painting a given landscape quite differently from another as regards tone and general and particular colourings.

An instructive way of testing colour vision comparatively would be to provide a few carefully-selected bright pigments and request the various persons to be examined to paint with those pigments the best representations they can of the spectrum obtained by means of a prism. Professor Piazzi Smyth did something of this kind a few years ago (but for a very different purpose) in a paper he communicated to the Royal Society of Edinburgh. In the "Transactions" there is a plate which I have been told was carefully prepared under the professor's supervision, in which he gives us his representation of the spectrum. This representation shows that he is colour-blind to the violet or purple of the spectrum—a fact which he may not yet be aware of, and which he may not believe. The plate also seems to show that whereas the professor does not properly see the true violet of the spectrum, he can see purples and violets when produced by combining the red and blue of the spectrum.

I believe that a large proportion of people are more or less colour-blind to the violet of the spectrum; and in connection with this it may be noticed that the violet of the spectrum is to be found in pigments and other natural objects in a very small proportion as compared with other colours, although there are plenty of violets and purples composed of red and blue. I think it very probable that Clerk-Maxwell was, to some extent, colour-blind to spectrum violet, and, in my opinion, Mr. Benson, the author of treatises on colour, is so also. Quite recently Professor Stokes has described the colour of the phosphorescent light of calcium sulphide (Balmain's luminous paint) as "deep blue," whereas to my eyes it is a blue-violet. Clerk-Maxwell, Benson, and others, who have advocated the three-primary theory, with red and green for two of the primaries, have persisted in calling the third primary "blue"; whereas it is held by many authorities that the colour of the third primary must be that of the most refrangible end of the spectrum, which is undoubtedly to normal eyes a colour very different from pure blue, and which, I think, should be called purple.

No theory of colour vision can be accepted which does not admit of complementaries being deduced from its first principles in a manner to agree with the complementaries actually obtainable. The best way of obtaining actual complementaries independently of theory, is by means of polarised light passed through quartz; but the precise thickness of the quartz is a matter of great importance, and even at the best it is only an approximation that we can get. It is necessary to see all the colours at once, in order to obtain anything like satisfactory results. For this purpose, I have used a concave conical surface of suitable inclination, coated with a black varnish or japan, which I find to be as good as, if not better than, any other reflecting polariser, this concave cone being combined with a smaller convex cone of the same inclination, arranged so that rays parallel to the axis of the two cones are reflected from the concave cone to the convex cone, and are by the latter reflected so as to be again parallel to the axis. This combination gives us a circular field of reflected light, which is polarised at a different angle for every diameter; and if it is looked at through a tube containing at the front end a piece of quartz, and at the back or eye-end a Nicol prism, one sees each diameter coloured differently; and if the quartz is of suitable thickness, a complete graduated series of colours is shown. I have the quartz cut into a pair of wedges, by adjusting which the effective thickness can be varied. If the quartz is of a thickness such that rays at the violet end are brought to coincide with rays at the red end of precisely double the wave-length, a defective colour-field or disc is shown, green being almost absent, and it follows from this that in colours there is nothing agreeing with the octave of music. I adjust the thickness of the quartz so as to get the colours as uniform as possible throughout the series, and the colour then seen by a normal or perfect eye at any diameter is very approximately the true complementary of that at the diameter at right angles thereto. Having got at a correct thickness of quartz in this way, a double-image prism may be substituted for the two cones, and will show any pair of complementaries by themselves.

With the apparatus thus indicated, I find that the true complementary of pure blue is not pure yellow, but a decided orange or golden colour; and, therefore, pure yellow, when combined with pure blue, should not make white; and if it seems to do so in such very defective experiments as Tyndall's, and as others put forward by some persons, some other explanation must be found for it than that ordinarily given. As regards such explanation, however, I will defer further remarks to a future occasion.

Glasgow, July 29. **E. H.**

[20340.]—I would inform Mr. Westwood Oliver and "X. N. X.," that there is a vast difference between despising the aid of science and differing from some of the dogmas of the scientists. Some people say a man despises religion if he happens to doubt anything told him by a priest. The scientists are the priests of science, and as such are entitled to respect, but the best of them are not infallible.

"X. N. X." is mistaken in supposing I wrote to trouble Sir John Lubbock for information in the sense in which he puts it. I simply wrote to a gentleman for whom I have a great respect, upon a subject about which I consider my knowledge, in some few points, may be superior to his. Surely, it is not unreasonable to suppose that one who devotes himself to a single subject, professionally, is likely to obtain a more comprehensive knowledge of it than even a cleverer man, who, in the leisure he can spare from business, studies the same subject, amongst many others, as an amateur.

With regard to my statement that a mixture of blue and yellow invariably produces green (which I strictly adhere to), "X. N. X." writes, "this is altogether untrue of mixing blue and yellow lights"; and then suggests an experiment to prove his assertion, but stipulates for an important point; he writes, "choose blue glass, not cobalt blue." Now, in the first place, I am afraid he rather lets the cat out of the bag here. Does he mean that if the glass used is of the hue he understands as cobalt—in fact, something approaching pure blue, the unfortunate result may be green? (I am afraid any of our readers will find it difficult to obtain anything approaching a blue glass, the blue of which is not cobalt. If "X. N. X." does know of any blue besides cobalt suitable for staining glass, I shall be greatly obliged for any information about it.)

2nd. If the round spot shown through "X. N. X.'s" wheel is compared to a second portion of the same light, shown through a piece of the yellow glass only, it will be seen that the mixed light is darker than the yellow. It is, therefore, unscientific to say that the blue added to the yellow has made it white, for a tint that is darker than yellow cannot be white.

3rd. No transparent blue or yellow glass is made, that will stop all free white light, and the success of the experiment entirely depends upon this circircumstance; for any free white light will tend to obliterate the green otherwise visible, and I am afraid that any coloured glass our readers are likely to obtain would let through as much or more free white light than colour.

4th. Instead of only allowing the light to show through a small hole, it should be thrown over the whole of the screen, giving a shadow of the whole of the revolving disc; when, if the coloured glasses are not too impure, the shadow of the affair will not only be darker, but greener than the rest of the screen. In this case the colours are not really mixed, and I should imagine, from experiments I have made, that the resulting hue would be yellower than if the colours were fairly mixed or superimposed. I do not consider the experiment as a fair method of showing any colour mixture, and certainly should not expect to obtain a vivid green by such means. "X. N. X." not only stipulates that the blue must not be too pure, but requires the experiment as usual to be performed in the dark. It is impossible to form a true judgment under such circumstances, and I maintain that all experiment in forming compound colours by flashing single ones before the eye, are likely to mislead any one who has not formed a sound judgment on the subject by long practice with coloured pigments. Indeed, this method of dodging different colours before the eye, savours much more of sleight of hand than of sober science. No experiment in colour-mixing can be fairly judged of, that cannot be shown in open daylight with stationary colours.

I had written the greater part of this letter last week, but waited until another number of the "E.M." was published, to see if there was anything else to reply to at the same time.

I am glad to see Mr. George Smith's letter, if only to show there are people who are not afraid of being sat upon, for daring to speak their own minds, when they differ with the recognised authorities; I am sorry I was not a reader of the "E.M." when Mr. Smith's former letters appeared. The theory that a mixture of all the colours made white, though evidently unsound, was not very easy to refute, as any neutral tint may be called white, if it is much the lightest object visible; but in propagating the novel methods of producing white and yellow (by the bye, no one has troubled to defend the latter discovery), the scientists have furnished weapons for their own defeat. I consider the experiment of producing a more or less neutral light with so-called blue and yellow, is rather a proof that colour and light are quite distinct, for the stronger the light the weaker the colour, and the stronger the colour the weaker the light. I hold that a coloured light is an imperfect one, and if a number of imperfect lights are concentrated upon one spot, whether the weak lights are coloured or neutral to start with, the result must necessarily be a brighter light.

I take it that the best test for the white or green question would be, not to try if any blue and yellow lights can be found that do not give a green, as this may be owing to various reasons, such as the impurity of either of the colours, or to the surplus white light; but by showing that a green can be produced by using intensely strong blue and yellow with a minimum of light, and then obtaining a fair judgment of the green by comparing it with a white light of the same power as that used for the blue and yellow. The green rendered visible by these means must not be expected to be very intense, as, according to my theory, the blue and yellow light simply drive away their equivalents of complementary colour from the black or shadow which was previously on the screen, so that as the blue light drives away its equivalent of red and yellow, and the yellow light its equivalent of red and blue, there may be very little blue and yellow left; but as more red was driven off than either of the other colours, the resulting light will certainly be green, however faint. We here see that any surplus white light, or any impurity in the blue or yellow in the direction of red, will tend to destroy the green effect otherwise visible.

If we combine red and blue lights, we find the resulting light is a purple (in this experiment it is essential that the blue is not a purple, to start with; that is to say, it should be free from red), which may just as reasonably be called white, as the mixture of blue and yellow light.

I do not suggest combining red and yellow lights, as I find so many—indeed, most—people, accept a red orange for a red, and a yellow orange for a yellow, and, under these circumstances, the orange obtained by the combination is liable to be more successful than the green.

Mr. Smith remarks that, "the eye cannot distinguish between yellow and orange." This is certainly true with a great many people; but is, I think, greatly due to defective education.

It is very common to have one or more of the senses less developed than the others, and I am sure many people who may not be suspected of colour-blindness have a very imperfect sense of colour; and I think the power and delicacy of one sense is often cultivated at the expense of another. In my own case, I regret to say that my sense of smell is very imperfect. This I am only aware of by believing other people, when they call my attention to scents of flowers, &c., which I am often unable to appreciate. For instance, even an escape of ordinary illuminating gas has to be very strong before I am able to detect it.

It would be interesting to have an examination of our professors of colour for colour-blindness, and to know how many of them are incapable of distinguishing the hue of faint semi-neutral colours; but I must say I should decline to be examined under the misleading conditions in which these experiments are usually tried, and should claim to examine by comparison.

Finding the scientists made such a stand upon the rotating system of so-called mixing colour, I have made a number of opaque discs, and succeeded in making various good greens. A mere scientist, starting with a knowledge of blue-and-yellow, and a desire to make green, might also succeed; but if he starts with the determination that they shall not make green, and with a very hazy notion that any hue in which blue predominates must be blue, and then tries his experiments in the dark, he may easily go astray.

It should be understood that pure blue means a certain fixed colour, free from red or yellow; while green, on the other hand, being a compound colour, embraces an unlimited number of hues, and signifies any mixture or shade in which blue and yellow predominate; though red may enter largely into its composition, neutralising its brightness, and tending to form black.

In my earliest experiments, I found a difficulty which I had not anticipated. A disc which I had painted with equal quantities of blue, red, and yellow, and their combinations, purple, orange, and green, with the idea of producing a grey, happened to have a remarkably strong orange appearance when rotated; and another, which I had expected to appear vivid green, was not remarkable for its success. At these results, I must own I did feel a little low-spirited; but on thinking the matter over, I found it was a success, and not a failure. I had discovered one of the rocks, or rather mud-banks, on which so many scientists had been wrecked. It appears that with this flashing or dodging method of seeing colour, the bright hues, such as yellow, orange, and red, have a much greater effect upon the eye than dull ones, such as blue, green, and purple. As, for instance, we know that a scarlet coat is distinguishable at a much longer distance than one of a darker hue. I also found that blue has the strongest effect upon the eye when washed very thinly over white paper, and that the blue must have a considerably larger surface than the red or yellow to hold its own in the combination. I here discovered why the scientists always prepared their discs with such pale chalky colour.

If the red and yellow are intense, and of equal surface to the dark blue, the disc appears strong orange, and not the celebrated (philosopher's) white; but if the colours are all very pale, it is more an effect of light than of colour. The blue is better able to stand its ground, and helps to form a neutral grey, just the same as it does when the colours are mixed, before being painted on the disc. It is a great mistake to suppose that a coloured surface only reflects colour: it also reflects white light (this can be demonstrated with a prism). A coloured disc, especially if the colours are weak, reflects a greater quantity of light than colour, and although the colours neutralise one another to form black, the surplus light will also be visible as a degree of white. The experiments with blue and yellow on a disc require much the same explanation. If painted in strong colour over equal surface, on being rotated, the disc appears bright yellow, with a tinge of green grey; the yellow having so much greater effect upon the eye, that the dark blue is almost lost.

This explains how easily a tyro may be misled when experimenting in the dodgey manner.

In all experiments of so-called mixing colour, by presenting different hues alternately to the eye, it must be borne in mind that all the colours should be of about the same tint, as regards light and shade; and to arrange this is a very delicate matter. It is not reducible to writing, and can only be learned by experience. In fact, there is a great deal respecting colour that it is as impossible to learn from books as it would be to learn the taste or smell of anything by a written description.

If alternate segments of the purest blue and yellow obtainable are washed thinly over a very clean white surface, the blue having nearly double the surface of the yellow, a decided green effect is obtained, especially if the centre and border of the disc are left white for comparison. A slight taint of red in the blue, insufficient to be recognised by the unpractised eye, will spoil the green, and render its hue greyish olive colour.

Finding that a blue surface reflected so much more light than colour, I set to work upon some transparent discs, as it is easier to get an intense blue by refracted, than by reflected light. Having failed to obtain stained glass with anything like purity in blue, red or yellow, I made mine of tracing-paper mounted on wire hoops; these I fastened on a fly-wheel, something after the bicycle pattern, about 12in. across. To avoid the colours running I painted the blue and yellow on opposite sides. Penny cakes of Rowney's gamboge and Prussian blue will do, although both colours are inclined to red, especially the gamboge, if it is laid on at all thickly. See that everything is kept as clean as possible, and do not let the colours overlap. I painted the blue and yellow in 80 equal divisions; but finding on rotating the wheel that the yellow overpowered the blue, producing only a greenish yellow, I pasted strips of tracing paper one inch long over the yellow, round the outer part of the disc, and found the blue stood its ground much better when the yellow was thus darkened. I then covered the yellow with thicker paper (foreign note) for another inch round the centre; so that I had three varieties of green, with the same quantities of blue and yellow, simply by regulating the light in the latter colour, the hues ranging from yellow-green to blue-green. The colour is well seen by daylight, with a white window-blind for a background—of course with the disc between you and the window.

It is interesting to watch the change of hues according to the position in which the revolving disc is held. For instance, when held up against the blind, the yellow has much the strongest effect upon the eye; but if the disc is held so that one-half has a dark and the other half a light background, it may be observed that what appears yellow-green in the latter case appears blue-green in the former. So that we have in this position six varieties of green at one view, all with the same quantities of blue and yellow. This shows another example of the liability of error in experimenting with moving colours.

Now for any of our readers who may be willing but unable to try "X. N. X.'s" experiment (being unable to obtain suitable glass) I will suggest a much simpler and certain test.

Prepare pieces of yellow and blue glass as follows, say about three inches across. Put about $\frac{1}{4}$oz. of gamboge in 1oz. of methylated spirits, shake occasionally, and in a day or two pour off the clear portion into about $\frac{1}{4}$oz. of thick but clear spirit varnish. To coat the plate, warm it slightly over a lamp and pour on the mixture, returning the surplus to the bottle; then dry the plate carefully over a lamp, holding it at an angle of about 45°, to prevent any surplus varnish from flowing back and spoiling the surface. For blue I used an aniline dye, dissolved in water and thickened with gelatine, the plate being coated much the same as the other, only that it takes much longer in drying, and must not be made too hot, or it is liable to crack and leave the plate. This blue is unfortunately not very pure, as it contains a perceptible tinge of red, especially if the plate is coated thickly; but the two make a very fair green, and are quite good enough for our present purpose. Next, paint two surfaces of white paper, one with gamboge (and water, not spirit), and the other Prussian blue. The aniline blue is not suitable for this, as its red hue is so much more apparent on paper.

Now, it is only necessary to let the shadow of the blue glass fall on part of the yellow paper, or the shadow of the yellow glass fall on part of the blue paper to see the true result of mixing blue and yellow. This is best seen in broad daylight. In fact, the better the light and the steadier the things are held, the better the result.

I was lately shown one of the philosophers' discs by daylight, on which were pasted about 48 segments of tinted paper (it was made at a well-known scientific depot.) This, upon being rotated, produced a muddy effect, which the owner was pleased to call white. This disc had a black centre to set off the mixture; I leave the centre white in my discs for the same reason. The gentleman said these were the old kind, and then showed me another disc, which he said was of a more recent make, and with the same colours produced a *better* white. So it would appear that the old white was not altogether satisfactory. The new pattern disc had a much smaller number of segments (as I remember about seven or eight), and only one of each hue. As it happened, all the colours on the disc were miserably impure and chalky. The red, for instance, I should have described as red, yellow, and blue, mixed with a white body to prevent its being too dark; but what struck me most was that the greater part of the disc was covered with pale, almost neutral tints, slightly tinged with blue, purple, and green. The segments nearest approaching strong colour being much the smallest, I asked the gentleman what colour the largest division, about $\frac{1}{4}$ of the disc, was supposed to represent, but he did not know, or was afraid of committing himself. Upon being rotated slowly, the disc produced a painful effect upon the eye; the intermittent light producing much the same impression as you experience when walking with a paling between you and the sun.

The proud owner then rotated the disc so rapidly as to prevent the various muddy combinations from being separately recognised, and said triumphantly, that "it was the purest white that had ever been produced." I then covered half the disc with a piece of paper, and showed him that his white was considerably darker than a piece of tinted paper covered with writing.

It was quite evident the poor fellow, from misguided education, accepted as white what in reality was as near an approach to black as the small quantity of colour on the disc could produce.

The scientists say that blue and yellow make white; also that blue, yellow, and red make white. Now, do they maintain that red added to white does not affect its hue, or have they a number of whites of different hues?

It is really quite time for the old dogma of white being composed of colour, to be exchanged for a more rational theory. Newton's error was excusable, as a proper mixture of colours will produce a neutral tint, which may be called white, or black: according to its surroundings; but no mixture of pure blue and yellow will make anything but green. The fact is, green is composed of blue and yellow, exactly as much as brass is composed of copper and zinc. It is argued that it takes a greenish blue and greenish yellow to make green; this is equivalent to saying that it takes a brassy copper and brassy zinc to make brass; but the educated eye will as readily estimate the quantities of blue and yellow in any green, as a chemist may estimate the quantity of copper and zinc in a sample of brass.

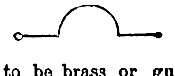
S. Calton.

GRAVITY - ESCAPEMENT CLOCKS: THEIR WEIGHTS, PENDULUMS, PINIONS, DIAL, &c.

[20341.]—When I was young, twenty to thirty years ago, there was, in Thirsk, a watch-maker named Groux. One day he called me in, and showed me a clock he had made, and which he said, owing to its construction, could only vary very slightly.

I was then mechanically minded, but knew nothing of clocks, so I saw the clock and did not know its merits. Of late I have taken to reading how to make clocks, and have tried to make one; and I then remembered this clock of Groux make. He left Thirsk twenty years ago or so, and it was sold amongst his other effects. I tried to find it, and have done so, and it seems to possess some features that although they are new to me may not be new to many:—

1. The pinions are of pinion wire, not lanterns.
2. Its hour hand is stuck on the winding square. Fig. 1 is where eleven usually is.
3. Its weight is on three strings, and measures only $7\frac{3}{4}$ by 2, falling 5in. in 24 hours; the calculated weight would be under $9\frac{1}{2}$lb.
4. The pendulum rod is wood gilded, the bob is round, $8\frac{1}{2}$ by 2.
5. The pallets are apparently brass wire No. 16, or so, bent to shape, which is not the shape shown in Sir E. Beckett's book, but this shape. The 'scape



wheel appears to be brass or gunmetal, and I think not quite 3in. diameter. The measures are accurate, but the other is only what I saw of the clock in its case. Is not $9\frac{1}{2}$lb. a light weight for such a clock? Its present owner says it goes well.

W. N. B.

THE FOREGROUND IN SKETCHING.

[20342.]—I am afraid "Country Sketcher" will not have had his difficulties removed by any of the answers up to the present. Beginners are very apt to be puzzled by their foregrounds; it is so seldom that a view from nature composes well without management. An old hand, if he does not find what he wants on the spot, sticks in some odds and ends out of his pocket-book, which every artist should have well-filled with bits of rustic life—a group of peasants, of children, old stumps of trees, &c. I believe, on one occasion, Turner stuck in an island in the middle of the Rhine which never existed, simply because he found himself embarrassed with too much water. If this anecdote be true, it is carrying license very far. I will now make two suggestions: 1. If "Country Sketcher" will paint in his four fields, and place, say, a hay-waggon in the first, it will nearly hide the four fields, improve the distance, and add a bit of interest to his sketch; or 2. Let him paint his distant building standing up, then let him sit down, or even crouch down, and paint his fields. This will foreshorten them, and by introducing a few large weeds in the very front of his picture the trick is done. Theoretically this is wrong, as the perspective of his buildings is, of course, altered; but *practically* the difference is imperceptible, and I very much question whether anyone who knew the place ever so intimately would spot the trick. It is hardly possible to introduce too much detail in the immediate foreground; but he must beware of making the colours too glaring. They may be as dark or as light as he likes, but the tones must be low, the tertiaries preponderating.

G. W. S.

[20343.] — Apparently, what "Country Sketcher" (letter 20291, p. 451), wants to know is whether, in sketching a distant scene, he shall represent it as being immediately near him! It is rather a curious question, and one which evidently answers itself. If Green's book fails to give him what he requires, and the lengthy reply he has had to the particular point he raised, has not satisfied him, he has but one thing to do—viz., use his own judgment in the matter. I should like to say that if he wants a truthful representation of the scene, he must portray it as a photograph would; but that, if a picture be required, or the scene idealised, discrimination must be used in what is included or omitted; and this resolves it solely into a matter of personal taste. I do not wish to be ill-natured, but I think that the information generally included in "Country Sketcher's" own letter is amply sufficient for the guidance of any ordinary intelligence in drawing from nature.

A Casual Sketcher.

RAILWAY SIGNALS.

[20344.]—Apropos of this question, allow me to suggest that a real improvement would involve a radical change. At present a signal "line clear" means either an arm hung at an angle or concealed altogether, while the stop-signal is an arm extended at right angles, the normal position of the semaphores. I cannot help thinking that it would be much better to reverse this order altogether, and to make the signal a positive one to come on—not as if giving permission, but a positive order. Thus if line is not clear no signal at all would be shown —nothing but a bare pole; if, however, line is clear the arm would be put out, and it would be the duty of the driver to go past. This arrangement would avoid delay and provide for accidents; for if the chains or wires broke the signal-arm would fall. No inconvenience need follow, as drivers could be signalled as now by flag from the box, and as they would by means of an indicator see that the gear was out of order, they would pass the outlying posts and pull up at the boxes or cabins. A special signal for danger might be employed, which would, probably, be more efficient than the present arrangement, as it would be exhibited only when danger existed and it was imperatively necessary to stop. The objection to these suggestions is the radical change in working, which might for a time produce confusion. It is not a little singular that the old hand-signal for "all right" or "come on" is an arm extended at right angles to the shoulder, and I have often wondered why, when the semaphores were introduced, the position known as "on" was not adopted to indicate that the road is clear. The Great Western had, and still has, I believe, a compound signal, by which the driver is told positively to come on. This is a pole carrying a cross-bar to represent "danger," and a disc to represent "safety," so placed that when the bar is turned end on, parallel with the line, the disc faces an approaching train, and the driver has a positive signal to come on. When the bar is placed at right angles to the road, the disc is seen only on edge. I have been unable to discover why, when Gregory's semaphores were introduced, the position with the arm extended was chosen to indicate "danger." I imagine it was a mere arbitrary arrangement, which has been persisted in out of mere follow-my-leader imitativeness; possibly the idea was taken from the G. W. "danger" cross-bar. However, if Mr. Stretton, H. Stooke, or any other of your readers can point out any substantial reason for maintaining the present style (save the objection to change) I should like to read it. By the present arrangements, to put it briefly, drivers proceed unless "obstructed." I think it would be better to allow them to proceed only when positively signalled to do so, and there need be no delay or any trouble in working on that system, which obviously would lend itself equally as well to the electric slot and interlocking arrangements as the present.

Nun. Dor.

[20345.]—The idea of Mr. Stooke (letter 20267, page 427) is very good in theory, but in practice it will never do to lay down a hard and fast line of angles. The drawing shown gives the "all-right" arm too much lowered. The best authorities, and also many drivers, wish the "all-right" signal to be the old "caution," or angle of 45. The angles should be taken from the under side of the arm, not from the centre. I also wish that all lines would fix the signal-posts always on the left-hand side of the line to which they refer, not as now—some on one side and some on the other.

A Driver.

THE SECTIONS OF THE MIDLAND RAILWAY.

[20346.]—In reply to your correspondents, "V.," "C. R. M.," and others, I shall be happy to give the sections of the Midland Railway for which they ask if space can be found for their insertion.

[We cannot find space for the graphic delineation of railway sections. We give a general description of the section kindly sent by Mr. Stretton, which reaches from Leicester to Desborough. Starting from the former, the line is level for a short distance, and then for three miles rises about 1 in 400 to Wigston North Junction. Passing that there is a short sharper gradient, and then with a level interval a steady rise of about 1 in 200 to within half a mile of Glen station, which is on a falling gradient of 1 in 220; about a quarter of a mile past Glen the line rises to Kibworth North Box 1 in 165 for about a mile and three-quarters. Then commences the Kibworth Bank, which with level places here and there falls at an average of 1 in 150 for about four miles; then for 2½ miles the line goes up and down with level intervals until Market Harborough is reached, where a short fall of 1 in 132 leads to the Desborough Bank, which for four miles rises 1 in 132, and then falls to Desborough station, 21 miles from Leicester.]

In addition to the up and down main lines, there are two up goods lines on the up side of the main lines between Knighton South Junction and Wigston South Junction.

A down goods line on the down side of main lines from Wigston South Junction to Wigston North Junction. There is also an up goods line upon the Desborough Bank between Little Bowden Junction and the North Box, Desborough.

July 28th. **Clement E. Stretton.**

THE PRESSURE OF WIND.

[20347.]—Some misconception appears to exist as to the wind-pressures mentioned in a paragraph which appeared on p. 413, and I observe that Mr. Romanes, p. 478, has ventured to remark that "the figure in the 'E. M.' is evidently a misstatement." If so, the Astronomer Royal is responsible for it, as the paragraph is obviously taken from the Greenwich Visitation Report. There may be some "erroneousness" in the registrations of these high pressures; but the mere suggestion that such is the case is not sufficient, whether made by Mr. Hawksley or any one else. The instruments at Greenwich may be defective and obsolete; but one would think there can be no difficulty in arranging an instrument to record with accuracy the exact pressure on the surface of an exposed plate, whether that plate is 1ft. or 20ft. in area. The report of the Astronomer Royal is clear and distinct. He says: "A velocity of 61 miles an hour was recorded on October 14th, and one of 58 miles an hour on April 29th, these being both greater than any recorded in previous years." Now, I happen to know that on April 29th the wind did not blow steadily, but came in terrific gusts of such a character as to be rather alarming to passengers in the trains running up the bank from Nunhead to Honor Oak on the Crystal Palace line. Clearly the report gives the average for the hour, not the velocity during the middle of one of the terrific gusts, which must have been vastly greater, and may have reached Mr. Simmons's rate on his recent balloon voyage—about 130 miles per hour. Similar remarks apply to the statement of the Astronomer Royal that "the greatest pressure was 53lb. on the square foot on October 14th. . . . On April 29th, a pressure of 49½lb. was recorded at a time when the hourly velocity was 50 miles." That appears to me to be definite and distinct. The hourly velocity—that is, the average speed during one hour—was 50 miles; and during that hour—it may have been only for one minute, or even a second—the pressure was recorded as 49½lb. For all that the Astronomer Royal says to the contrary, the velocity of the wind at the instant when the record was made may have been 100 miles an hour. The formula and table given by Mr. Romanes are, therefore, worse than useless, for they may mislead. For instance, a builder or an engineer in working out his calculations might say the highest velocity recorded at Greenwich was 61 miles an hour; and the corresponding pressure by formula and table is something less than 21lb. If, then, the building is calculated to resist 42lb., it is practically thoroughly safe. But the pressure-gauge recorded 53lb., and if the builder trusts to 42lb. his structure will come down in one of those violent gusts as the Tay-bridge did. The only trustworthy data are the actual pressures registered, for houses and bridges are not like reeds, that can yield to the blast and jump up again; hence, "velocity per hour" is misleading when pressure applied for one second will destroy.

F. M. S.

[20348.]—Mr. Shaler Smith, in a paper read to the American Society of Civil Engineers last year, quoted an instance of wind-pressure of 93lb. per sq. foot, and another of 83·3lb. The former gust overturned a locomotive. According to Mr. Hawksley's formula, this represents an enormous velocity—hardly credible, indeed.

July 29. **J. A. Westwood Oliver.**

SMALL DYNAMOS.

[29349.]—As the following remarks bear on the subject of small dynamos, which have of late been denounced on account of their supposed inefficiency by Mr. Lancaster, I think it would be well for the benefit of the many readers of "ours" who are interested in the subject, that they should be published.

Being anxious to obtain a small dynamo for experimental purposes, I looked in the advertisement column, and saw there advertised castings and wire for dynamo to drive six 10-candle incandescent lamps. I determined to see what these were like; but before I did so, I saw the note that small dynamos were useless, or thereabouts. Instead of deterring me from my purpose, it spurred me on, intending as I did if not up to description to expose the whole thing. Well, I inquired, and finding a small dynamo made of similar castings as advertised, I requested that I might see what it would do. My request was at once complied with, and the machine being driven from a foot-lathe, produced current enough to light up well five 10-candle power incandescent lamps. I must add that there were only five in the shop, or else we should have put six—the full number—on at once. After seeing that the machine would really do what was said about it, I asked the loan of it to try certain experiments by myself, and so thoroughly test the full power of the machine. The maker, after ascertaining that I was an electrical engineer, connected with a well-known London firm, readily consented to my proposal, and accordingly I took it to my own place, and having steam-power at hand, put to it what I calculated about a quarter-horse. I found that running at about 1,700 revolutions per minute, it drove at their full power six five candle-power lights. Increasing the speed to 2,000 revolutions, it drove from four to six 10-candle lamps; and to further test the machine I increased the speed to about 4,000 revolutions), and (contrary to the maker's expectations), drove two 20-candle power Swan (parallel), five 10-candle power (two in series), and four five-candle power (all in series). I must own that in the latter experiment the light given out was not their full power, whereas in the previous experiments the lamps gave as much light as they should do, to last their proper length of time.

I had no more opportunities for testing them; but was informed that the same machine would drive a small arc-light with three or four millimetre carbons. However, I shall soon be able to take the measurement of the current and E.M.F. of my own machine, which I am having made in the same style as the one I tested.

Although our friend, Mr. Lancaster, has denounced these small dynamos, I trust readers of the "E.M." will not be discouraged, but go on and succeed, as I firmly believe success is attainable. I would willingly give any other information in my power to any one who may need it. I may add, that with the castings of machine with which I have experimented, directions are given how to proceed to complete it.

Tried.

THE BERLINER VIOLIN.

[20350.]—Since I sent you the violin to be criticised, I have been told how risky it was for me to do so, not only on account of the prejudice existing against innovations on this instrument, and not only because it is an easy matter for a player to produce an unfair comparison between two instruments, but also because of the thousands of violins on which a high value is set by their owners, and who would enter into an alliance of self-defence to decry the innovation and seek out every argument to sustain their ground. But this is unavoidable, and I am perfectly satisfied that there are many others who will fairly test an improvement offered, in the face of the difficulties which now beset violin making, and which my invention is intended to overcome.

If, however, as is done by Mr. Schucht, assertions are made based upon mere hearsay or tradition, and which cannot be sustained by scientific principles, I am bound to defend myself. Mr. Schucht says that in the ordinary violin "gravity" is used to produce tension on a small quantity of wood. Can anyone explain this? Or, will Mr. Schucht point out a single action of gravity on the fiddle he plays? He further says "that no such pressure as 75lb. being exerted upon the new violin, it must be deficient in quality or intensity of tone." This is mere theory! Supposing I have a simple sounding-box, to which I apply a tuning fork, will that box resound louder if I compress it between two opposite points? Not much! As far as quality is concerned, one player prefers this, one that kind of sound for a violin; but the general demand is for a free and sympathetic tone, and I have not found a single instance in which this was not the case when a resonator was applied.

Loudness of tone, however, is depending upon the age and sonority of the wood, and with the G and D strings upon size of strings and the bass bar. Furthermore, the general "graduating" of thicknesses and other points in workmanship have a good deal to do with it.

The violin sent to you was a cheap factory-made one, on which no special care or graduation is usually applied, and which is made of unselected new wood, and if it sounds free and sympathetic and fairly loud, these qualities are the right ones, and they are but rarely found combined in any violin.

Far-reaching power comes as the wood seasons, and the violin is played upon a while.

I hold the difficulty in making a good sounding violin (or two violins alike good) lies in adjusting its structure and quality of wood to the compressing influence of 100lb., a pressure which must necessarily affect the fibres and their molecular vibrations, and the reason why old violins are better-sounding than new ones is because the wood by long seasoning has acquired stiffness of fibre and porosity of texture (hence of greater sustaining power), the two prime qualities of good violin wood. In taking away 75lb. pressure of the 100, the vibrations at once become free and pure, and the violin can be subjected to such alterations as the new string holder admits of. Such changes will be that we can reduce the thickness, and that graduations can be modified so as to enhance the quality of the tone regardless of danger arising now from the pressure of 75lb. tension.

That Mr. Anderson, by putting a light mute on his violin, produced "a similar quality of tone" as in my violin, merely says that his became soft and sympathetic, and most likely it is otherwise, a loud but hard-sounding instrument; but if it is meant to indicate that the tone of my violin is "muty," this is against the experience of other critics who would not have hesitated in making known so glaring a fault.

Let me say in conclusion that before long I will enter upon such challenges with "first-class old violins" as will leave no doubt of the superiority of my device, and, until then, I am ready to meet those critics who base their arguments upon a scientific basis; but I must leave it in future to the intelligence of your readers to refute the criticisms of all who argue with such loose theories as Mr. Schucht. **E. Berliner.**

"A BLIND MAN'S VISION."

[20351.]—The insertion in No. 901 of my lines respecting A Blind Man's Vision, incites me to send you a description of my two discoveries.

As I have said, when I have long observed the sun without sight-protection my eyes are deeply insolated; if, then, I turn my back to the sun and look at the white ceiling of my room, I see all the solar phenomena reproduced but in reverse colours—that is to say, I see in black what was white, and *vice versâ*. If I shut my eyes and look—so to say—through the eyelids, I again see the same phenomena, but the colours are not the same. If, then, I place my hand over the eyelids to shade them, the same phenomena persists, but again their tints are changed. If I strongly contract the eyelids, new tints are the result. If I go in a dark place—a cellar—then again the phenomena are altered, and light replaces darkness. For several days the central visual point forms a dark disc through which I can discern nothing—I can only see objects in a diffused light round the dark disc. After a few days the disc changes, and instead of black appears coloured. The colour is not constant—it changes, and, on repeating the above operations, numerous changes of tints are observed. The darkness of the disc gradually fades away, and the changes agree with the scale of the spectrum colours, and concords with the complementary colours. The effects are innumerable and all very curious.

The insolation persists about two months. Having most attentively observed all the physico-physiological facts produced, and seen in what manner the insolation decreased, I suspected that by reinsolating my eyes successively, not with solar light but with coloured light, and following the spectrum colours and their complementary ones, I could shorten the period of deinsolation. I tried and completely succeeded, so that ten minutes or thereabouts after a complete insolation, I had obtained a thorough deinsolation.

Such was my first discovery. Since, I never failed; therefore, I consider this process as suppressing the consecutive actinic action of light on the organ.

On the 17th of May last I observed with unprotected eyes the partial eclipse of the sun, and as it lasted long, I made four successive observations. Not only could I see perfectly the eclipse phenomena, but in the mean time I observed a spot on the sun with all its details. After these four observations my eyes were not only deeply insolated but also deeply fatigued and painful. I deinsolated them as usual in about fifteen minutes, but I remarked that a sort of reddish disc remained, which did not vanish for several days. At last it disappeared, but then I observed a sort of cloudy shade in the right eye, not in the left. How shall I describe it? It was something like a drop of milk in a glass of pure water. After a few days it seemed to settle. A sort of delta-like shading was nearly in the centre. On moving the eye the whole cloudy matter moved; but I observed that the delta was not on the same plane as the circular shade. It was evident that the circular shade was in front on the border of the crystalline, and that the delta was at the bottom of the eye towards the retina.

I then took a small optical instrument, which is something like that which Robert Houdin named Retinoscope, in which my eye can see its own internal image. Then I saw plainly that the phenomena were caused by a coloured substance swimming in the vitreous humour, part of it on the brim of the crystalline and part on the deep part of the eye. Then, by a peculiar contraction of the eye, I could realise by the effect of light that the cloud was composed of microscopic circular rings formed by an internal dark line bordered by light each side; these rings were swimming in the vitreous humour. The delta had become thicker and was of a dark brown, also lighted each side. I arrived at the conviction that it was part of the brown pigmentum that coats the choroid, that had been dissolved and diluted by the powerful action of the solar light, and, in my opinion, M. Plateau's blindness has no other cause. It is his eye's pigmentum that has been totally dissolved, separated from the hyaloid membrane, and is expanded in the whole extent of the vitreous humour, and thus prevents light reaching the retina's fibrils; hence no sight possible, but shaded tints passing through the dissolved pigmentum still act on the retina, and quite naturally after such action, the reaction of the retina produces the complementary colours.

Having arrived at this conviction, I could not help thinking that a cataract, which, of course, was much thicker than my cloud, could be dissolved, removed, and cured by electricity. But in this case could I expect that the fluid would carry off the substance or recoating hyaloid? This seemed rather too much. But I thought that it could act so as to move the matter and carry it in a place where it would not much interfere with vision.

Unfortunately, I live in a small village where I can procure nothing of a scientific order, and I had not any electrical apparatus at hand. I possess two small magnets. Directly, I thought of applying them to my eye. I used both of them, uniting for a greater action their like poles. I shut my eye and placed the north pole on the centre of the eyelid and the south on the cheek, expecting that a repulsion would occur towards the south pole. The first effect I observed was the production of a great brightness (*clarté*) at the place of contact of the north pole, which brightness interfered largely with the cloudy substance, which was agitated. The small rings were disappearing, forming a sort of milky cloud. The delta seemed darker, and bordered by a bright line. Presently I saw discharges, the forms of which were similar to those produced by the electric spark on a looking-glass. At first I felt no sensation, but after a short time I felt a gentle tickling gradually increasing. I wetted the magnet's poles with saliva, and the tickling was transformed into a prickling sensation. Opening the eye, I put the pole in contact with the mucous membrane and the sclerotica wetted by lachrymal fluid; then the prickling intensified, the intermittent discharges became painful; some were so strong that my hand moved in consequence of the sensation. The action of the magnet was self-evident. There is not the least doubt that it acts powerfully on the fluids and liquids of the eye. Mine is now almost entirely cleared, the diluted pigmentum is confined on the brims of the crystalline and hyaloid, and the delta, which is smaller and darker, is now situated on the right towards the bottom, and does not prevent sight, although remaining visible.

For the present I will say no more. I leave it to medical men to experiment for themselves.

Ch. Rabache.

MEDICAL REPLIES.

[20352.]—Oatmeal Porridge Again.—Letters continue to reach me asking for information as to oatmeal and oatmeal porridge; the writers generally saying that they have mislaid their numbers of the English Mechanic, or cannot find my articles. I cannot undertake to look up the index of the "E.M." and write private letters on this ground. Such writers should send 2½d. in stamps to the publisher, and ask him to forward by post the number containing any article that may be referred to. The index of the "E.M." gives "subjects," but not "author's names," and therefore querists must look, not for author's name, but for the subject, when they want to refer back to any such letters. My letter upon oatmeal porridge will be found in No. 848 (June 24, 1881, [43944]), and some supplementary remarks will be found in No. 852 (July 22, 1881, page 479. I observe two *errata* at page 479, where (last line in first column) "best" should read *test*, and (last line but eleven in second column) "table" should read *talk*. These queries upon oatmeal porridge being, however, of such general interest, I reproduce some of my former remarks.

1. Oatmeal porridge and milk is one of the most digestible and sustaining of all foods. For growing young people it provides the "bricks and mortar" which are required for building up solid bone and healthy tissue. For dyspeptics, with some rare exceptions, and for people who have defective teeth, it saves dyspepsia and maintains the patient's strength. For nursing mothers it is *the* food which makes the very best milk with the least strain to the mother's system. For intellectual or physical workers it meets every requirement at a minimum of digestive effort. The limitations which I observe in my own practice are these. Full-grown adults, who require repair rather than additional building, do not benefit so much by it if their teeth and stomachs are robust. The finer meal, in which a larger proportion of earthy matter has been eliminated, should be chosen by persons who no longer have their teeth and bones to build. Some dyspeptics cannot take the porridge without getting souring of stomach. In most cases of this kind the souring is due to the use of bad oatmeal, or to bad cooking of the porridge. In others it is due to the fact that the stomach and system are damaged by the use of alcohol, tobacco, or by the abuse of tea. There remain a few cases in which, however, it is found not to agree. In most cases, after alcohol, tobacco, and tea have been left off for a week it agrees perfectly. The souring will be remedied by taking a small teaspoonful of heavy calcined magnesia in a cupful of ginger-tea whenever attacks of souring and flatulency come on.

2. To make good oatmeal porridge, four things are necessary—clean boiling water, a clean saucepan, good meal, and some good sense. When young people will not eat oatmeal porridge and milk, it is a sign that the mother has not been provided with all these requisites, and it may be safely assumed that the fault lies in the porridge. As to the saucepan, it must be not only "clean" in the vulgar kitchen sense, but it must be fit to drink out of. Breadstuffs and milk can never be nice unless they have a saucepan to themselves. Saucepans in which meat or vegetables have been cooked never again are got into such a state that one would like to drink out of them. There is always a coarse flavour adhering to the saucepan. As to the meal, it should be clean, dry, coarse-grained, and so sweet that one is tempted to eat of it. It must be bought from some shop where the master knows "what is what" in the shape of meal, where it is stored properly so that mice, beetles, or mildew do not get at it, and where, there being a large sale for it, it is always to be had fresh. The consumer, again, should store his meal in a dry jar or large bottle or tin, as carefully as if it were tea or coffee. Now, having clean water boiling upon the fire in a clean saucepan, and your meal in a basin (2 or 3 ounces to each pint of water) draw the saucepan off the fire, and as soon as the water ceases to boil sprinkle the meal in through the fingers, free from lumps, and so that the meal is fairly distributed in the water. Then push the saucepan back on to the fire and boil briskly for a few minutes, so as to mix the water and meal thoroughly up before it has time to thicken or get lumpy. After this, the saucepan may stand aside and be allowed to boil slowly for three-quarters of an hour, the porridge being kept on the move by stirring with a clean wooden spoon. The porridge should be boiled so that its starch granules are all burst, and the meal efficiently cooked; and being neither burnt, nor smoked, nor lumpy, it should be poured out into a vegetable-dish, and put aside uncovered until it sets like a jelly. It should then be eaten with cold rich milk, and if the porridge be right, and the milk be good, no nicer, purer, or more nourishing breakfast or supper can be had than a saucerful of this porridge with a half-pint of milk. A little salt may have been put into the water according to taste. The porridge, when taken upon the plate, should be a

soft tremulous jelly, uniform in consistency, and not damaged in flavour by burning, smoking, or by dirty cooking. With young children, and with adults not disposed to corpulency, a little treacle or golden syrup may be put upon the porridge before the milk is poured over it. Such porridge keeps perfectly for twelve hours, if put away carefully, and it comes in well for supper or for a light scratch meal.

3. As to the standard of what I call "good meal," and as to getting good meal, the following data will start any one who wants to begin right. The meal for my own household is obtained from Jackson and Co., 45, Piccadilly, and I know of no one more up to "what is what" in table knick-nacks, preserved meats, fish, fruits, biscuits, &c., than Mr. Jackson. He sells various grades and qualities of meal, all very choice, and which make delicious porridge. After my first letter on this subject, a specimen bag of nice meal was kindly forwarded to me by Thompson and Sons, 5, Leven-street, Edinburgh. I found their meal everything that could be desired, and by sending 2s. 6d. in stamps to either or both of these firms, a sample bag of meal will come on at once. Some persons like a finely-ground meal; some a clean, coarse, granular meal, quite free from flour. In all cases, the oats must be of the finest quality, free from foreign seeds, and perfectly cleansed from grit and husk before they are made into meal. Another meal which is very choice is the "A B C" meal. This is put up in packets by the "American Breakfast Cereals Company." It is very fully dried and partially cooked in long iron tubes, heated by high-pressure steam-jackets, and the meal is forced through by an Archimedean screw, which keeps the meal always on the move. I found the A B C meal expensive but very choice. It goes much further than undried meals and needs much less boiling, but to my taste it is not cooked sufficiently in the "ten minutes' boiling," which is prescribed on the label.

Tender Feet (47497).—Indigestion (47498.)—Read former replies. Querists need to get personally examined, so as to define the cause of their sufferings and learn something about their constitutions and mode of life. If I were to prescribe for patients who, without ever yet having learnt what is the cause of their disease, have "tried everything, including homœopathy and allopathy," whatever these two things may be—I should only be standing in the way of many well-meaning writers who are always ready to prescribe remedies of which they know infinitely little, for diseases of which they know infinitely less—their practice being, I suppose, based upon the principle of *similia similibus curantur*, or likes by likes are cured. **James Edmunds, M.D., &c.**

Grafton-street, Bond-street.

LEGAL REPLIES.

[20353.] — Intestate (47503). — The state of things described as existing by this question is an instance of the confusion caused by the omission to take legal advice at the proper time. It is not easy to make out what happened. If the wife survived her husband she should have taken out letters of administration to his estate, and divided it so as to take one-third for herself, and portion the rest amongst the children. But this apparently was not done; and as matters now stand, any one of the children, if of age, can take out administration to the estate left by the father or mother, and, after payment of debts, divide it between himself and the other children in equal shares. The elder brother can only claim his share, as this is personal property, and his marriage does not prevent the other brother having his portion; while the house, being in the elder brother's name, has nothing to do with it, presuming the house to be no part of the estate.

(47519.)—The words of the will, as quoted in this question, are quite correct and valid, and are indeed the proper legal phrases to use by a man who wishes to leave his wife all the property, both real and personal, of which he may die possessed. It was once the law that a will only spoke from its *date*, and consequently did not pass any real property acquired by the testator after that date. But this was altered by the Wills Act, 1837, and since then it has been, and is the law, that every will is to be construed as if it were made immediately before the death, so that its date becomes so far immaterial. If a testator specially referred to property then in his possession at date of will, it would be different, but here the words are general, and would pass all he had at his death.

(47536.)—The form given in this question is very badly drawn if it were intended as an acknowledgment of rent; for the word "rent" is not even mentioned as it should have been, with a description of what rent, when due, where, and the like. But, in fact, the paper is far more than an acknowledgment. It is really a promissory note, and should have been written upon a threepenny stamp. Regarding it as a promissory note, the want of a stamp cannot be cured afterwards. But looking upon it as an agreement, which it is also, it should have a sixpenny stamp, and this can be put on it within fourteen days afterwards. If, however, this time has elapsed, then a penalty of £10 must be paid before it could be used as evidence in a court of law, with a further £1 if actually stamped in court.

(47547.)—Contracts in general restraint of trade are wholly void, as being contrary to the policy of the law. But a contract in partial restraint of trade, if made for a valuable consideration, is perfectly valid. If, therefore, it is agreed between master and servant that, in consideration of the employment, the servant will not, either during or after his engagement, set up in the same trade within certain defined districts; this is a contract that will be legally binding on the parties. The form quoted is very badly done, and is insufficient, as it does not state the consideration for B.'s promise, while the word "encroach" is too vague to be of much use. But I really cannot draw an agreement of this kind without further facts.

[47354.]—The magistrates having made their order upon the husband to pay so much a week for his wife's support, and having done so upon the application of the parish, the husband's only course is to give notice to the workhouse authorities that he will apply to rescind or revoke that order, and to apply accordingly. If the husband means by the word "misconduct," that his wife has committed adultery, there would be a good ground upon which to ask to have the order revoked. Should this be the state of things, the husband had better proceed at once with his notice and application, and have his witnesses ready to prove his wife's adultery before the magistrates.

(47557.)—By the last Real Property Limitation Act, which, though passed in 1874, did not come into operation until the 1st January, 1879, it is enacted that actions to recover possession of land cannot be brought after 12 years from the time when the cause of action first accrued, instead of 20, as it was before. If, therefore, the neighbour has been in possession of the piece of land in question for 14 years, he would have a good defence by pleading the statute to the action. The date from which the 12 years reckon would be the time when he obtained possession. If "Loser" has looked on for 14 years without asserting his rights, he has only himself to blame. But even should the mistake have been mutual, and although he has only recently discovered it, the statute would run from the day when his neighbour got possession, and so bar his remedy.

(47559.)—In this case the querist should take out letters of administration to his mother's estate; as, until he does so, he has no legal right to proceed for the recovery of her property. As administrator, he should then bring an action in the Chancery Division against his brother for a declaration that the houses in question form a portion of his mother's estate. If what he says as to the houses having been bought with her money, and being about to be transferred to her name just before her death can be proved by him, the Court will declare them to belong to his mother's estate, and he will then, as administrator, be able to sell the houses and other property under the order of the Court, and the estate will afterwards be divided between himself and his brother equally.

Fred. Wetherfield, Solicitor.

TRICYCLES.

[20354.]—I am glad to see the subject of tricycles is not quite dead in our favourite "E. M." I quite agree with H. A. White, that tricycles are not fully developed yet; but they are making rapid improvements. I have been experimenting for some months. I have just completed the arrangement Mr. White speaks of. I tried my machine last night, and found a decided difference in regard to the power obtained. I set my cranks back 3in., and handles forward 2in.

In respect to the handles being placed directly over the axles, I do not agree, as you would be liable to tip forward in going down hill, and get an ugly spill.

I may have something to say soon about brakes

July 30. **Ex.**

GAS-ENGINE EXPLOSIVES.

[20355.]—In No. 903, July 14th (20274), "Ll.B A." says:—"I should like to hear the opinion of other correspondents on these points, which are of great interest." He had said before: "If we burn one gramme of hydrogen with sufficient oxygen to form water, we develop *about* 34,000 (gramme degree centigrade) units of heat. Now, Sir, science admits of no *about*, it being unscientific. If you would kindly permit me to intervene in the question, I would first say that the number of calories elicited by such combustion, are not *about*, but exactly 34,560, which, so far as I know, is not yet known to scientists. At least, I never noticed it in any English text-book or other publication. There have certainly been many figures given as the true one, but all are empirical, and not stœchiometric — *physical stœchiometry* being still at this moment unknown to chemists and physicists. In a communication to the Académie des Sciences, 7th February, 1881, I said: "Récemment M. Berthelot informa l'académie qu'il avait observé que la combustion de H_2 *produit* 69,000 calories; mais il ne dit pas *avec quoi* elles sont *produites*, ni pourquoi c'est 69,000 plutôt que tout autre nombre. Si H_2 produisent 69,000, H produit 34,500. Est-ce bien là le véritable nombre? Quels en sont les constituents? Comment le prouver? Selon quelle loi physique et quelle stœchiométrie? De nombreux savants se sont préoccupér de ci sujet, tous ont obtenu des résultats différents. Laplace et Lavoisier ont obtenu 23,352 calories, Clément Désormes a trouvé 23,294; Despretz, 23,640; Dulong, 34,601; soit moitié plus, ou 3 au lieu de 2. En 1843, Andrew trouva, 33,613; en 1845 Fabre et Silberman trouvèrent, 34,462; en 1860, Pelouye et Frémy trouvèrent 30,000; en 1872, Thomson trouva, 33,971; en 1877, Than trouva, 33,867; Schuller et Warter trouvent, 34,126; et M. Berthelot, 34,500. Tous ces chiffres si dissemblables ne peuvent être vrais; en est il un seul qui le soit? Aucun de ces habiles expérimentateurs ne donne *le mode de production de ces calories de cause à effet selon une loi*, n'en indique *les éléments ou équivalents constituents et leurs proportions*, de sorte que tout contrôle *scientifique* est impossible, et qu'il faut *croire*, non savoir, *douter*, ou *nier*. Mais de tous ces savants également habiles, lequel croire? Le mieux n'est il pas de *douter* encore? Les quantités poids, et volumes der gaz employés, celle de l'eau produite, sont exactement les mêmes pour tous. Pourquoi donc la chaleur développée diffère-t-elle de 2 à 3, et ne se ressemble-t-elle chez aucun? Évidemment les élements constituents *chimiques* et *physiques* de l'eau et de la chaleur sont les mêmes pour tous. Qu'advient-il de la chaleur qui manque chez les premiers expérimentateurs? Le savant doit au public ces explications précises, incontestables, et autant qu'elles sont connus.

> "Ex nihilo nihil; in nihilum nil posse reverti,
> Omnia mutantur, nil interit.

"De tout les chiffres donnés, celui qui se rapproche le plus de l'exactitude est celui indiqué par M. Berthelot, bien qu'il ne sait par exact. Celui de Dulong est trop élevé, celui de Fabre trop bas. Qui donc indiquera le chiffre vrai? = qui? — ce sera *la loi physico chémique* et *les deux Stœchiométries chimique et physique*. Ce sont elles qui donnent l'équation incontestable qui suit:—

"$1 \times 3 \times 4 = 12 \times 12 \times 12 = 1723$; $\times 20 (= 4 + 16) = 34{,}560$ ou $34{,}560 \times \frac{2}{3} = 23{,}040$.

"34,560 calories sont obtenues quand la combinaison est obscure, et 23,040 lorsqu'elle est lumineuse; les proportions et équivalents constituents qui produisent la lumière sont exactement ceux qui manquent à la chaleur. Les premiers connue les derniers expérimentateurs ont donc également à peu-près autant raison l'un qui l'autre; leur empirisme approche de la loi. Les chiffres de l'equation ci-dessus ni sont point de fantaisie, ils reposant sur les faits, les corps, leurs formes, leurs volumes, leurs poids, leurs éléments constituents chemiques et physiques, pondérables et impondérables en proportions fixes et absolues de leurs équivalents. M. Berthelot a lieu d'être fier d'avoir approché la vérité a 0 000 près. Mais il ne sait pas pourquoi." Your correspondent thinks that the combustion of the two gases HO invariably produces the same quantity of calories in every possible combustion; but he is mistaken. The same quantities of the same gases contained in bodies composed of the same chemical elements in same proportions, but differently arranged, do not produce by combustion the same heat, and a calculation based on the chemical atomic weight exclusively will not prove correct. Imponderous elements acting as factors of heat must be accounted for. *Heat is not produced by chemical or ponderous substances*, but by their imponderous elementary constituents. Bodies of exactly the same chemical composition, the ones odorous, the other inodorous, or of different smell, do not produce the same number of calories—e.g., essence of turpentine and essence of lemon are both composed of $C_{20}H_{16}$; but the density of the first is 0·864, the second 0·847, their odour differs, and their combustion does not produce the same heat. The difference in the arrangement of the constituents of smell makes the difference of heat. I submitted to the Académie a table of eleven different states of bodies composed of $C_4H_4O_4$ = weight 60, the combustion of which did not produce the same heat. On page 416 there is an article on "The best Gas for the Gas-Engine," in which details are given of empirical experiments respecting the correspondence of light and heat produced by gas-combustion, in which the author takes no notice of the respective elementary constituents of these two fluids. Of course coal, as well as all other combustible substances, by combustion elicits light and heat, which are in a right ratio with the proportions of the constituent elements of each they contain, and their arrangements. If, therefore, a chemist knows *the elementary constituents of heat and light, the quantity of them contained in the combustible and combinant bodies, and their special arrangement*, he is sure to be able to tell and explain a priori what quantity of light and heat will be elicited by their combustion; but vice-versâ, he would be mistaken who would believe that all sorts of coal always produce a same given quantity of same gas—that cannel coal, for instance, always produces the same quantity of gas of the same quality—that is to say, always produces the same number of calories and of candle-lighting power. These vary according to circumstances, and the manner in which the gas is extracted. If, for instance, the retorts are heated under 800° C, there will be a great quantity of coal-tar produced, but less gas of middling lighting and heating properties. If at 800°, it will be superior both in quality and quantity; if above 900°, 1,000°, the quantity will be greater, its lighting properties will be inferior, its heating ones will be superior. In such case a quantity of carbon oxide is produced which increases the volume of gas and its heating properties, but diminishes its lighting ones. In all cases the proportions of heat and light in gas are in correct ratio with the respective proportions of elementary constituents of each fluid contained in it, provided nothing else interferes. Therefore I repeat that any one who knows which are these respective constituents will be able to tell beforehand the proportions of heat and light that will be elicited in their combustion; and this is simple and easy to any one who knows chemical and physical stœchiometry, but is totally impossible to any one who is ignorant of them. Every one knows gunpowder explosions; but who knows in what they differ from boiler explosions? who can explain it according to a law by mathematical equations. Textbooks say nothing of it. I will here explain gunpowder explosions, which can be controlled, but, for fear of committing blunders in writing English chemical terms. I will express myself in my native language. La poudre à canon est = $KOAzO_5, C_3S$. L'azotete de potasse $KOAzO_5$ a la formule $KOAz.\overset{+}{O}\overset{--}{E}_5$. Le soufre $S = S\overset{-}{E}_3$, et le charbon $C_3 = C_3\overset{-}{E}_9$. 1°. Le potassium se combine avec le soufre $S\overset{-}{E}_3$ et les équivalents négatifs $\overset{-}{E}_3$ du charbon, et devient du sulfure de potasse $K\overset{-}{E}_3S\overset{-}{E}_3$; 2° Le carbone C_3. Se combine avec les O_6 restant, et forme l'acide carbonique C_3O_6. L'azote Az devient libre. En admittant un atome double de poudre on obtient les résultats suivants:

$$K_2O_2Az_2\ \ \overset{+}{O}\overset{}{E}_{10} + C_6\overset{-}{E}_{18} + S_2\overset{-}{E}_6 = K_2\overset{-}{E}_6S_2\overset{-}{E}_6 + C_6O_{12}\overset{+}{E}_3 + Az_2\overset{-}{E}_2 + \overset{-}{E}_{10} + \overset{+}{E}_7. +$$

L'explosion est produite par les équivalents $E_{10}E_7$—devenus libres. Elle produit peu de lumière et beaucoup de chaleur

$$3\ \overset{-}{E}_{10} + 3\ \overset{+}{E}_7 = 4\ \underset{-\ \ +}{\overset{+\,-}{E_2E}} = \underset{-\,+}{\phi} \text{ Lumière} + 13\ \overset{+\,-}{EE}_2 =$$

θ = Chaleur. $E_{10} + E_7 = EE_{17} = \psi_4 + \theta_{13} = \psi\theta_{17}$. Until now gas-engines could only be used in places where gas can be procured from gas-works. Owing to my process for producing gas on the spot, without gas-holders, and in successive quantities proportional to the supply of every piston-stroke, it is possible to use them anywhere. Besides, a day will soon come when coal will be replaced by water for heating and other purposes, either by my system or by instantaneous transformation in gas, or by any other more perfect one. Then setting the Thames on fire will no longer be nonsense—it can easily be done now. Then it will no longer be the ship that will carry her own combustible, but the combustible that will carry the ship. This will cause a great revolution in industry at large, in which I feel happy to think I shall have my share.

Ch. Rabache.

Morchain, par Nesle, Somme, France.

CROWN-GLASS ACHROMATISM.

[20356.]—I SHOULD have sent this note sooner, but have been waiting with the expectation of seeing more particulars about the crown-glass telescope proposed by your esteemed correspondent, Mr. W. G. Penny. To my mind, it completely proves the impossibility of making such an instrument achromatic.

Let us turn to page 273, on which appears the equation of achromaticity, viz.:—

$$(f_1 - d)^2 = f_1 f_2.$$

Since the dispersive power varies inversely as the focal length f_2 must be less than f_1; for if not, the convex chromatism would exceed that of the concave when the lenses were in contact, and the error would be increased by separation.

Also, in order that a real focus may be formed, it is absolutely necessary that the reduced focal length $(f_1 - d)$ of the first lens shall be *less* than the focal length f_2 of the concave lens; for if not, the rays would diverge on emerging from the second lens.

Can these two most essential conditions be satisfied by the preceding equation?

By taking the square root of each side we have:—

$$(f_1 - d) = \sqrt{f_1 f_2}.$$

Now, since f_1 is greater than f_2, the square root of their product must be greater than f_2; therefore $(f_1 - d)$ is *greater* than f_2. But we have just seen that it ought to be *less*; therefore, the two conditions *cannot* be simultaneously satisfied.

I trust "W. G. P." will examine the matter, and see if I have in any way misunderstood his reasoning. Like a valued friend who writes thus to me—"I cannot yet see Mr. Penny's telescope a success, but I should like to be wrong."

Orderic Vital.

REPLIES TO QUERIES.

◆

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46744.]—**Marble.**—Thanks for replies. I have been told that Kilkenny is paved partly with its black marble. Could "H. O'B." tell me where the variety known as "Irish Green" is found? I think it would be interesting and useful if readers of "ours" would say where marble from different quarries can be seen in public buildings. What do English marbles cost per foot (cubic) at the quarries? Is there no blue marble?—MURANO.

[47059.]—**Iron Chimney Rusting.**—If "J. R." will mix soot and boiled oil together to the consistency of thick paint, and put that on to his chimney, I think he will find that it does not come off, except close to the bottom of the chimney. The bottom part of the chimney requires painting once a week. Occasionally rub the chimney over with an oily cloth or cotton waste.—W. J. B.

[47174.]—**Pedal Reeds.**—To MR. J. H. HUXLEY.—Would you kindly give an outline sketch of the arrangements adopted in the instrument named on p. 385 for the pedal work, showing windchest, bellows, &c.?—J. H. T.

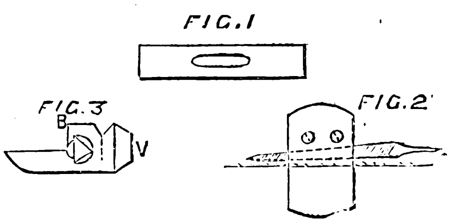
[47215.]—**Embossing Glass.**—According to "Phonetic's" account he has either got hold of peculiar glass or does not give long enough time. If the etched parts are wanted clear, the glass must be in contact with the acid. What does querist mean by saying he used the acid "pure"?—A. B.

[47219.]—**Textbook of Physiography.**—The best books for this subject are Archd. Geikie's "Lessons in Physical Geography," and Huxley's "Physiography," both published by Macmillan. If you study those books thoroughly, you will be able to answer more questions than some of the examiners themselves could.—S. R.

[47223.]—**Bird-Cage Making.**—You want a pair of cutting-pliers, an archimedian drill, and two boards, in one of which you have a number of pins stuck in zigzag fashion to straighten the wire, and the other for sticking pins in to bend the wire to the shapes required.—T. P.

[47226.]—**Picture-frame Making.**—In reply to "Beta," I may state that I made my shooting-board after the pattern of those used by professionals, thus:—Take a piece of inch stuff, say 3ft. long by 10in. broad, plane it up true, on top of this glue and sprig another board same length, but say 4in. narrower, and about ⅜ thick when planed up. On top of this and in the centre of its length, glue and screw a piece at an angle of 45°, say 1½in. deep by 2½in. wide. From "Beta's" query it appears that he drives his plane alternately with the right and the left hand; but this is not according to "Cocker." Place the thumb on the piece of moulding, and the rest of the fingers against the opposite side of the angular piece, and squeeze firmly; then turn the moulding end for end, and ditto ditto. Memo.—Ascertain by means of a square as is square. (Amateurs' squares are not, as a rule, more than nearly square; and should you, or any other man, doubt my assertion, you or the other party need only to plane up carefully the edge of a board, and place the square against it; draw a fine line with a sharp chisel, then reverse your square, and adjust your error, which it is extremely probable will appear.) By means of this adjusted square, ascertain if your trying plane, when lying on its side, is exactly at right angles to the part where the moulding lies, as I had to sprig and glue a thin strip along the outside edge in order to adjust this error. Finally, have a fat goose for dinner as soon as possible, and preserve the grease to put on the sole and side of your plane, and you will find these directions to be "plane" sailing.—J. J. A., Liverpool.

[46748.]—**Sharpening Carpenters' Saws, &c.**—Just a little more to conclude this subject. Last, but not least, in the sharpening of saws, of whatever class, they are apt to get out of order—that is, in hills and dales, and they will need the doctor. The following sketch will give you an idea. Fig. 1,



a piece of ash or beech, 1½in. by 2in. by 6in.; a mortise cut in it, and a flat, oval pebble inserted, held against a circular-saw to show where it runs out; touch up where wanted with a file until true; the other, Fig. 2, a piece of ash, birch, or any firm wood, 2½in. by 2in. by 1in., about 1½in. from the crown A; bore a hole in the centre of edge, the size that a piece of saw-file will drive in, and cut as shown. B and C, Fig. 3, show it in operation.—JACK OF ALL TRADES.

[47230.]—**Unhealthy Trades.**—Wool-sorting, fork-grinding, and similar occupations, are the most unhealthy. I should say it is decidedly not impossible, though probably very difficult.—S. R.

[47231.]—**Insulating Material.**—Yes; insulite. This substance was described under head of "Scientific News" a few weeks ago, but I cannot refer you to exact place.—H. STOOKE.

[47239.]—**Deafness.**—"Another F.R.M.S.," in replying to the above, at page 481, advises the querist to "take one-half of his vegetables after their conversion into beef or mutton," on the plea that "the vegetable food he is groaning under is, without doubt, deficient in bile elements." As the question is of great interest to many, perhaps your obliging contributor, Dr. Edmunds, would say whether there are valid grounds for this dictum. My experience is the other way. For years I suffered from sick headache about every six weeks. Cure: bed, and 5-grain blue-pill, with seidlitz powder next morning. Ultimately, the attacks culminated in a sharp attack of congestion of the liver. On recovery I determined to make a complete change in my diet, taking meat only as gravy with my vegetables, winding up with some light pudding and no pastry. Under this *regimen* my headaches vanished, although I sometimes "see stars" on suddenly stooping. I have always thought that what is called "biliousness" arose from an overplus of bile, and not from a deficiency, as we are now told. Further elucidation on this point would be of great interest to many, as well as to—H. J. NOLAN, Clifton Villas, W.

[47239.]—**Deafness and Vegetarianism.**—"Another F.R.M.S." seems to think he has a capital argument against vegetarianism. However, I imagine he is not a vegetarian himself, but has been totally deaf for twenty years. As a fact, I have never before heard of a deaf vegetarian, though I know many flesh-eaters who are so. I have myself been a vegetarian ten or twleve years, and certainly have full use of my five senses. My hearing is very acute—I can distinctly hear the "dtt dtt dtt" or "sst sst sst" of the bat, which I read, I think, in "ours" was a test for hearing, and my sight also is very good. I have frequently distinguished objects at a distance when people with presumably average good sight said they could see nothing. I have counted 15 or 16 stars in "Charles's Wain," and I am by no means wanting in taste, touch, or smell. However, I never had beer, wine, spirits, tobacco, coffee, or tea before I was 16 years of age, and I practically abstain from them now. Never drink spirits, and not smoke quarter of an ounce of tobacco yearly. I cannot say I have ever felt evil effects from wine, but I always eat plenty before drinking it, and should not think of taking it when I had any great strain on mental or muscular powers, nor in very hot or cold weather. I should fancy Mr. Ollard takes, or has taken, largely of tea, coffee, or some drug or drugs, which has injured his digestive organs. Let him try oatmeal porridge before breakfast (a plate of porridge and a basin of cold milk, and have your meal from the Highlands. A miller advertises in the "E. M." who supplies excellent meal, and not too coarse). Have good bread made of the whole of the wheat, ground very fine—if it can be got, or Vienna (Hungarian) bread. I have a great dislike to the coarse whole-meal bread myself. Why is it recommended so? The only time I ever had heartburn it was caused by eating a loaf of this bread for tea. Mangoe chutnee would be, very probably, beneficial. Try a third of a shilling-bottle every day at dinner for a week. It is nice with rice boiled in water, with sugar.—MURANO.

[47239.]—**Deafness and Biliousness.**—Life is what we make it, and I should be indeed ashamed if such slight inconveniences as deafness and biliousness were to take all life's enjoyments away. What I wanted was an answer from so sensible a man as Dr. Edmunds as to the best exercise, and if I might use such a term, "natural cures," not artificial, such as drugs, &c., which, except in extreme cases, are my abomination. I am certainly anything but groaning under a vegetable diet. Life has never been happier to me. I never took ale, very rarely wine, and left off spirits (which I used to take occasionally) by the advice and orders of an F.R.C.S. They are the worst things for an invalid stomach. I cannot refrain from a few words as to vegetarianism. People who know nothing about a thing are always the first to abuse it, as they do not believe in what they have never tried. They think that others are committing nothing short of suicide by following what they cannot understand. When a flesh-eater (I still take all animal products) I had a double curvature of the spine, inflammation of the lungs (three attacks), and lastly, a severe attack of chronic catarrh of the digestive organs (from which, owing to the skill of my kind doctors, I am better). I turned vegetarian purely by accident, and before I even knew of a vegetarian society. Before becoming a vegetarian, I was never free from the kind care of my doctors, and for some years never passed a day without taking some concoction intended to make the digestive organs perform feats they were totally unable to do, owing to my having given them stuff which they could not naturally digest. Since becoming a vegetarian, I have banished pepsine, pills, &c., as I never now need a digestive or purgative, only once having had a bottle of medicine. On what plan my stomach is built I leave anatomists to say, but it certainly declines to take vegetables in any other than their natural conditions without serious inconvenience to its owner, and is far better, and so is its owner now, that instead of getting a chop (4-5ths of which are water) it has only a plate of lentils and haricots or potatoes. I should have thought that a man who has been deaf for twenty years without hardly feeling it, would have tried or fully convinced himself of a thing before publicly attacking it. Personally, I cannot speak too highly of a vegetable diet, and were a little common-sense exercised by others to try, they would, as I have done, 'bout ship, not for a month or two, but for many, very many months. Although fond of alcoholic drinks, and passionately fond of smoking, since becoming a vegetarian, I have voluntarily given them up, as I have felt no desire for the use of the one or the other. My letter is far longer than I had intended, and I hope the Editor will pardon me. I suffer chiefly from biliousness at the change of weather. I have never heard of a vegetarian who spoke badly of the diet. I always hear the same. I was never so well as when a vegetarian. I would further state a fact I had forgotten—that, before I became a vegetarian, I suffered fearfully from flatulence. It is a thing of the past.—JOHN ALEX. OLLARD, F.R.M.S., Enfield.

[47240.]—**Oil-Silk.**—I don't know the trade way of making this material, but I suppose it can be made by dipping silk in linseed oil, and hanging it up to dry between each coat.—H. G. R.

[472744.]—**Illuminated Clock.**—In his reply to the above (page 455), Mr. Phibbs mentions certain necessary precautions that should be taken before applying Balmain's paint to iron. Would Mr. P. kindly give further particulars on the point?—H. J. NOLAN, Clifton Villas, W.

[47247.]—**Product of Brick-burning.**—Is it possible that it is dust from the fuel, as it is only on the surfaces exposed to the draught? Have you analysed the substance?—E. G. M.

[47251.]—**Carriage Varnishing.**—Possibly the underground was not properly finished, and absorbed the varnish. It is impossible to say what is the cause without examination. See a recent article on "Cart and Wheel-making," where the art of painting and varnishing is fully described.—T. L. W.

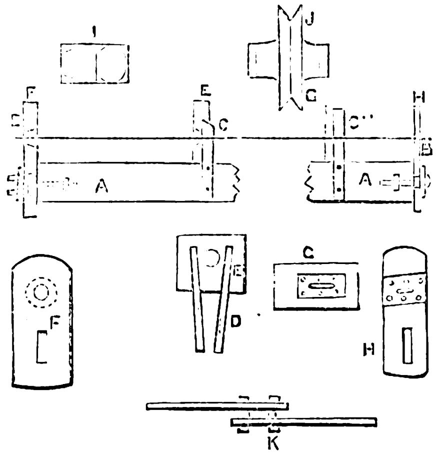
[47255.]—**Lacquer.**—You might try dipping into best French polish, or best pale paper-varnish. For lacquer you require to heat the objects, and that would be as objectionable as the brush.—UPSILON.

[47263.]—**Boiler-Cleaning.**—If I had a steam-boiler it would never receive 56lb. of cutch per month if it were as large as the *Great Eastern*. All that any steam-boiler wants is as pure feed as possible, and regular washing out. The water should certainly be filtered, and as much of the lime, &c., as possible taken out of it; then an occasional dose of common washing-soda will do all that is needful, and the boiler will last twice as long. Cutch or catechu contains nearly half its weight of tannin, and will certainly injure boiler-plates. About 1 to 2lb. of soda dissolved and added to the feed will be enough for any ordinary-sized boiler per day; but the quantity obviously depends on the quality of the water as well as on the number of gallons used per day.—ESSAR.

[47267.]—**To Chemists.**—CaO and H_2O mixed in proper proportion would probably do what you want, and do it in less time than six hours after mixing; but that could be arranged, I think, by putting the H_2O under such conditions that it could not reach the CaO until after the lapse of some time. You may ask the query again, and get no better answer; but as, from the last sentence of the query, you appear to think that you are entitled as of right to a reply, I send the above suggestion.—VIDEO.

[47271.]—**Waterwheel Grease.**—What is partly working in water—the journal you want to grease? What sort of waterwheel is it—only 30in. diameter? Railway grease, tallow, or one of the heavy shale oils might suit, but can't say unless have more particulars of conditions.—LUBRICATOR.

[47285.]—**Gymnastic Apparatus.**—I think it is very doubtful whether you will get a machine for the purpose you want, and therefore forward the following sketch, which, I have not the least doubt, will put you right. A A is a batten 6in. by 3in., 14ft. long, or a deal 9in. by 3in. if you like it better; but I think the first strong enough if bolted to three uprights in the ground, the top jacked up true. Do not touch the other part, as it will be more likely to cast. At B B are two tenons, B′ for cone chuck or headstock, B″ for guide for drill; C″ C″, horns joggled into the side, 2in. wide ⅜in. thick, of ash, beech, or oak, C to hold the other cone chuck; these—cone, head, and chuck—should be made of hornbeam beech. A good hard piece of mahogany will do 1½in. or 2in. thick. In these bore a conical hole at about an angle of 65°. The position of horns is shown at D C″; carry the other guide-plate, G, thus, and the end may be ½in. or ¾in. thick, with an iron plate screwed upon with a mortise through ½in. by ¼in. full; the first guide near the chuck should be about 8in. from it, the other, H, at the extreme end. When you have bored as far as you can get, remove the end one; the headstock and guide at the end are put upon a tenon, the same as a bedstead, with a nut let into a mortise, and a bolt and plate through. Soak your chucks either in linseed, or, what is better, put a warm iron over them with some paraffin wax, and lubricate ends with soft soap and powdered French chalk made into a paste. Your bars being square and straight, make the angles (see I) with a chisel to fit cones as near as you can; put pulley upon square, J being a pulley the size you require, with a square hole in it, and hooped at each end. K is two pieces of wood 1½in. wide and 8in. long, with two 5-16 nuts and bolts to hold the drill with to push it into the work, and pull out for clearance, to be used at first between C″ and H′. Let your drill be 1ft. longer than your job, or more if necessary. When you have jacked up your battens true, strike a line and make it deep from end to end through the centre to set your other fittings to, and make all square and lineable. When boring, do not be too greedy, and clear very frequent, for you must have a bit strong enough to stand the twist, and therefore but little clearance. Your tool must be sharp, but not too proud, or it will pull itself in, and it will take you all your time to get it out, unless you split your job.—JACK OF ALL TRADES.



[47292.]—**Mildew on Vines.**—Will Mr. Albert Smith kindly say how "permanganate of potassium" is to be applied to vines? "Nemo's" plan I have tried, but it has failed with me. I have just met with a person who has treated his vines much the same way as that recommended by "W. B. L." (leaving out the manuring and slabs of glass with sulphur), and this year he is quite free from the pest. I shall therefore adopt "W. B. L.'s" advice, and prepare the vines as he describes for next season. Thanks to all three for their kind replies to my query.—AMATEUR GARDENER.

[47363.]—**Watch Cylinder.**—My instructions to "Hall" for putting in a cylinder plug are genuine, and, as far as the working part is concerned, the method is quite as satisfactory as turning them in; in fact, in some instances it is superior. At any rate, as far as an amateur is concerned, I will undertake to say that he would be more likely to succeed with the file than with the graver. The following are full instructions for putting in a cylinder plug with the file:—First remove old plug, shown Fig. 1. A is the punch, B is the plug, C is stake, D is cylinder; you see that the hole in stake is slightly chamfered at top on which the cylinder rests, while the plug has a free passage right through the stake. Fig. 2 is the punch (A, Fig. 1) and is about the size. Now make the plug: take a piece of steel wire (a pivot drill if you have one large enough) about the temper of a pivot-drill, put a ferrule on one end and a small piece of brass rose on the other, take your graver and turn the face of brass rose true—this is easy; and then you have Fig. 3; but before you face the rose you make two true small centres as follows:—place the piece of steel wire in the turns and file a piece off each end with a 3-square file. As the file cuts through it will find its own centre; now file down the end outside the rose to half the size of plug required—this is to be done in the turns; now remove rose and file down body of plug—i.e., where the rose came off, until it enters into the cylinder, as shown Fig. 4; now mark it where shown by the arrow. Replace and cut part of the way through with a file; now measure length of new plug by the old and cut off end, not shorter; of course, allow for pivot, now break off new plug, put it in the mouth of cylinder, and drive in new plug the same way as you drove out the old, only using a smaller hole in the shake. Now make a hole in the end of a piece of brass plate, Fig. 5, of sufficient thickness to allow for length of root, now place it in the turns, as shown Fig. 6, and file down pivot; polish and round off in the usual way; Fig. 6: A is ferrule, B body of cylinder. Fig. 5; D end of root intended for pivot, E piece of turns, F guide-screw for file; place the file on D, let the side rest against C, and that will give you the right length for pivot.—A FELLOW WORKMAN.

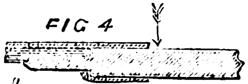

FIG. 6

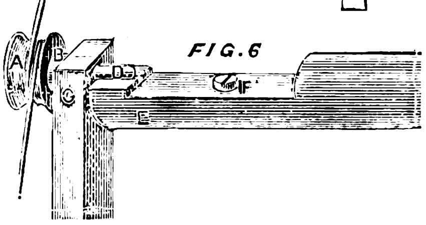

[47386.]—**Riveting Ships' Kelsons.**—If A. Rutt will get the *Marine Engineer* for July, he will find an illustration showing about ten different applications of machine riveting to shipbuilding.—LONDON RIVER.

[47387.]—**To "Aldebaran."**—It is not every telescope that will raise a spurious disc upon a star, neither is every condition of the atmosphere favourable, and still less could every amateur appreciate such a disc if raised. Rays or wings do not necessarily prove a telescope to be worthless, since they may be caused by a field-lens soiled by the fingers, or by any of the lenses being out of square to the axis of the tube. An apparently sharp definition of bright objects, such as solar or lunar detail, proves nothing more than that an excess of light overpowers such defects, and render them difficult to detect. As it appears your correspondent has separated the lenses of his object-glass, it is very possible that he may not have replaced them in their original position, which, in lenses of the size he mentions, is often a very important item. If there is no mark at the edges to guide him, I should advise him first to make a pencil line showing a certain position, and to gradually turn the crown-lens until a better definition of bright points is attained. A permanent ink mark can then be made for future guidance. I have more than once tried to improve faulty object-glasses by cementing, though I cannot say I have ever been very successful, at least I have never noticed any difference. A little light would be gained, but that would probably be all. Still, if all other means fail, there would be no harm in trying.—Aldebaran.

[47434.]—**Lathe.**—In answer to "Miner," if he will be kind enough to state more clearly what he really desires to know, I shall be glad to render what information he requires. I must plead ignorance in not knowing what is required to Babbitt mandrel-bars.—J. H. Evans.

[47436.]—**Steam Pipe.**—To cut steam-piping the standard pitch for any size is eleven threads to the inch.—W. Bradshaw, Derby.

[47456.]—**Canvas Boat Making.**—The keel should be of elm or oak, 2in. by 2in. For a canvas boat there should be, instead of planking, six or eight stringers on each side (of oak, elm, or larch, ⅝in. broad, by ¼in. thick), running in a fore and aft direction. A gunwale of oak or ash, 1½in. by 1in., should be fitted to the top of the boat, and fastened to the stern post, &c. The ribs should be ½in. wide and 3-16in. thick, of ash, and placed every 6in. The ribs of some canvas boats are made out of hoop-wood, such as can be got off casks and butter tubs. A few yards of new stout sail-cloth would do for the skin of the proposed boat; and one of the following receipts for waterproofing from "Yacht and Boat Sailing" (Mr. D Kemp), would make her quite water-tight: "Boil 12oz of beeswax in 1 gallon of oil for two hours; paint the cloth with this mixture twice or thrice. If black is required, add the necessary quantity of black for the second and third coats." The following plan is recommended in America:—"To waterproof cotton-drilling, boil a mixture of 6oz. hard yellow soap, ½ pint water, ¼lb. patent driers, 5lb. boiled linseed oil." If L. Nelson wishes it, and will advertise his address, I could supply him with more information and particulars of one or two other canvas boats, &c.—Nemo.

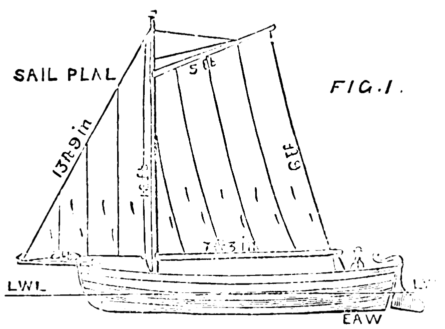

FIG. 1.

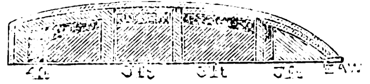

FIG. 2.

[47463.]—**Change Wheels for Screw-Cutting.**—I would advise "Try Again" to purchase one of Calvert's Almanacs. There is a list of change-wheels in every year, and they are only 4d. each at any bookseller's.—W. Bradshaw, Derby.

[47463.]—**Change Wheels for Screw-Cutting.**—Suppose we require to cut a screw 24 to the inch, the leading screw having 4 threads to the inch, we proceed in this way. Now, it is quite evident that the lathe-spindle must revolve 24 times, while the leading screw revolves four times; we then multiply these numbers by 5, to make them correspond with the wheels usually in stock; therefore, a wheel of 20 on the lathe-spindle, and a wheel of 120 on the screw, would cut 24 to the inch; but as these wheels would be too far apart to gear, we must make use of the stud to gear up; so if we put a wheel of 20 on the lathe-spindle, and one of 120 on the stud, then on the same a wheel of 80, and another of 80 on the lathe-screw, we have a train that would cut the required pitch. Now, as the wheels all increase by 5, we have not two of 20 teeth each; therefore, we must select some others. To do this, arrange the wheels thus:— $\frac{20}{120}\ \frac{80}{80}$. To keep these relations correct, whatever number one of the upper or driving wheels is divided by, one of the lower or driven wheels must be divided by the same; therefore, let us divide by 4, and we have a train thus—$\frac{20}{30}\ \frac{20}{80}$, which will not do, because we have two wheels of 20 teeth each. If we now multiply by 5, we obtain the required train, thus—$\frac{20}{150}\ \frac{100}{80}$. The wheel of 20 teeth drives one of 150 on the stud, and on the same stud a wheel of 100 driving one of 80 on the lathe-screw.—Thos. J. O'Connor, Dundalk, Ireland.

[47468.]—**Transit of Venus.**—There is probably no better place than Jamaica to get a good view of the transit from ingress to egress. The times given in *Nature* for a spot in the Blue Mountains, long. 77° 30′ W., lat. 18° 5′ N., are Dec. 6, local M.T. First external contact, 8h. 52m. 37s. a.m.; sun's altitude, 30° 15′. Last external contact, 3h. 0m. 22s. p.m.; sun's altitude, 28° 29′. The Bermudas are also a suitable locality, and will form a nice holiday resort for the winter months.—J. R. H.

[47470.]—**Watch Repairing.**—Read my reply to "G. K., Stockton."—A Fellow Workman.

[47471.]—**Watch Repairing.**—You cannot do either without a mandrel. I gave instructions for making one a few weeks ago. My next article will be on jewelling.—A Fellow Workman.

[47474.]—**Astro.-Eyepiece.** — "To Aldebaran."—The ring sometimes seen inside a telescope-tube is only a shadowy reproduction of the object-glass, and is caused by a mutual reflection from its inner concave surfaces, refracted to a smaller diameter. A more striking effect is often produced by the double sets of lantern lenses, when the illusion is occasionally so complete as to lead one to imagine another set of lenses suspended in mid air. A still more remarkable effect is when a bright image is reflected by a concavo-convex or meniscus lens, the convex side being used as the reflecting surface. In this case both the surfaces exposed to the light are convex, from which it might have been supposed the incident rays would have been scattered rather than concentrated as they are to a sharp focus. Perhaps our valued contributor, "Orderic Vital," will kindly explain the phenomenon. The nominal power of a telescope is calculated from the solar focus of its object-glass, though its actual power must vary according to the angle of the entering rays, or, in other words, in proportion to the distance of the object viewed. The closer the object the more divergent will be the rays. This will result in a longer focus and a larger image; hence, if the focus of a gas-flame be 41in. and the eyepiece equal to a single lens of 1in. focus, the power would be 41, whereas celestial objects might, with the same telescope, be increased to 30 diameters only.—Aldebaran.

[47477.]—**Waves.**—Mr. White's "Manual of Naval Architecture" has an article on waves which might perhaps be of use to "The Sea." The following is taken from "Yacht and Boat Sailing" (Mr. D. Kemp).:—"Captain Molter, of the French Navy, measured a wave in the North Atlantic 2,720ft., or half a mile from crest to crest; and Sir James Ross, one 1,920ft. long. In the Bay of Biscay, where the sea is usually turbulent, waves have been seen 1,300ft. in length. . . . . Dr. Scoresby measured some Atlantic storm waves with lengths of 500ft. to 600ft. . . . . Professor Rankine, in his work on "Naval Architecture," speaks of waves on rocky coasts rising to 150ft., and waves have been known to fly over the Eddystone Lighthouse. However, the greatest heights of deep-sea waves measured by Dr. Scoresby, and other accurate observers, have been 48ft.; but it is rare to find waves exceeding 30ft. in height. Ordinary storm-waves, such as met with in the Atlantic of about 200ft. in length, have a height of about one-twentieth of their length; but the ratio becomes lower as the length of the waves increase, and waves of 1,000ft. in length have been observed with a height of 10ft. On the other hand, waves of 600ft. in length, have been observed of unusual steepness, and with a height of one-eighth of their lengths. . . . . The speed of waves is generally proportional to their length. Thus a wave of 20ft. long will travel 6 miles per hour, and one 50ft. long, 9 miles; 120ft., 15 miles; 200ft, 19 miles; 400ft. 27 miles; 600ft. 32 miles; 1,000ft., 42 miles."—Nemo.

[47488.]—**Indigestion.**—I am no doctor, but I can help you. Your diet is not nourishing enough. Abstaining from food will not cure indigestion. Tea is very injurious. A friend of mine suffered wretchedly from indigestion, but owing to the following treatment is now completely cured. For three months this diet was persevered in without any change. Dinner and supper: the lean middle of a grilled mutton chop, juicy, and rather underdone; bread; one tablespoonful of pale brandy in two of warm water. Breakfast and tea-time: No tea or coffee, but a small cup of cocoa, made with milk, and bread and butter or toast—if toast, either dry or buttered cold. After three months, this strictness was a little relaxed in favour of light milk puddings, eggs, boiled chicken, &c. You should give up tea, coffee, sugar, and beer. Sugar causes much acidity of the stomach.—J. E. A.

[47490.]—**Loco. Engine with Broken Crank-Shaft.**—You pack the driving-wheels under the boxes on the stays or keeps, whichever you call them at your shop, which lifts them clear of the rail, and then you back on the top of the leading and trailing boxes.—W. Bradshaw, Derby.

[47498.]—**Indigestion.**—Tea is most injurious to a weak stomach, as well as the nervous system. Cocoa-nibs, boiled for about five hours, taken with milk, I find from experience the best stomachic. Next to it, Schweitzer's cocoatina can be made in a moment with boiling water; and in violent stomach attacks, where solids give pain, it is sufficiently sustaining, if taken frequently. I find sleep and all wonderfully improved since leaving off tea. The cocoa can be varied with coffee and milk in the morning, for instance, if it agrees. Tidman's Sea-salt in the bath is very invigorating.—C. M. Y.

[47501.]—**Clock-Wheel Cutting Engine.**—What is the reason a circular cutter will not answer if passed through at right angles with the plane of the wheel? It will cut them true, and finish them off. A snapping machine or punch will not make a job of them; a slotting machine is out of the question, and where are you going to get, or how make, a filing machine with file, whose section is what is required—i.e., shape of tooth?—Jack of All Trades.

[47502.]—**Transparent Photographs.**—The process which the querist describes as a "secret," and having been "recently introduced," has been well known among photographers for a number of years. In the first place, two unmounted photographs of the subject to be operated upon must be procured. One of them is then rendered transparent with a mixture of castor-oil and oil (not spirit) of turpentine, in equal parts; this is rubbed into the *back* of the photo three or four times a day, for three days; at the end of that time it will be sufficiently translucent. The next step is the colouring. The transparent one must be coloured very finely, putting in as much detail as possible; the other photo. is to be coloured very strongly, without any detail. Now take some hot melted white wax, and dip the transparent photo in it; then take it out and press it against the previously cleaned glass, holding both over a hot stove. This must be done very carefully, or failure will be the result. It is best to commence at the corner, and work gradually over the whole surface. A pad of cotton wool, covered with chamois leather is best to do this with; if any bubbles appear it must be pulled back, and a fresh attempt made. When this is satisfactorily accomplished, it is allowed to cool; when cold, the opaque photo. is placed at the back of it, so as to register in the same place, and be seen through it; a piece of gummed paper is then passed round the edge, and the process is complete. I should advise the querist not to commence with concave glasses, but try with flat ones, as it is very difficult to make the photo. adhere to the glass without air-bubbles; but patience and practice will soon overcome that difficulty.—C. Huffell.

[47502.]—**Transparent Photographs.**—I should think it scarcely worth while to pay five guineas for the secret of making the paste with which to fix the photographs to the concave glass when it can be bought for a shilling a bottle. Evidently "Greenhorn" does not live near London, or he would know how general this so-called art has become, and how easy it is to obtain materials and instructions. I tried to find out for myself how to get the photo without mark or air bubble on the glass, wasting much time and many photos—then I took a 5s. lesson, which taught me all I wanted to know. Materials, with papers of instructions, can be got in London at a moderate price; but I see it is against the Editor's rules to print any such addresses, so I can only advise querist to find out for himself, and to avoid any professional who pretends to hold a valuable secret. Materials required are paste with which to fix the photo to the glass, parchment paper, a piece of wood called an extractor, by means of which, having placed a piece of parchment paper over the photo, you extract as much of the paste as possible, commencing from the centre and working carefully and slowly towards the edge of the glass, looking constantly on the right side to see that you are getting all air bubbles out; fine sand-paper to remove as much as possible of the paper from the back of the photo; a cake of wax, sold on purpose, which is made hot, and in which the photo must remain an hour, and ordinary oil paints for painting. There is no occasion to buy the specially prepared colours which the professionals try to persuade you to do, if you know how to use the others.—M. E. F.

[47505.]—**Hot-Air Engine.**—The simple engine described in No. 796, p. 369, will, I should think, suit Mr. Smith, especially as he only wants to work a blowpipe—that is, presumably, a bellows. —Essar.

[47506.]—**Cement for Knives in Handles.**—Black rosin and a little red brickdust.—W. W. W.

[47506.]—**Cement for Knives in Handles.**—There is nothing better than a mixture of powdered rosin and bathbrick.—Essar.

[47506.]—**Cement for Knives in Handles.**—Use rosin and bathbrick, both finely powdered, about equal parts, but rather more of the rosin; heat the metal, and push it into the handle into which you have previously shaken the above powder. A few minutes will harden it for use.—H. O'B.

[47506.]—**Cement for Knives in Handles.**—Fill the socket with a mixture composed of equal parts of powdered rosin and bathbrick, then heat the end of the knife and thrust it into its socket and allow to cool. When set it is not liable to become detached by putting the handles in hot water.—C. Huffell.

[47506.]—**Cement for Knives in Handles.**—"Mater" will find the following answer his purpose well:—Fill up the hole in handle with finely-powdered shellac; make that part of the knife which fits in handle sufficiently hot to melt the shellac, then, while hot, place the knife firmly in handle. When thoroughly set, scrape off the overflowing shellac. This method, which is very simple, will not fail to give satisfaction, if done as I have described. I have fastened knives in handles in this way, and have found them last for years.—G. Fryer.

[47506.]—**Cement for Knives in Handles.**—"Mater" will find the following good:—Powdered rosin 4, brickdust 1, beeswax 1. Fill the handles with the above mixture, and having made the tang of blade nearly hot, plunge into handle, and keep it upright till cool. This plan will last for years, if the knives are not thrown into hot water when dirty, as is usually the case, loosening the blades, and cracking and discolouring the ivory handles. If the blades *only* were wiped with a wet cloth previous to cleaning, instead of being thrown anyhow into boiling water, knives would no doubt last three times as long.—Ape.

[47506.]—**Cement for Knives in Handles.**—The best cement that can be used is shellac, well crushed, and mixed with about an equal proportion (or less) of bathbrick-dust. Scrape out of the socket in the handle any loose material or dirt. Scrape also the "tang" of the knife-blade. Fill the socket with the above-mentioned mixture. Then heat the tang (not red-hot) in a gas flame, and run it gently, firmly, and quickly into the socket, "working" it a little to make set in a good position. You can plunge it into cold water to insure the cement being hard. Shellac is superior to common rosin for this purpose.—Murano.

[47508.]—**Weight of Girder.**—You may make the models of any materials you please, and compare the strength of various combinations, taking care, of course, that the several models are made under equal conditions. The question of the best form of girder, box, and plate was very fully experimented upon before the Britannia bridge over the Menai Straits was erected, many years ago, and the results may be found in Fairbairn's "Application of Iron to Building Purposes," and other works.—Ditton.

[47510.]—**Cistern.**—I have not gone into the details of affair, but premises covering about the same area, found for years a cistern in the ground, built of bricks and lined with cement, 8ft. deep, 8ft. long, and 5ft. wide, was all that they required. Jack of All Trades.

[47513.]—**Water Filter.**—A good deal would depend on the position of the filter; but at least an "Enquirer" will not depend on charcoal alone to take out the lime and iron. As much as possible ought to be caught by hair, felt, or woollen screens. Thus, suppose it possible to arrange an inclined trough, the filtering materials would be arranged as diaphragms sliding in grooves in the sides. The water would first reach the screens, and lose its mud, &c., and would then pass the charcoal, which might be solid slabs or fragments packed between wirework.—Nun. Dor.

[47515.]—**Dry Collodion.**—Sensitise and prepare the plate as for wet process, wash in distilled water, and dry in the dark; when dry, pour uniformly over the plate a two-grain solution of pyrogallic acid. If the plate turn brown, more washing in distilled water will be necessary; these plates are not so sensitive as when wet.—Nerog.

[47515.]—**Dry Collodion.**—There are several preservatives for collodion plates, but I will give the querist the one I am best acquainted with. The plate is coated and sensitised in the usual manner. On coming out of the silver bath it is thoroughly washed with distilled water, and the following solution is applied—Coffee, 1dr.; hot water, 1oz.; let stand till cold, and filter. The first application must be poured away, but after, the solution may be returned to the bottle. When the film has been thoroughly permeated with it, it is reared up to drain and dry. When dry it is ready for use. The exposure I have known to be as long as a quarter of an hour on a dull day. Before developing, the plate is well washed. Develop in a flat dish with the ordinary iron developer, or else it is liable to stain. But the querist may take my word for it that after years of experience I have found nothing to equal gelatine emulsion.—C. Huffell.

[47524.]—**Acetic Acid.**—The sp. gr. of acetic acid at 15° is 1·0553. If water be added the sp. gr. rises at first, until a liquid is obtained containing 70 per cent. of the pure acid. On a further addition of water the sp. gr. remains unaltered, so that the aqueous acid containing 76·5 to 80 per cent. possesses the same sp. gr.—viz., according to Roscoe, 1·0754 at 15·5°. The sp. gr. then diminishes, so that the acid containing 43 per cent. has at 15° the same sp. gr. as the anhydrous acid. Hence it follows that the concentration of the aqueous acid cannot be determined (as that of alcohol can be) by the sp. gravity, but you must triturate with an alkali.—Caius.

[47524.]—**Acetic Acid.**—The following is an extract from Oudemann's table of the strength of acetic acid, corresponding to its specific gravity. The entire table is given in "Bayley's Chemist's Pocket Book," published by Spon, price 3s. 6d.:—

$C_2H_4O_2$ Per cent.	Sp. Gr. 60° F.	$C_2H_4O_2$ Per cent.	Sp. Gr. 60° F.
1	1·0007	35	1·0470
2	1 0022	40	1·0523
3	1·0037	45	1·0571
4	1·0052	50	1·0615
5	1·0067	55	1·0653
6	1 0083	60	1·0685
7	1·0098	65	1·0712
8	1·0113	70	1·0733
9	1·0127	75	1·0746
10	1·0142	80	1 0748
15	1 0214	85	1·0739
20	1 0284	90	1·0713
25	1 0350	95	1·0660
30	1 0412	100	1·0553

If "Phosphorus" has a specific gravity apparatus of sufficient nicety, he may determine the strength of his solutions from this table; but the usual plan is to neutralise the acid with a standard alkaline solution. This may be prepared by dissolving one equivalent in grains—(viz., 106gr.) of pure dry carbonate of soda in 10,000 grains of distilled water, and adding from a Mohr's burette to a measured quantity of the acid liquor until it fails to redden blue litmus paper. When the acid is nearly neutralised it should be heated to expel the carbonic acid which has been absorbed during the operation, and the addition of the alkaline solution cautiously continued. The quantity of the latter required is then read off from the burette, and each grain measured corresponding to ·0106gr. of carbonate of soda will represent two equivalents, or ·012 of acetic acid ($C_2H_4O_2$). If great accuracy is required, it will be necessary previously to estimate the sulphuric acid, which is present in all commercial acetic acid. This may be done by precipitation, in a measured quantity, with barium chloride, the resulting barium sulphate being dried, ignited, weighed, and calculated into H_2SO_4. In making the alkalinity estimation, it will then be necessary to first add enough standard alkali to neutralise the previously found quantity of H_2SO_4. Further particulars if required.—E. S. Beaven.

[47527.]—**Microphone.**—In a small room it is nothing out of the common, though not very loud. —Nerog.

[47528.]—**Sowing Conacre.**—This is an inaccurate expression. Letting and taking in conacre is when a farmer lets, at a rent, a small piece of ground tilled by him, and ready for manure, to a poor person who supplies the manure, and plants, or assists to plant, the ground (with potatoes generally), and takes the crop, after which the land reverts to the farmer. Legally there is no tenancy, but the practice is very common in Ireland.—J. F. E.

[47528.]—**Sowing Conacre.**—It is customary in Ireland to let out fields in "conacre" for potatoes or other crops, i.e., the farmer holding the field gets it divided into quarter acres, and these are taken for the crop only by other people, who supply the labour and seed themselves. A whole field let for one crop to one single person is not, strictly speaking, let in "conacre." Generally speaking, any field let by the holder to another for the crop only is let in "conacre," and this letting by conacre is not considered in law as a breach of the usual covenant against subletting, introduced into leases. "Sowing conacre" is the action of the person who plants the crop; "Letting" or "Setting conacre" is the act of the farmer to whom the land belongs.—C. M. W.

[47530.]—**Softening Hard Water.**—Simply boil and expose to the atmosphere; then pour off the water carefully from the sediment, as the neutralised lime, when freed from its extra quantity of carbonic acid, falls to the bottom of its own weight.—Camera.

[47530.]—**Hard Water.**—I should think the best method of softening your water would be Dr. Clark's process; allowing lime water to flow into the water to be softened, when the lime combines with the carbonic acid which is in solution, forming chalk which is precipitated, together with the chalk which rendered the water hard; the precipitate sinks to the bottom and the clear water can then be drawn off.—Caius.

[47530.]—**Softening Hard Water.**—If the hardness is due to carbonato much of it can be taken out by the addition of cream lime; that is known as temporary hardness. If it is permanent hardness, due to the presence of sulphates, for instance, it would be necessary to know the exact nature of the hardening salts before a remedy could be suggested—if then. If due to calcic or magnesic sulphate, washing soda will soften to a certain extent, but the addition of that might be objectionable.—Nun. Dor.

[47535.]—**L B. and S.C. Locomotives.**—"The Terriers."—The class of 6-coupled tank-engine Mr. Tratman asks about are known as "Terriers." One of them was sent to the Paris Exhibition. Full dimensions were given in back vols., I think in 1877, but I have not time to hunt them out in my copies—all unbound. The East London Railway is worked by the L. B. and S.C. Co., consequently the engines belong to that company, and were built at Brighton. I think "Wapping," No. 71, is one of the first built, which was in 1872. A great many were built in 1874 and 1875.—Murano.

[47513.]—**Hardening Hammer-Faces.**—I would suggest that probably your smith has faced your hammers with ordinary blister-steel; this will not stand to strike cast-steel gads. Have them faced with double shear-steel, and cool in running water; never mind the salt.—J. J. A., Liverpool.

[47543.]—**Hardening Hammer-Faces.**—See reply 47383, Hardening. But you need not use more than one of prussiate potash to 6 or 8 of salt, and do not make them too hot. A bright cherry red ought to be sufficient, but you cannot depend upon the steel you get for your jobs.—Jack of All Trades.

[47544.]—**Electrical Measurement.**—To "Ll. B. A."—I am afraid "Student" has hardly yet grasped my last answer. First, let me remark that by altering the resistance in a circuit of a *constant* battery, we do not alter the E.M.F., which depends only on the materials of the battery. To take the case, however, which "Student" mentions, let us first get a deflection of 10° in one circuit; now we know that this means so many ampères. Now, 1 volt gives 1 ampère through 1 ohm, and 10 volts give 1 ampère through 10 ohms, and n volts give 1 ampère through n ohms, so that even if we get the same deflection in another circuit we cannot tell what the E.M.F. and resistance are, unless we are sure of one, when we can find the other. The current is merely the ratio of the E.M.F. to the resistance; and hence tells us nothing of their true magnitudes. The galvanometer only measures current; hence the same deflection only shows that the same ratio exists in each case, between E.M.F. and resistance, and tells nothing beyond this. I hope I have made this clear; if not, do not feel afraid to ask further help.—Ll. B. A.

[47544.]—**Electrical Measurement.**—"Student" is a little confused. Given a current of so many volts, ohms, and ampères, that is $E/R = C$; he assumes "that if we insert a galvanometer, *we know* that it alters the resistance, and also the E (E.M.F.) in proportion." This *knowledge* is absurd and *perniciously* misleading, because there are cases where E varies, as R is changed; but the variation is due to other causes, which must be considered exceptional. If $60/4 = 15$ ampères, then $60/6 = 10$ ampères, and for a right comprehension of the law of Ohm, we must insist that the variation of R has no effect whatever upon E. All laws have their qualifying aspects, and "Student" would not say that a balloon has no weight or gravitation, because it recedes from the earth. We may imagine the force or *potential* of a column of water, *of small area*, determining a given current, through a given resistance, and in that case the potential would vary in the ratio of the quantity discharged, or of the diminished resistance. This is quite true of electricity, under analogous conditions. The second point is equally confused, because $60/4 = 15$ ampères just as $120/8 = 15$ ampères. To think that the same quantity of current must imply "the same E.M.F. and resistance" only shows that "Student" must be very young.—Eclecticus.

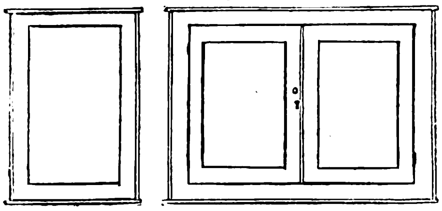
[47549.]—**Bloater Paste.**—Is usually made from red herrings; it can be made from any salted herrings, except those oily midsummer fish. I do not know that there is any special way of taking out the bones; but if expense is no object, it would be advisable to take only the back and most fleshy parts of the sides, leaving the ribs attached to the backbone. Pound up with a little bay-salt and cayenne pepper, rub through a sieve, and put up in pots, excluding the air.—Yarmouth.

[47561.]—**Pot-Pourri.**—Dry your rose-leaves, sprinkle a little salt on them, and put them in a covered jar until wanted for use. Take of rose leaves 4oz., dried lavender-flowers 8oz., vanilla cloves, storax, and benzoin, all bruised, of each 1 drachm, ambergris 20gr., otto of rose 20 drops; mix.—Amateur Mechanic.

[47561.]—**Pot-Pourri.**—Prepare your rose-leaves in the following way:—Spread them out in the sun or in a warm room to dry them, sprinkle a little salt on them, and put them in a jar, in which they are to be kept covered up till wanted for use. Take of these rose-leaves 4oz., dried lavender flowers 8oz., vanilla, cloves, storax, and benzoin, all bruised, of each 1 drachm, ambergris 20gr., otto of roses 20 drops; mix.—J. W. Bond.

[47562.]—**Meat Safe.**—As "Fritz" does not say, I presume it is to stand under cover. You want it a foot from the ground, and for convenience of removal, I should make a frame of 2in. by 2in. stuff, with four legs a foot high, separated from the safe. The safe should be made of good yellow deal 1¼in. thick, 1in. top and bottom, ¾in. back; 1 shelf in the middle, to be in two pieces, so that they can be taken out to hang a joint of meat up. The end is a separate frame from the front, but a return bead is stuck on the front edge, and half a dozen 2in. brads or lath-screws put in; a bead is also stuck on the meeting stile of one door to break the joint. The doors and ends are rabetted on the inside, and a ½in. bead worked on the outside. Put the zinc in, and brad or screw a ½in. bead in the rabbet; the top and bottom to project ½in. all round, and slightly rounded off. When finished, stain, size, and varnish satin wood. I send sketches, hoping they will suit you. They are ⅓in. to the foot, front and side elevation, with sheets of perforated zinc where shown.—H. B. C., Lambeth.

SCALE ⅓ IN TO THE FOOT



[47567.]—**Slide-Rule.**—If "Mechanicus" will give sundry examples of such calculations as he requires to solve by slide-rule, no doubt many of your readers will gladly furnish the information sought by means of the "E. M.," or on application by post.—Buttershaw.

A Small Ice-Machine.—An ice-machine suitable for private houses, especially in India and the colonies, or for steamers, ambulances, and so on, has been devised by M. Raoul Pictet on the principle of his larger machine. It is capable of producing 2lb. of ice in 15 minutes, or about 10lb. per hour, with an expenditure of less than a horse-power of energy. It consists of a compression pump actuated by the motor employed to yield the power; a freezer surrounding the cylinder of the pump; and another in which is placed the vessels containing the water to be frozen. These parts are all grouped into a machine standing about 4ft. high and 18in. square. The process is as follows: Sulphuric anhydride is placed in the freezer around the cylinder, and on working the pump the evaporation absorbs a large quantity of heat from a well of glycerine constituting the freezer by which the water to be frozen is surrounded. The sulphuric anhydride is carried by the pump into a condenser, where it is liquefied, and in the act yields up a certain quantity of heat. The condenser is kept cool by the circulation of water.—*Engineering.*

Patents in 1882.—The number of applications for patents during the first six months of the present year amounted to 3,102, exhibiting a marked increase over those of the corresponding period in 1881, when only 2,865 applications were recorded. London furnished 775, or almost exactly a quarter of the whole, 397 came from the United States, 261 from France, and 250 from Germany. The number of foreigners who seek the protection of the English patent laws is greatly in excess of the number of Englishmen who take out foreign patents, and the disproportion appears to be gradually increasing. As regards the subject matter of the patents applied for during the period above named, the electric light and velocipedes seem to be the most popular.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

46996.	Italian and Spanish Locomotives, p. 271.

QUERIES.

[47568.]—**Legal.**—Will Mr. F. Wetherfield kindly state whether, in a three years' agreement to take premises, a clause or an endorsement giving the tenant option to remain a further term is binding? Whether an agreement holds good if for a longer period than three years, unless it bears a stamp the same value as required on a lease? Can an additional stamp be added at a future time?—B. R.

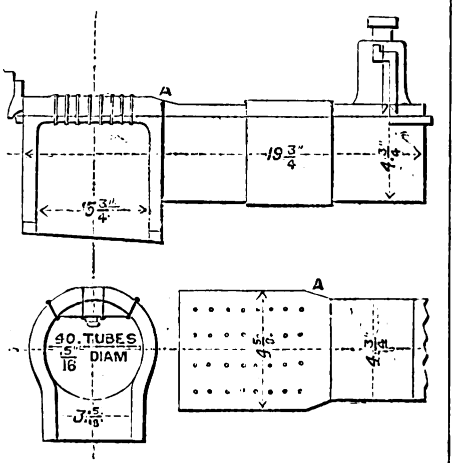
[47569.]—**Barrel Piano.**— Will some reader kindly give description and, if possible, sketch of the action of a barrel piano, and also of barrel harmonium?—Musa.

[47570.]—**Bronzing Cardboard.**—Will some one kindly explain the best way of bronzing cardboard?—J. J.

[47571.]—**Polishing Bobbin-Ends.**—I wish to make a machine for polishing the ends of ordinary thread-bobbins after being dyed black or any other colour, and should esteem it a great favour if some correspondent would give me a sketch and particulars of such.—H. J.

[47572.]—**Midland Tank Engines.**—I have noticed lately a new class of tank engines running on the above line, one of which is numbered 1553, I believe. Will any of ours kindly give me dimensions, and, if possible, a sketch of same?—F. B. W.

[47573.]—**Model Locomotive Boiler.**—I should be much obliged to any reader who would tell me how to make the boiler in sketch? There is a bend at A, which I have been unable to make as yet. I have tried several ways, but none will answer;—hard soldering will not do. Should the rings of the barrel be made in one or two plates? Will 40 $^5/_{16}$in. tubes be too many? The shell is of brass $^3/_{32}$in. thick. How can the steam-dome be fastened on?—for, if riveted on, I shall be unable to get at the regulator-valve, which is at the top of the dome, or very nearly. Working pressure 100 or 120 on the sq. in. Any information on the subject will be acceptable.—Shakespear.



[47574.]—**Pressure.**—Can any of "ours" tell me whether it is possible for a horizontal engine to work at a pressure of 500lb. to the sq. in.?—Steam.

[47575.]—**Electric Pendulum.**—Would Mr. Lancaster be so kind as to inform me how to make an electric pendulum for a clock, with quantity of wire and size for bobbins? I also wish to know the simplest method of transmitting the motive-power of pendulum to the clockwork? I wish the pendulum to vibrate half-seconds, or length about 19½in.—T. J. O'C.

[47576.]—**Arsenic.**—In my business I frequently have to perform an operation which necessitates my keeping my finger-ends in a 5°/o solution of arsenious acid for some hours at a time. Every time that I have yet done this, the ends of my fingers have been sore for about a week afterwards. The pain on pressing the nail or finger-ends is similar to that caused by having the nails cut too short. The nails which have been immersed turn a bright yellow colour. Can any reader explain to me the action of the poison in this case, as its effects never seem to get further than my finger-ends? Also, what is the cause of the yellow colour?—Bertram T. Ord.

[47577.]—**Watch-cleaning.**—Will any one kindly give the best way to remove oil and grease from watch movement before using chalk and brush, and also the best way to clean watch-cases?—Anxious One.

[47578.]—**Egg-End Template.**—Will some reader oblige with description how to make an egg-ended template?—B. M.

[47579.]—**Deal made to Imitate Maple.**—I have had a wardrobe made in deal. Will any reader inform me the best and cheapest method by making it to imitate maple?—J. G,

[47580.]—**Nightmare.**—Will Dr. Edmunds or any reader kindly inform me what is the best to do to prevent nightmare, as the writer's mother has it repeatedly, leaving her much distressed and exhausted?—J. G.

[47581.]—**Large Lathe.**—Could any one tell me who has got the largest lathe in England or the Continent, and oblige?—W. Bradshaw, Derby.

[47582.]—**Casting Small Articles in White Metal.**—To "Jack of All Trades."—Thanks for your answer so far, but I should feel obliged if you will inform me in the following:—What are the mixtures, if any, and should the mould be warm? I find a difficulty in running them in thin places.—Metal.

[47583.]—**Glazing Sanitary Pipes.**—Will some one kindly favour me with particulars how sanitary pipes are glazed?—W. M.

[47584.]—**Coil.**—To Mr. Tolman.—Will you please give me length and breadth of core, weight and size of wire; in short, full particulars of how the small coil you speak of in reply 47449 was fitted up? Also, what battery did you use with it?—Electrician.

[47585.]—**Electro-motor for Tricycle.**—Will some one notice the anxiety felt by thousands for the application of electricity as a motor-power for tricycles? I had hoped that Mr. Tolman would have led the way; but unfortunately, he seems to have given it up. Will no one try to give such a great boon?—W. L. Ollard.

[47586.]—**Pure Silver.**—Will any of "ours" kindly tell me how to procure chemically or absolutely pure silver from some odd scraps I have, about 2oz. How can I test it when obtained?—Ape.

[47587.]—**Crossbow.**—Can any of "ours" tell me the best wood to form bow of for crossbow? I want it about 3ft. long and powerful spring.—Ape.

[47588.]—**Moss-covered Steps.**—The steps (stone ones) are in a passage which runs along the side of the house, and are from time to time covered with moss. Is there any method of preventing this?—Camera.

[47589.]—**To Mr. Lancaster.**—In last week's "E. M.," in an extract from the *Electrician*, it is said:—"Two rapidly revolving discs, not in contact, but so close together as to admit only of an air-space between them, develop electricity in a most powerful form from the rubbing together of the molecules of air between the discs." Can this be applied practically to a small machine to work by hand?—Camera.

[47590.]—**Honours Chemistry.**—A sample of air free from carbon dioxide, which measured 651·4 volumes at a pressure of 537·4mm., and at a temperature of 4·0°C. was mixed with hydrogen and exploded. After the addition of the hydrogen the bulk of gas at 0°C. and 760mm. was 657·06 volumes, and after explosion it measured 374·73 volumes. Calculate the per-centage of nitrogen and oxygen present.—L. B. S.

[47591.]—**Indiarubber.**—Is there a method of melting old indiarubber soles, taken from tennis shoes, so that it may be used again? Any information would be thankfully accepted. Also, how is the cement made for fixing them?—W. H. S.

[47592.]—**Telescope.**—Could any of the optical readers of ours inform me what two telescopes 2in. aperture, 36in. focus, mounted as a binocular, would equal? I want to know—not think. I think they should show object faint enough and points minute enough to strain a 3½in. single telescope. There would be less strain upon the eyes, as both would be used, which would greatly aid vision.—M. Herbert Bridle, Phila., Pa.

[47593.]—**Paper-making.**—Can any of your chemical readers kindly inform me how to obviate the wire mark? Has the shake-motion, suction, couching, or length of stuff anything to do with it?—W. D. T.

[47594.]—**Chemical.**—Can any of your many chemical readers explain the action that bisulphite of lime has upon wood when boiled under pressure? I want to know what products are produced by the action of the bisulphite upon the resin and other extraneous matters in the wood. Also, what would be the action upon the silica of straw if boiled under like conditions?—W. D. T.

[47595.]—**Copper-Plate.**—How can I tell if one I have is worn out or not? I inked it with thin printing ink, rubbed it well with a rag, and then rubbed a piece of tissue-paper well on with my hand, without any effect whatever. How can scratches (deep) be repaired?—Murano.

[47596.]—**Legal.**—To Mr. Wetherfield.—A. insures B. for a certain sum of money to be made payable at the death of B., A. knowing at the time of entry that B. was suffering from a severe illness, from which B. died three months later. The agent continued receiving payments the whole of the time, and did not examine B. to test the state of B.'s health. Can A. recover the amount insured for?—Telewag.

[47597.]—**American Organ.**—Will some reader please give method of making and attaching Octave coupler, and also for adding one or two rows of reeds to instrument now containing one row?—J. P. C.

[47598.]—**Electrical.**—Will "Sigma," Mr. Lancaster, or some other of our electrical correspondents, explain the following experiment, given in Guthrie's

"Magnetism and Electricity," Art. 112? It is given to prove that, although a di-electric may readily allow the inductive effect to take place through it, its own electricity may undergo comparatively slow decomposition. An insulated and charged ball is placed on one side of an ebonite plate, which can rotate on an axle. Opposite to the first ball another ball, also insulated, and connected by a wire with an electroscope, is placed. The leaves of the electroscope diverge, but gradually collapse. If, however, a fresh portion of the plate is brought between the balls, the leaves again diverge. I can understand the experiment as far as the first divergence of the leaves, but I do not see why the collapse should then take place. I do not understand the explanation given with it, nor does any one else whom I have asked. It is probably due to some circumstance that I have overlooked, but I cannot see any such. If the question is not improper, might I ask "Sigma" if he intends to give us a second volume of his electricity now? He gave us an intimation of his intention to begin a new volume or edition a few weeks ago, and I would like to know if he intends to carry out the intention mentioned in his preface, as I have been asked about it?—A Student.

[47599.]—**Drilling Bicycle Hubs.**—Will any of ours kindly give sketch of a simple method for drilling bicycle-hubs in the lathe?—Ex.

[47600.]—**Deodorising Paraffin.**—I have tried mixing scent with the paraffin used for lubricating my lathe, as recommended by one of your correspondents, the result not being satisfactory. Will some of your chemical friends oblige with suggestions?—Amateur Mechanic.

[47601.]—**G.W.R. Engines.**—Can any reader give me the dates and principal dimensions of the following engines?—9, 455, 619, 730, 866, 981, 1,016, 1,070, 1,219, 1,452, and 1,514.—C. H.

[47602.]—**Turkey Red.**—I should be greatly obliged if any of your readers could inform me what stuff is used or means are employed by Turkey-red dyers to obtain the soft oily feel they impart to red twilled cotton cloth? —A Constant Reader.

[47603.]—**Plating with Gold Inside and Silver Outside.**—Will any one tell me how to electro-gild a small metal cup gold inside and silver out? I understand gold and silver plating, but not how to put two on one article.—A Amatube.

[47604.]—**Bicycle Tires.**—Will any reader kindly give me some information respecting fixing on bicycle tires? I bought some cement, cleaned the rim and rubbed it with turps, heated it on an iron stove with coke fire, poured in the cement hot, rubbed a piece of hot iron round the rim to spread cement, and quickly put on tire and held on red-hot irons against the rim. But it is needless to say it is a queer-looking job from the cement sticking to outside of tire, which makes it look so unsightly. I cannot think of riding the machine. Is there any means of cleaning off cement without injuring tire, or a more practical plan of fixing on the tires, as I do not think mine has stuck any too well, and I have the other wheel to do? I have no gas.—Apprentice Boy.

[47605.]—**Probable Errors.**—Can any mathematical reader enlighten me as to the following points? I can find no satisfactory explanation in Merriman's "Method of Least Squares":—1. Suppose that a quantity z is expressed in terms of some unit whose mean value is a, with a probable error r—how can the mean value and the probable error of z be determined? To take a simple example: the graduations on a scale professing to give hundredths of an inch correctly are found to be each = 0·0101 $\pm$ 0·00005in. Six measurements of a certain line (taken with a vernier reading to tenths of a graduation and assumed correct) give these results:—0·783, 0·785, 0·791, 0·780, 0·783, 0·782. What is the most probable length of the line and its probable error? 2. Suppose that q quantities connected by p conditional equations are made the subject of n observation giving n observation equations; that from the p conditional equations the values of p quantities in terms of the others are found and are substituted in the observation equations; that then the mean values and the probable errors of the other $q - p$ quantities are determined in the usual way; and that finally the mean values of the remaining p quantities are found by substitution in the conditional equations. How are the probable errors of these values of the p quantities to be determined? To take again a simple example: the angles of a plane quadrilateral A B C D are observed as follows:—A = 6° 15′ 1″ (mean of 3 observations); B = 59° 4′ 3″ (mean of 4); C = 168° 59′ 59″ (mean of 5); D = 125° 40′ (mean of 6). Eliminating D by means of A + B + C + D = 360°, we get the adjusted values A = 6° 15′ 21″ $\pm$ 18·3″; B = 59° 4′ 18″ $\pm$ 11·7″; C = 169° 0′ 11″ $\pm$ 10·4″. Then by substitution D = 125° 40′ 10″. But with what probable error? 3. How may De Morgan's criterion be applied to the observations in 1, so as to determine the true weight that should be assigned to each?—J. H. G.

[47606.]—**Brake Power on Goods Trains.**—I shall be glad if any one will inform me if experiments have been made on any railway with the ordinary tender and one van hand-brake with heavy coal trains, as in many instances they are very deficient in brake-power.—A Driver.

[47607.]—**Kitson's Steam Brake.**—Please state if Kitson's steam brake was tried at Newark, as I do not find it mentioned in Mr. Reynolds's useful new book? Was a water-jet attached to the Midland engine 892?—A Driver.

[47608.]—**Preserving Rhubarb.**—Can any of ours oblige with recipe for preserving rhubarb? I saw a recipe some years since, but I did not sufficiently notice it at the time. I believe it was cut in 3in. lengths and dried by some means.—W. W. W.

[47609.]—**Soldering.**—Would some brother-reader tell me of a simple method of heating a soldering-iron at the bench where gas or a fire cannot be used. Could I use an oil-stove for that purpose?—T. J. O'C.

[47610.]—**Defective Sewing-machine.**—I have a sewing-machine, the "Penelope," made by Newton Wilson and Co., and cannot get it to sew. It appears in good order, but when I attempt to work it, the cotton cobbles under the plate. Will some kind friend help me?—Sewing Machine.

[47611.]—**Silicate Cement.**—Would be glad to know the best work to study on this subject. I want to make a very fine description of cement (or spirit varnish loaded with silicate) to paint into small cracks that would bear submersion in water after 5 minutes to dry, become very hard, and stand a temperature of 95° F. Expense of preparation would be no objection.—J. P.

[47612.]—**Re-Whitening Stucco Figures.**—Can any reader inform me the method of re-whitening stucco figures?—Young.

[47613.]—**Photographic Camera.**—To Mr. Parkinson or Mr. Robinson, Junr.—Will any of these friends advise me?—I wish to purchase camera which I shall mostly use for architectural subjects, but should like to be able to take portraits now and again, when I think proper. What is the best kind of camera for this purpose, and at what price should I get a good article? The cost is of first importance to me, so I should like to get a reliable article at once.—Camera.

[47614.]—**Gas Analysis.**—Wanted to know the routine of a gas-works laboratory?—Nina.

[47615.]—**Insanity.**—Will Dr. Edmunds, or any person competent to give an opinion, kindly answer me the following?—I am engaged to a young lady aged 33 years. I have recently been told that 13 or 14 years ago she lost her reason through a bereavement, but soon regained it, and has ailed nothing since. I desire to know is it wise to marry her, or break off the engagement?—Amant.

[47616.]—**Abyssinian Tube Well.**—I am thinking of putting down an Abyssinian tube well, and should be glad of some information in regard to them: as to the wear and tear, whether they are liable to get out of order, also the probable cost with 10 or 12ft. of tubing, and if it is possible to hire one for a trial, also the utility of them generally as a substitute for sinking wells where there is supposed to be plenty of water?—Abyssinia.

[47617.]—**Logarithms.**—Will some one of "ours" assist me by showing how to work the following question out in logarithms, in simple arithmetic? I can work it out by the ordinary method, but do not understand logarithms.—The cylinder of an engine is 3ft. 6in. dia., the stroke is 5ft., and the steam is cut off at $\frac{1}{3}$ of the stroke. If steam be admitted into the cylinder at 45lb. pressure, find the work done in one stroke (log. 3 = 1·0986).—A Student.

[47618.]—**Bill of Sale.**—To Mr. Fred. Wetherfield.—About 12 months since I applied to a "Loan Company" for £20, and received it on signing a bill of sale on my household effects, and agreeing to pay monthly instalments until £29 was paid. This has now been done and duly acknowledged, showing that it is all paid; but certain documents (a fire assurance policy, a tenancy agreement of my house, &c.) which were deposited with them to show my *bona fides*, they have not returned. I take it for granted that they must give these up; but ought I not to have the bill of sale returned to me as well, and if so, how should I proceed to recover it, supposing they refuse to give it up on a second demand? I may mention that I reside in South London, and the loan was obtained when the "Company" had offices in the City. Shortly after having obtained it, I was notified that future instalments must be paid or sent to a country town. An answer will perhaps interest others less fortunate than—Argentomeder.

[47619.]—**Universal Joint.**—Can any of ours tell me what loss of power is incurred in the employment of a "universal joint," as applied to a motive shaft of machinery?—Universal Joint.

[47620.]—**Plumbing.**—Will any one experienced in the matter kindly say in what manner the difficulty arising from connecting tin-lined lead-pipe to continuations of pipes and taps of other metals—viz., iron, lead, brass and copper—is overcome? The danger arising from the use of pure water in contact with pure lead is well known; but the difficulties experienced in making sound joints with connections of other metals is said by some plumbers to be great, and often results in choking the bore with solidified solder.—J. W. B.

[47621.]—**Faded Cloth Cushions.**—I shall feel obliged for information how to restore the blue colour of my dog-cart cushions, which are considerably faded. The cloth seems good, and I should be pleased if only freshened up, as I can't afford new ones.—Old Subscriber.

[47622.]—**Bisulphide of Carbon Prism.**—I wish to construct a bisulphide of carbon prism, and should be obliged if some one with practical knowledge of the subject would kindly inform me whether a tin-plate framework would answer for the purpose, and if so, what would be the best way of cementing the glass plates to the tin, so that the junctions would not be affected by the liquid bisulphide? Would common glue be suitable for the purpose, and would ordinary plate-glass bear the application of a telescope of sufficient power to show the D line double?—Student.

[47623.]—**Electro-motor.**—Will "Conrad" kindly give description of his electro-motor, as promised in letter 19985, as soon as possible?—Electro-Motor.

[45624.]—**Heberlein Brake.**—Can any reader give a description of this brake in its latest form?—A Driver.

[47625.]—**Clock Dial.**—I have a good old American one-day lever clock which has very good works. The dial is in very bad condition, and I wish to paint new figures on it; but before doing so, I should like to re-enamel it. How is this done? What kind of paint must I use in painting the figures? I should like to know of a good black paint that will dry quick, as I want to get the job done as quickly as possible.—G. Fryer.

[47626.]—**Warping.**—I think as you have noticed the fact that the Zuyder Zee is going to be reclaimed, that it would be in the interest of the public if some engineer would tell us the benefits of warping, and the preliminary expense of banking, the warping being carried to such a degree as to raise the surface ground above (all?) floods. The practice of warping in England to raise the surface of the ground more than a few inches, appears to be considered no more than an expensive amusement. In Italy it is practised as a beneficial engineering operation. Is it so in Holland?—F. N. C.

[47627.]—**Pneumatic Bellows.**—Can any reader of the "E. M." give me a hint as to the best way to make the above-mentioned piece of apparatus to move a piston a distance of 1in., to hold it in that position until the pressure of air is withdrawn, and then bring the piston back to its original place? The resistance to the movement will be about 3 or 4oz. The whole to occupy the smallest possible space, and work with the least possible friction, and be moderately durable.—A Harmless Slug.

[47628.]—**Private Study of French Language.**—Will some one kindly advise me as to the best course to pursue and books to procure for one who has the ordinary school knowledge of the language (of which, from disuse, much has been forgotten), and who wishes to gain a more perfect acquaintance with it?—Nemo.

CHESS.

All Communications for this department must be addressed to the Chess Editor, at the office of the English Mechanic, 31, Tavistock-street, Covent-garden, W.C.

NOTICES TO CORRESPONDENTS.

Correct solution to 763 by G. Hume.

Problems received with thanks from F. A. Hill.

ANSWERS TO CORRESPONDENTS.

⁎ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁎ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Aug. 2, and unacknowledged elsewhere:—

J. T. Chapman.—J. and H. Grace.—F. and H. Randell.—E. Gay.—C. V. de Santz.—S. G.—Jack of All Trades.—H. A. Wassell.—T. F. N.—H. Sto ke.—Philip Vallance.—L. G.—B. J.—X. Y. Z.—H. F. L. M yer.—Inquirer.—S. J. Simpkin.—Ignoramus.—B. N.—W. M. Gardner.—Ipse Dixit.—W. A. Hunter.—J. H. Schucht.—J. R. G.—Cantab.—Hosein Ibrahim.

F. B. W. (There are so many that it is impossible to cite the "best." Consult the bookseller's catalogues.)—Young Photo. (You mean what is called ferrotype. The process is described in the manuals. Write to Piper and Carter, 5, Castle-street, Holborn, for a list of their books.)—The Freehold, Minster. (Warm the tube and tap it smartly down. If no effect, empty and refill.)—New Zealand. (They are cut with drills and the groove made with a milling cutter. They are cheaper to buy than to make.)—Quero. (Either you do not remember the instructions or they are very peculiar. Full directions have been frequently given in our columns. See pp. 237, 261, 285, 308, 381, last volume. The arrangement depicted will not do. 2. It is a portion of a Bunsen cell. Place in an earthenware jar. Into the porous pot put a stick of carbon and strongest nitric acid, and into the jar dilute sulphuric acid—that is, 1 to 10.)—Walter L. Nash. (Perhaps he has no time to devote to correspondence; but we believe a letter addressed Clerkenwell-green, E.C., would be delivered to him. If you had read the par. on p. 325, or Mr. Sprague's article on p. 343, you would not have written the last sentence in your letter. At any rate, we are not aware that a man is obliged to forward his address to any person who may choose to advertise for it.)—G. Hayes. (Heat the plates and run sealing-wax in, or grind up the required pigment with copal varnish very stiff, and fill in. Query has been answered many times.)—Electrician. (You can only tell accurately by means of a gauge, and then only to the numbers on that particular gauge. So far as we can guess roughly, the thickest is about one millimetre, and therefore say No. 20 or 21 B.W.G.; the other is about No. 22. 2. Wash over with hot solution of oxalic acid, and then with weak solution of chloride of lime. Go over with clean water several times afterwards, using blotting-paper to take up the moisture. 3. The new edition of Mr. Sprague's book will be the best when it comes out; but you can gain elementary information on the subject by referring to recent back numbers.)—A Constant Reader, Plumstead. (Cassells publish a book on "Drawing for Bricklayers," price 3s., and Lockwood and Co. publish "The Rudiments of Practical Bricklaying," price 1s. 6d.)—D. W. Salter. (The duties are very much those of a general valet or body servant, combined with cook and waiter. Such berths are to be obtained only by application to the masters of the vessels or their deputies.)—John Neville. (Pitman's.)—E. Hall. (There are several things that might be used, but their publication would be neither wise nor beneficial. A moment's consideration will convince you that such information might, if possessed by wicked or foolish persons, do much mischief.)—Aspirant. (All such applications should be addressed to the Secretary of the Civil Service Commission, Westminster, S.W.)—Fair Play. (It is a fact, doubtless, that there are dishonest photographers, just as there are rogues in every trade—"but ours"; but no respectable photographer would do what you mention, and we do not see that it in any way reflects on the honour or honesty of photographers generally.)—H. R. (We should think you would have little difficulty. Why not advertise in the "Sale Column," under the head of "Situations"?)—L. W. (The proposed form of will is legal; but it is advisable to appoint an executor. In your case you would, of course, appoint your wife. 2. Cannot find room to notice queries about hair falling off, &c.)—One Ignorant. (It depends where the land is. If in Cornwall, the license would probably be granted by the Duke. Probably the owner of the land knows.)—Eureka. (It is simply nonsense. Put some phosphorus in water and distil it, and then ascertain, if you can, how much phosphorus there is in the distillate.)—One Whom it Concerns. (It depends entirely on the build of the engine—the uneven road has nothing to do with it. The springs are needed to prevent shocks, but their play depends on the load carried. We suppose 2½in. is the extreme, but it is a question that can be settled only by actual measurement.)—Handy Man. (We do not see the connection between tinplate working and the manufacture of coal-gas, and, as to the manufacture of the latter, what do you mean? You can make a few cubic feet by means of an iron retort, a few feet of pipe, and a holder; but to make any quantity you would require suitable plant and space to put it in. Further, if you had to pay 20s. a ton for coal, you would find it cheaper to purchase of a gas company.)—J. C. George. (What sort of leather is it? If plain dressed, rub in dubbin. If patent or enamelled, coat with one of the varnish blackings now advertised. 2. Ask at one of the county courts.)—Blowpipe. (Send stamped envelope to the Secretary of the Pharmaceutical Society, Bloomsbury-square, W.C., for the syllabus.)—Varix. (See p. 211. No. 867, for a reply by Dr. Edmunds on the subject.)

USEFUL AND SCIENTIFIC NOTES.

The Perception of Light.—M. Charpentier has experimented recently as to the time which elapses between the appearance of a light and the making of a signal announcing its perception. The subject of experiment looked into a large blackened case and towards a window. A hole in the further side of the case was closed by a metallic shutter held in position by an electro-magnet, though not touched by it. A person behind the case broke the circuit of the magnet, so that the shutter fell; his act also produced a mark on a rotating cylinder. On seeing the light the person looking into the case pressed a spring with the forefinger of his right hand, and this act also, by electrical agency, produced a mark on the cylinder. The interval between these marks, compared with the *data* of an electric chronograph, afforded a measure of the so-called "duration of luminous perception." It appears that with the same person, and like conditions, this duration varies, without apparent regularity, to the extent of double. But a constant average may be arrived at from say a dozen observations; this, in the author's case, was 13-hundredths of a second (direct vision). With different persons it varied from 9 to 15-hundredths. The duration is sensibly the same for both eyes (if sound). It is notably increased by other brain occupation—*e.g.*, speaking or attentive listening, during the experiment. It is always greater in indirect than in direct vision, and greater the further the point of the retina struck from the centre. This difference between the two kinds of vision is considerably reduced by many days' practice, but is never entirely suppressed. Practice also considerably shortens the duration of the reaction for different points of the retina. The exercise of an eccentric point affects the different points of the same retinal hemisphere, abridging the duration; but not those of the other hemisphere. Further, this shortening influence of exercise of a point in the inner half of the left retina extended to the outer half of the right retina, while the inner half of the latter retina reacted much more slowly than the same exercised part of the left eye.

A Super-sensitive Thermometer. — Since the days when Mr. Edison brought out his micro-tasimeter, which proved so sensitive to heat, until now, we have had no instrument devised for measuring extremely delicate changes of temperature. Such an apparatus has, says *Engineering*, been recently devised by M. Michelson, and brought, at least in its experimental form, before the French Physical Society. It is based on the principle of bi-metallic thermometers, but ebonite or hard caoutchouc is chosen instead of one metal. Hard rubber is 10 times more dilatable than platinum under heat, and a spring, composed of platinum on one side and ebonite on the other, will curve under the least increase of temperature. At the extremity of the spring is fixed a small glass stem forming an elbowed lever, which abuts against a light mirror suspended by a silk fibre. When the spring curves or straightens, the mirror is deflected, and a ray of light from a lamp reflected from its surface to a scale moves up or down the divisions of the scale. By giving to the spring and lever a relatively great length this instrument can be made very sensitive, and the inventor hopes to be able to measure the thousandth of a degree Centigrade.

As the result of carefully conducted analyses, Professor Ledebur, of the Freiberg School of Mines, gives the following examples of the quantity of oxygen in various samples of iron and steel:—Oberhausen open-hearth steel, 0·035 per cent. oxygen; bochum Bessemer steel, 0·047 per cent. oxygen; basic steel, previous to complete dephosphorisation, 0·068 per cent. oxygen; basic steel, after complete dephosphorisation, previous to addition of spiegeleisen, 0·111 per cent. oxygen; Gute Hoffnungshütte wrought iron, 0·515 per cent. oxygen.

To obtain luminous photographs, a film is made of perchloride of iron and tartaric acid on a surface of softened glass; when it has been exposed, sulphide of calcium, rubbed to a very fine powder through a sieve, is dusted over it. The image is formed in the same way as if it had been dusted with any other powder, and the *Scientific American* says it can then be transferred to paper.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁎ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words..	0	6

Front Page Advertisements Five Shillings for the first 40 words afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁎ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

Holloway's Pills are admirably adapted for strengthening debilitated and nervous constitutions. Weak digestive organs are invigorated and poor blood enriched by this purifying medicine. The most delicate may take it without apprehension, the most timid need have no fear. The balsamic nature of Holloway's Pills guarantees their strengthening powers.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Wanted, all the back-numbers of the "**Electro**-Metallurgist and Electric Light Journal." **Exchange.**—G. C. T. Carter, 3, Castle-street, Reading.

Boiler (slow-combustion), Hot Water Pipes, &c, wanted, for Heating Coil and cash.—Mr. S. Hewett, South Norwood, London.

128 odd numbers from the 10 first volumes of the "**Eng**lish Mechanic," in exchange for any useful book or numbers the *Builder*, or send offers.—Jas. Levesque, St. Helier's, Jersey.

Organ Bellows and Windchests (new and second-hand), in good condition, ready for wind and pipes.—Address, William Johnson, No. 12, Moxley near Wednesbury.

Bicycle, 52in., **Bown's Æolus Ball Bearings** both wheels, saddle, brake, bag, light, splendid machine, nearly new, condition perfect. Value £8. Exchange Astronomical Telescope or Microscope.—Davies, Giles, and Co., Sedgley, Dudley.

Bicycle, 48in. What offers in exchange value £7?—G. Moore, 59, Westbourne-road, Barnsbury, London.

Street **Electrical Machine**, with bells, mirrors, clock face, indicator, and battery complete, with travelling case, cost £10. Exchange for Lathe or Bicycle.—J. Skinner, Sutton Bridge.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, AUGUST 11, 1882.

A PRACTICAL TEST OF THE RIVAL BRAKES.

THOSE of our readers who study railway accidents and the rival brake systems, are aware that lately two of the best-known devices have been unintentionally submitted to a very crucial test of their merits, and they also know that the automatic pressure brake answered the expectations which had been formed of its capabilities by those who kept their minds unbiased. It may be remembered that an accident happened to an express train on the Great Northern Railway in June last, near Werrington Junction, and the curious accident which happened the other day to a Great Eastern express, will be fresh in the memory. A brief recapitulation of the principal features of the two accidents will serve to impress upon the mind the importance of the conclusions to be derived from them. The accident at Werrington Junction was caused by the breaking of a coupling-rod of the engine, one portion of which damaged the gear of the Smith vacuum brake, and knocked some part away, which, falling on the metals, threw a portion of the train off the line. The speed is said to have been about 45 miles an hour at the time of the accident; and, according to the driver, he applied the brake, or, at least, made the requisite motion for doing so, as soon as he became aware that something was wrong. The tender and coaches were found at a distance of 470 yards from the first indication on the metals of anything being wrong, the tender being on the up-line—its proper place—with the vehicles all off, except the last van, which, strangely, was on the down goods line. The carriages were all still coupled together, but the brake-pipes were broken in several places—an instructive fact. It would seem, from the position of the vehicles, and the condition in which some of them were found, that they must have run for some considerable distance after leaving the metals; in fact, it is clear that some of them were off the metals for the full 470 yards. The engine broke away from the tender, and was brought to rest about 1,100 yards in front of the latter. In his report, Colonel Yolland says he was not able to obtain distinct evidence whether or not the opening of the valve by the driver had the effect of putting the brakes on; but from the comparatively short distance which the tender and train ran, he thinks that some brakes must have been applied to the wheels of the vehicles.

Those remarks will, we venture to think, be read with surprise, not to say astonishment; for, in the opinion of a Board of Trade inspector, 470 yards is a comparatively short distance for a train to run with some of the coaches off the metals all the time, and all the vehicles off for a portion, at any rate, of the distance. Probably Col. Yolland has some special reason for believing that the brakes were applied; but, as the pipes were broken in several places, and the engine separated from the train in all probability directly the coaches were thrown from the rails, it is clear that the blocks could not have remained long on the wheels, if indeed the vacuum was sufficient to put them on at all, for, as we know, it takes an appreciable time to bring the blocks to the wheels with a vacuum brake. There is no doubt that the inspector reported to the best of his judgment and according to his interpretation of the evidence; but he will scarcely be surprised if engineers demur to his dictum that 470 yards is a comparatively short distance for a train to run with some, if not all, of the vehicles off the road, and two turned on to their sides; it is in reality a terribly long distance for the passengers inside, and much too long to be tolerated in days when really efficient continuous brakes are available. The Werrington Junction accident is, in fact, one of those instances, comparatively rare, we may admit, in which vacuum brakes of the simple pattern are utterly useless, and the most complicated arrangements on that principle of little avail. It is probable that the breaking of the coupling-rod was followed immediately by damage to the brake gear, which would effectually prevent the driver putting on the brakes; and as the engine parted from the train, very likely almost at the same instant, the power to apply the brakes, assuming the gear to be in good order, left with it. It is tolerably obvious, we think, that if each vehicle had been fitted with an automatic brake, practically independent of the system when the connection is broken, the train would never have run 470 yards, even if every vehicle had kept on the metals. Those who hold a different opinion may possibly be able to explain why a train on the Great Northern runs 470 yards, while one on the Great Eastern, travelling at the same speed, is automatically stopped in a little over 100 yards. The full details of the Great Eastern accident, near Ely, will not be published until the inspector makes his report, and there are not a few who would like to see Colonel Yolland appointed to investigate the disaster. The Great Eastern accident was an extraordinary one, so far as the direct cause is concerned—almost unique we imagine. The balance-weight of the link-motion of an up-express engine slipped off the levers, and escaping the wheels of its own train, appears to have bounded towards the down-line and lodged in the bogie of a down-express locomotive, which was thrown off the line into a ditch, but not before the driver had time to apply the Westinghouse automatic brake. This balance weight, a lump of iron weighing about 3cwt., appears to have slipped, from the nut of the pin working loose at a time when the levers were in such a position that the pin could escape and leave the weight free to slide off. It seems to have struck and damaged one of the axle-boxes of the second coach; but seeing how quickly wheels follow one another in a train travelling at 45 miles an hour, it is remarkable that the weight should have escaped as it did and bounded across the "six-foot" into the bogie truck of a passing engine. This engine appears to have carried the weight about 70 yards, and after oscillating sufficiently to break chairs and bend rails it turned over into a ditch, about 114 yards from the point of first injury indicated by the rails. The Westinghouse brake acted in a very efficient manner, for none of the carriages were telescoped or thrown on to the others, while the four hinder-most remained absolutely uninjured on the rails. Just in front of them a Brighton and South coast saloon had its headstock and a buffer broken, and the leading wheels off the rails, while the nearest coach to the engine rested on its leading end, the front wheels being gone. The intermediate coaches were upset, but there was no piling up or telescoping—a remarkable result in a train travelling at such a speed. The results of this accident demonstrate in an unmistakable manner the great value of the automatic principle when used in connection with a powerful brake that can be promptly applied, and that the Westinghouse was applied promptly in this case may be gathered from the fact that the train was pulled up in a distance—the "comparatively short distance"—of 114 yards, or about five seconds in time. It will be interesting to compare the report of the Board of Trade inspector on the Ely disaster with that of Col. Yolland on the Werrington Junction affair, for if we transpose the conditions it is not difficult to imagine what a terrible piling-up of coaches there would have been, had the Great Northern engine, instead of separating and running away from its train, turned over after running only 114 yards. The two instances afford a means of comparison which should effectually alter the opinions of some boards of railway directors, for neither the Board of Trade nor the public will be satisfied until a powerful automatic brake, efficient under any conceivable conditions, is fitted to all trains running at high speed, or passing over crowded lines.

REVIEWS.

Light: a Course of Experimental Optics, chiefly with the Lantern. By LEWIS WRIGHT. London: Macmillan and Co.

IN the preface to this work, which many of our readers will recognise as the reproduction, on an extended scale, of certain papers which appeared in these columns, the author alludes to the remark of Prof. Huxley—that there is a great difference between two kinds of "what persons call knowledge." Many teachers, according to Prof. Huxley, have no conception of any distinction, for they think it quite sufficient if their pupils are able to repeat with accuracy the scientific propositions they have learned by rote, whereas the object of the teacher is to convey clear and vivid impressions of the body of facts upon which the conclusions drawn from those facts were based. Mr. Wright has endeavoured in this volume to play the part of teacher from that point of view, and presents the reader with a course of experiments illustrative of the physical realities which underlie the phenomena of light and colour. The fact that the experiments are chiefly made with the lantern is of especial value, because the appearances presented on the screen and visible to a whole class, or to the entire audience, impress themselves on the memory and the understanding with more intensity than those experiments which are made privately in the laboratory without the use of the lantern and the screen. Mr. Wright's book is mainly addressed to teachers and lecturers, but the student and private experimenter will find that the author has never lost an opportunity of assisting them by suggestions as to the construction of apparatus. For many reasons the student of experimental optics will find most pleasure in the phenomena of polarisation: hence, perhaps, about one-half the book is devoted to that branch of the subject, which is freely illustrated with diagrams and plates—some coloured. Our readers, however, have doubtless not forgotten the articles on "Optics with the Lantern," which appeared in Vols. XXXII. and XXXIII., so that we need only say that, in an extended form, well printed, with 190 figures and eight page plates, they form one of the most interesting and valuable works on experimental optics that have yet been published.

The Hall-Marking of Jewellery. By GEORGE E. GEE. London: Crosby Lockwood and Co.

THE author of this work is one of the largest "hall-markers" of silver chains in the United Kingdom, and, probably, at one time, felt the want of such a reference-

VOL. XXXV.—NO. 907.

book as he has here given to the trade and the public. The former possess means of finding out what they wish to know, but to the general public the mystery of hall-marking is, to borrow a phrase from Dundreary, "What, no fellah can be expected to understand." In the minds of the public there is a possibly unfounded suspicion that the hall-mark, or what passes for it, is often the means of deceiving the ignorant purchaser, who believes that the article so stamped is of better quality than it would show on analysis. In fact, there is no doubt that many articles are bought with marks of some kind or other on them, in the firm belief that they are pure gold or silver, sometimes with the addition that they are "solid." It is only fair to say that the exercise of a little of that uncommon thing, "common sense," will prevent anyone from purchasing 9-carat alloy in the belief that the article is gold; but it is a question whether the trade would not benefit by a strict law that nothing below a tolerably high standard should be sold as gold, or be stamped with any of the hall-marks. As Mr. Gee tells us, 9-carat gold costing 33s. per oz. is composed of metals in about the following proportion:—Fine gold, 7dwts. 12gr., fine silver, 2dwts. 12gr., and refined copper 10dwts., so that, in reality, it is one-half copper, and is better entitled to that name than to the term "gold." That the laws relating to hall-marking require revision is a proposition which the majority of jewellers would not dispute, and we find the author actually speaking of the "necessity" for reform. "As regards the public," he says, "the present marks are too technical and various to be at all understood. Nine out of every twelve persons would not probably be able to distinguish a German-silver spoon plated with silver from a hall-marked one, on their own general knowledge of the marks, the same number of marks being upon each, and with a great similarity of design. . . . We do not believe there are many manufacturers even who could describe the whole of the marks on a piece of plate, with the purposes for which they are intended, right off, if incidentally asked the question, and we are quite sure that those who would be able to do so amongst our present jewellers would consist of a minority." Mr. Gee has been at the pains to collect a great deal of information in connection with the law and practice of hall-marking, and has given details of the marks and rules of the various assay offices, which will be useful to the trade and valuable to the public, who can refer to this work as a trustworthy guide. Mr. Gee would, however, permit the manufacture of "gold and silver wares in any alloy desired by the purchaser," with a system of optional hall-marking provided by law for all standards alike. The quality would, however, be definitely indicated by a Government stamp, which would give ample security to the purchaser, and leave the trade free to mix the metals in any way which experience might teach to be best for the special purpose of the articles. The hall-marking would be perfectly voluntary; but, if we understand the author, the Government stamp would be applied to all articles by experts under Government control, and Goldsmiths' Hall would be abolished. One executive, in fact, should manage all the assay offices, and the marks of different halls, dates, quality, and other "cabalistic signs," together with the duty mark, should be swept away. The marks would thus be reduced to two—the maker's mark and the Government stamp, which latter might easily be made to contain the date; or, where the articles are too small, the date could be impressed alongside. One great grievance of the trade under the present law is the practice of the assay office in breaking up work which is found to be less than the standard claimed. For instance, if only a quarter of a grain under the specified standard a cup or plate, on which a great deal of artistic labour may have been expended, is reduced to such a state that it is fit only for the melting pot, although a quarter of a grain represents in gold a difference of one halfpenny per ounce, and in silver the eighth of a farthing! Those who are interested in the question, or who require information as to hall-marks, will find Mr. Gee's work a valuable handbook, and if it should help to bring about a much-needed reform it will have served a double purpose.

The Theoretical and Practical Boilermaker. By Samuel Nicholls. Blackpool: The Author, Yorkshire-street.

We are glad to welcome an enlarged and revised edition of Mr. Nicholls's "Boilermaker," taking it as evidence that his labours have been appreciated by those whom they were intended to benefit. On p. 603, Vol. XXIII., we reviewed the first edition at length, and we may now say, to those who are unacquainted with the work, that it stands out by itself as the only practical treatise on the subject. It is, in fact, a vade-mecum for the practical boilermaker. The chapters on geometry and orthographic projection, or in other words on templating, with the numerous plates, are alone worth the money to any boiler-smith. Comparing the second edition with the first, we find that the work has grown by about fifty pages, although some portions have been omitted. The added matter, however, is of more value than the parts omitted, the new rules and the worked examples being admirably suited to the wants of those who will study the book. Formerly, managers or foremen were selected for their practical abilities alone, says Mr. Nicholls; now employers demand something more — they require men with technical knowledge, not mere rule-of-thumb workers, and that knowledge is what this book is intended to convey.

Art Instruction in England. By F. E. Hulme, F.L.S., F.S.A. London: Longmans.

This is not a treatise on art, nor in any sense a tutor; but is simply a manual in which an account of the position of art-teaching in this country is given. The various schools and the position given to drawing in their curriculum are noticed, while the art-requirements of candidates for posts in the public departments are indicated. Mr. Hulme points out what subjects are taught, and why they are taught, and endeavours to show that art-teaching is a necessity almost for all, whether rich or poor. In his first chapter, the author has some remarks on art-teaching now and 20 years ago, which leads him to discourse in a general way as to the method that should be pursued by the student; and, later on, to give an outline of the system adopted in the Government art-schools. Then follows an account of the position of art in the various public schools up to the Academy; and the author, by means of anecdote and excerpts from speeches, succeeds in making a readable book, which contains a great deal of dry but useful information.

We have also received *The Scientific Evidences of Organic Evolution*, by George J. Romanes (Macmillan), a reprint of a lecture published in the *Fortnightly*, which is so excellent an epitome of the Darwinian doctrine that the distinguished naturalist urged the author to issue it in its present handy form. ——*A Practical Treatise on Hand-railing*, by George Collings (Crosby Lockwood), is a handy little volume by a practical workman who gives plain instructions for working out hand-rails by new and simple methods, such as he has used himself in the pursuit of his trade.——*The Elements of Machine Design*, by W. Cawthorne Unwin (Longmans), is the fourth edition, revised and enlarged, of one of the best of the textbooks of science issued by the Messrs. Longmans. The work is extensively used in classes, and is carefully pored over by many amongst the more intelligent practical engineers, puzzled as they may be by the mathematical formulæ used in parts.——*A Treatise on Shoring and Underpinning*, by Cecil Haden Stock (Batsford), is a useful handbook for architects and students, as the author has carefully looked up authorities on the subject, and added additional notes and sketches from his own practice.——*Sydenham, Dulwich, and Norwood* (T. F. Unwin) is another of the half-holiday handbooks, the utility of which we have before mentioned. At present they all refer to districts south of the Thames; but, we presume, the north is to follow.——*Molesworth's Pocket-book* (E. and F. N. Spon) is the twenty-first edition of a work which has attained a well-deserved reputation. It has steadily grown in bulk until it now contains nearly 750 pages of "useful formulæ and memoranda for civil and mechanical engineers." Those who have previous editions will surely procure the new one, and those who are unacquainted with the work may be assured that it is an indispensable pocket-book for the engineer and mechanician. ——*The Photographic Studios of Europe*, by H. Baden Pritchard (Piper and Carter), is a gossipy account of a number of visits paid to the studios of well-known photographers, which is full of useful hints to the profession. The term "studios," perhaps, scarcely covers the contents, as amongst the articles are accounts of photographing prisoners at different establishments, and a description of Dr. Huggins's studio, in which he photographs the stars and their spectra.——*Micro-Fungi, When and Where to Find Them*, by Thos. Brittain, Pres. Manchester Microscopical Society (Simpkin Marshall), is a very handy and useful manual for the microscopist who wishes to study the minute fungi. The work is arranged to the months of the year, and an appendix gives a list of the fungi mostly to be found on the leaves of plants.——*The Open Fireplace in All Ages*, by J. P. Putnam (Trübner), is an American work, giving an historical sketch of the fireplace, and a large number of illustrations of fireplaces and over-mantels, ancient and modern.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By John Watson Warman,

Associate of the College of Organists, London.

It will be at once obvious that by this treatment the Driving-Wire will be rendered incapable of *turning* round while in its Cut, and that therefore the Regulation by the Button can always be performed with but one hand. The workmanship involved cannot fairly be considered greater than with the Threaded method, because the Clothing furnishes an *additional* advantage.

Defect No. 3 (stated at *n*, ante, 5th parag.). It will be equally manifest that this blemish likewise is got rid of by the preceding device,—all necessary to effect the disconnection of the Coupling Backfall being, first, the freeing of its rear end from the Sticker-top, and then the raising of the end containing the Cut, so that the Stirrup-bottom leaves the latter, and can so then be drawn forward and entirely freed from the Nose.

Defect No. 4 (stated at *n*, ante, 6th parag.). The removal of this also will be accomplished, so far as is ever practicable with the present Form of Man-to-Man Coupler, by the Nose-Stirrup Device. That is to say, all the while it is not found necessary to detach the Driving Wires from the *Great Organ* Backfalls, the position of the Regulating-Buttons on such Wires will obviously remain entirely undisturbed.

Defect No. 5 (stated at *n*, ante, 7th parag.). This is remedied by keeping both the sets of Manual Keys perfectly straight on Plan, and obtaining the "Passing between" of the Great-Org. Sticker by the device of making such "Passing" portion to be of *Wire*, suitably Cranked: see now the Description, given at *z*, ante. Thus there is no Skewing whatever, either of Keys or of Action, in the entire Manual portion of the Instrument,—the especially unpleasant Anomalous Skew of the Coupling Backfall (see *m*, ante, 11th parag.) being of course got rid of along with the rest. Of more importance than the latter is the fact that there is *not* now the counter consideration of the *second* Skewing (see *m*, ante, 2nd parag.; and *qq*, next, 4th parag.) to militate against the adoption of one same Setting-out for both the Manual Roller-boards. [If the *Clear* Coupler should be here attempted (see at *m*, ante, 8th parag.), it will manifestly be necessary that the *Great-to-Ped.* Stickers also be Crank-wired (see again at *z*, ante) at and past the Square-Noses which lie upon the Swell-Org. Key-tails.]

At this stage see again (at *h* ante, 9th parag. and on) the method of *Front-Regulation* for the Swell Clavier,—remembering that such Regulation is here rendered slightly more practicable by the fact of the Wire-cranking of the Stickers affording less hindrance to the required access to the Regulating Buttons than do the ordinary—Wooden entirely—Stickers. Whenever such Front-Regulation is resolved upon, it will generally be best to plant the Great-Org. Stickers back at the extreme [rear] end of their Key-tails,—so of course causing the Noses of the Swell-Org. Squares to enter and lie between such Stickers: the latter, being of wire at such point, will accommodate these Noses in a sufficiently free manner (see *m*, ante, last part of 2nd parag.). The Notching of the Swell-Org. Key will thus, in such case, take the form of a simple removal of the corner portion of the extreme [rear] end of each side of such Key. The Sticker of the Coupler Great to Pedals must now obviously be set close inside of the regular Sticker of the Great-Organ.

By the forgoing arrangement the Swell-Org. Square-Noses—already lengthened by having to receive the Swell-to-Ped. Stickers—will be prevented from becoming still further extended, and the Regulating Wires carried by such Noses will be fairly accessible to a proper Tool. The contact of the Action Great-to-Pedals is not of course rendered so satisfactory as when made behind the said regular Sticker which is on the same Key; but still there will exist no real risk of fore-lifting the latter (see again *m*, ante, last part of 2nd parag.), provided only that such Great-to-Ped. Sticker is planted as close as is possible to such regular Sticker contact, and that the [Great-Org.] Key itself be of ample length (see here at *rr*, Bis, ante).

With regard to the abstract *advisability* of the preceding positing of the Great-Org. Stickers, and consequent entry of the Square-Noses between them, it may be considered that such a treatment is not usually to be adopted, unless either the Backfalls or the Keys of the Great Manual are already as long as is well admissible (see *n*, next), or else that the Front Regulation of the Swell Manual is a matter determined on. As to the first of these points, see what has been said (at *m*, ante, 16th parag.) as to the shortening by diminution of overlap: with respect to the second, go again over what has been given, with the *Faringdon* Arrangement, concerning such Front Regulation (at *h*, ante, 8th parag.), —the same *non*-necessity holding good in the present case. The alternative and preferable method has also previously been set forth (at *m*, ante, last part of 2nd parag.).

q. As a *Verdict* on this present (No. 4) *Treatment* we may confidently pronounce that it is, with the exception already implied in favour of some Treatment which comprehends a Clear Coupler (see fully at *r*, next, 2nd parag. and on), the best practicable for the General Lay-out indicated (see *m*, ante and on);—bearing in mind that the design will not suit a *Detached Buffet* (see *r*, next, 14th parag.), and that the Great-Organ Backfalls are prevented from ever being Fanned; but—on the other hand—that the work is quite simple, that Skewing is eliminated, and that friction is reduced to a minimum (see at *v*, ante). The Merits and Defects of *Treatment* No. 4, therefore, like those of No. 2, rise or fall along with those of the said General Lay-out itself. Concerning this the reader is to be again referred to *Department* Entire Organ,—in supplementation of what has already been given at *m*, ante, 4th parag. and on; and at *n*, ante, 9th parag. We may, however, here summarise, by saying that the General Arrangement and Design of the present Instrument are palpably superior to those of that at Faringdon; and that the only real Defect (the absence of Clavier Projection cannot fairly be called blameworthy) of Willis's general Design, is that the Swell Section still retains the Order of Smallest Pipe at Middle. It is necessary to add that such Order was here rendered advisable by the limited width allotted to the Organ (see *Dep.* Building Frame, 43, *q*),—obliging the Pedal Pipes' being kept close to the Wind-chest Sides (Ends), and so preventing that access to latter which is desirable with all Sections which have their *Largest* Pipe at Middle.

With regard to the advantage of this last-named Ordering, as applied to the Swell Section, the reader must be referred to *Department* Windchest, and also again partly to that of Entire Organ. It will suffice here to observe that a Swell-Organ which has its largest Pipes in the centre, and is also planted behind and on a level with a Great or other Un-Boxed Organ which has its *smallest* Pipes at centre, will derive real benefit from the tones of its Bass Half being then more unobstructed in reaching the Auditorium; and also that such an Order of the Swell-Org. Pipes is agreeable to the giving of a *Coved* and *Lofty* form to the Swell-Box,—such a form very palpably assisting the reverberation and consequent enrichment of the Swell-Organ Tone.

See at this point with reference to the Coupler Swell to Pedale's being made of the *Part* kind (descrip. at *qqqq*, next and on).

qq. *No.* 4½ *Treatment.*—This consists simply in the Correction of the Imperfection last named —viz., the Order of the Pipes of the Swell Section.

In the present Treatment, therefore, the Order of the Swell-Org. Pipes is understood and enforced to be with the largest of them at Middle. Of course, the necessary space for Tuning Access must exist at the sides (ends) of the Swell-Org. Windchest. In every other respect of *General* Arrangement—including the Pipe Order of the Great Organ—such present Treatment is assumed to be the same as that of the Hoddesdon Instrument.

In the Manuals, and in the Action connected with them, the only essential alteration from the preceding Treatment (No. 4) is that the Hoddesdon model is also resumed for the *Manuals*, in so far as that the Swell-Org. Keys are now Skewed as in Treatment No. 3,—the Great-Org. Stickers being therefore of course not Cranked. But this resumption does not extend to the Key *Action* of the Swell-Org., which Action now runs from such Key straight to its Roller-board,—the Setting-out of the latter being thus made to start at the Half Semi-tonal Key-tail distance "out" (aside): but this shifted nature of such start is manifestly of not the least consequence in the present Treatment, because, the Pipe-Order being here totally different in the two [Manual] Sections, the Setting-out of the Great-Org. Roller-board could not in *any* case be made to serve also for the Roller-board of the Swell-Org.; and the Setting-out of the latter will not be in the smallest degree more difficult than if its start were made in agreement with the Key-tails of the Great-Organ. Of course, the Backfalls of the Couplers Swell to Great and Swell to Pedale will require to be Skewed; but such two Skewings furnish the *only* departures from the square which occur in the entire Manual Action: and it will be noted that the *Anomalous* Skew (see *m*, ante, 11th parag.) is now got rid of altogether.

The only remaining Skewing, that of the Swell-Org. Keys, ceases here to have that objection against it which existed in the Hoddesdon Instrument (see *n*, ante, 7th parag.), because now, the altered Pipe-Order of the Swell-Org. not only renders unadvisable any second [return] Skewing in order to bring the two Manual Roller-boards into an agreement, but, in such rendering, also (as just stated) abolishes entirely the Anomalous angle of the Coupling-Backfall of Manual-to-Manual.

See now again (at *h*, ante, 9th parag. and on) with reference to the Front-Regulation of the Swell Manual.

For the exact posit of the regular Stickers of the Great Manual, and the connection which exists between such posit and the Front Regulation just spoken of, see as already given in *Treatment* No. 3 (at *m*, ante, last part of 2nd parag.), and *Treatment* No. 4 (at *p*, ante, 9th parag.),—where also will be found the necessary directions concerning the Coupler Great-to-Ped., and the exact design for the Key-Tails of both the Manuals,—in connection with all these points. The actual model adopted in these several items in the present Treatment will preferably be the same as that with Treatment No. 3.

qqq. As a *Summary* concerning the present *Treatment* No. 4½ we may say that the *General Arrangement* (see *qq*, ante, 1st parag: and on) for which it is suitable is the best possible under all ordinary or *Normal* circumstances (see again at *qq*, ante, 2nd parag.,—as to Tuning Access); and that the *Treatment* itself is, *for* such Arrangement, also the best possible under all conditions *excepting* when someone of the still preferable *Clear-Coupler* Designs is adopted;—remembering also, as before, about a Detached Buffet (see *r*, next, 14th parag.).

qqqq. We have now arrived at the proper Stage to point out that either of the preceding Five *Treatments* may be—in the absence of either a Clear Coupler or of a complete Pedal Organ—very much improved by making the Coupler Swell-to-Pedale to be of the *Part* kind. This Device (an idea of the present writer's) has been already partly described in connection with the Bellows (at 10, *l*); but a few words are advisable here also.

For a *Part* Coupler it is first necessary to provide with a Partition, such portion of the Soundboard as will be operated upon by such Coupler; and each of the two divisions so formed will then receive its own separate Pallett. In the present case the Coupler to be understood is the *Part Swell-to-Pedale*; therefore about the lower half—i.e., the portion correspondent with the Pedale Clavier—of the Swell-Org. Soundboard will receive such two Palletts to a note; and one of thesePalletts should supply the Reeds and Chorus of the Section, and the other Pallett serve the remainder of the Registers of latter. Each of these portions of the Swell-Organ must have its complete Action in *permanent* connection with its Swell-Org. Key, the two No. 1 Squares or Backfalls preferably having their Noses lying side by side on, or in the Fork of the Tail of, each single one of such Keys. Also it is of course obligatory that the Coupler Swell-to-Great do act upon both of the said Palletts, or it will not be possible to unite the *whole* of the Coupled Manual to the *Great* Organ *at all*. The simplest means of doing this will obviously be by placing such Coupling *between* the two Manuals (see *s*, ante); but such a Form may as manifestly be not always practicable (see next parag. but one), and in such event it remains (preferably) only to cause the *Backfalls* of the [Man.-to-Man.] Coupler to act upon both of the aforesaid No. 1 Squares or Backfalls. The Stickers of the Coupler Swell to Pedale are now to be so arranged as to be in contact with, and Wired into, *only* the one of each two of Squares or Backfalls which is connected with the Flue Foundation portion of the [Swell] Section. Such *Part-Coupler* is then complete. A moment's reflection will show that by such a treatment the Pedal Organ can be much better supplemented than by Coupling to it the *Full* Swell-Org.,—with some deep, powerful, and perhaps snarling Reeds almost inevitably present. If the Full Swell be at any time desired to be placed upon the Pedals, it can of course be so obtained by merely employing the coupler Swell-to-Great *conjointly* with that of Great-to-Pedale. [Should some form of the *Puppet Chest* be adopted instead of the regular Soundboard, the Coupler Swell-to-Pedale will be made to act only on those particular "Puppets" (Palletts) which belong to the Registers which it is desired to so place in connection with the Pedals. See hereafter in *Departments* Coupling Action and Windchest.]

It is hardly necessary to point out that the Coupler just described should never exist in any Instrument that has, or is to have, its Coupler Swell-to-Great made of the *Clear* kind (see *r*, next, 2nd parag.); for in such event the Reeds and Chorus of the Swell Section would be cut off from the *Pedal* Organ altogether.

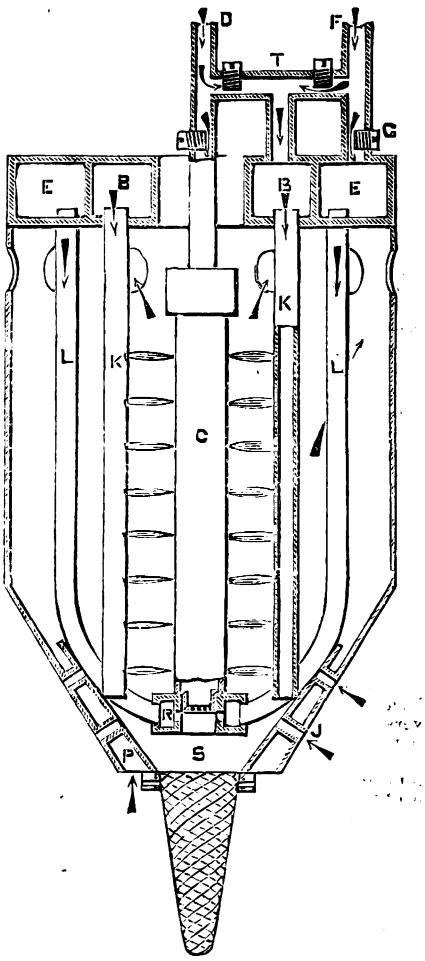
For a fuller description of the Mechanism of the Part Coupler see *Departments* Coupling-Action and Key-Action. It is here required only to add that any Coupler placed between the two Manuals will not, as a fact, be found well practicable in either of the preceding Five Treatments; because in every one of latter the lower portions of the Great Org. Stickers will be in the way of the Drumsticks Sliding forward, and in four of five there exists the additional obstacle that the hinder portions of the two Manuals are not set one vertically over the other.

(*To be continued.*)

CLAMOND'S INCANDESCENT GAS-LIGHT.

In No. 824, p. 419, we briefly announced that M. C. Clamond, of Paris, had patented a method of producing an intense white light by mixing hot air and hot gas, and directing the light upon a cylinder of lime. Since then experiment has led to modification, and another patent has been secured, the principal features of which are explained in the following description, with its accompanying illustration. The figure represents in vertical section one form of the improved apparatus, in which the heat of the products of combustion is partially recovered and considerable economy secured. The air current arriving by the pipe D descends the tube C, which is made hot by the small jets of gas playing on it, and becomes heated before reaching the jet S. A portion of the air regulated by the screw branches off by the pipe T and descends into the angular space B. The gas supplied by the pipe F enters the space E in quantity regulated by the adjusting screw G. From E four tubes L conduct the gas to the ring R which distributes it to the jet. A portion of the gas regulated by the screw shown passes by the pipe into B, which thus becomes charged with a mixture of gas and air in proportions which can be easily regulated by the screws. This mixture descends the four tubes K and issues from them in jets, which are ignited and serve to heat the tube C. The whole is inclosed in a casing which operates as a chimney, having at the top lateral apertures by which the products of combustion issue. At the bottom the casing terminates in two concentric cones connected by cross tubes J, and supports a basket of woven magnesia. Through this basket the jet flame passes producing the light, and by the draught caused by the casing the products of combustion ascend by the annular passage P whilst air entering by the cross tubes J becomes heated and aids in supporting the combustion of the small flames. It is obvious that the tubes K and L, as well as the spaces B and E, are heated by the products of combustion as they ascend within the casing M, a considerable portion of the heat being thus recovered.

The magnesian threads or baskets are thus made:—Magnesia calcined and pulverised is rendered highly plastic by thoroughly mixing it with a solution of a salt of magnesia that is readily decomposed by heat, particularly the acetate of magnesia. The plastic paste being put into a cylinder and subjected to moderate pressure by a piston, is caused to issue in continuous threads or tubes through a suitable die. These are then dried and thoroughly baked, during which operation the acetate becomes decomposed and, the acetic acid being driven off, there remains only compact and solid magnesia in the original form. The magnesian threads as they issue from the die are wound on a bobbin or mandril which turns first on an oblique axis and then on an axis at right angles to the former, so that the threads cross each other and adhere at their crossings, thus forming a net work which being dried and baked constitutes the basket of magnesia thread. The basket may be cased over with paper or other combustible material so as to strengthen it for transport and handling, this casing being burnt away when the jet is ignited. The magnesian basket is supported in a basket made of platinum wire or other refractory metal, with large meshes attached to a ring provided with a bayonet catch or its equivalent, so that it can readily be removed. The apparatus it will be seen admits of considerable modification; but has still the defect that gas is used in heating the air supply. The use of magnesian threads supported by baskets of platinum wire would, however, appear to be an improvement, as the magnesia becomes incandescent whilst the platinum remains sufficiently cool to escape fusion, or that state of semi-fusion in which it is impossible to keep it in shape. It is mainly because platinum, when raised to a white heat, tends to run together that coils used in electric incandescent lamps have failed, for the platinum glows with the most intense brilliancy only when it is just on the point of fusion. It remains to be seen how M. Clamond's burner will act when used with different qualities of gas.



MEASUREMENTS AND AMPLIFICATION OF TELEPHONIC VIBRATIONS.

"Everybody is aware," says M. Salet, in a recent paper to the Paris Academy, "that it is possible to hear through a thin door of pine, words spoken in an apartment that is otherwise quite closed. In this case the sonorous vibrations transmitted by the air agitate synchronously the wooden board, and this in turn transmits its movement to the outer air as a piston would. This familiar experience must have struck physicists, as giving proof of the exquisite sensibility of the ear. The vibrations of the board are indeed very small, hardly greater than those of the membrane of a telephone receiver in action; but these latter are so weak that their existence has sometimes been called in question. They exist, however, and I proceed to give an idea of their amplitude."

The method adopted by M. Salet was as follows: He fixed on the iron diaphragm of a Bell telephone a small glass disc weighing 0·45 gramme, and in front of this was supported a second, furnishing with it Newton's rings. The arrangement resembles that devised by M. Fizeau for study of dilatation. When one speaks at a distance of about six yards from the telephone, or sends into the instrument the telephonic current from a good transmitter (that of Buttcher, *e.g.*), the rings are observed to lose their distinctness, and disappear if the voice be a little forced. They vibrate, indeed, synchronously with the diaphragm, and nothing is simpler than to calculate, from the amplitude of their oscillations, that of the vibrations of the membrane.

It is certain, however, that the surcharge of the diaphragm with the discs must lessen the movements slightly; thus the results obtained err probably by defect rather than by excess.

To estimate the displacement of the rings, M. Salet arranges before the receiver telephone, which is caused to emit a continuous sound, a turning disc pierced with slits, like that of a phenakistiscope. One finds that, with a certain velocity of rotation, the rings reappear with distinctness. On blowing then through the disc, so as to make it act as a syren, it is found that the sound produced is in unison with that transmitted by the telephone. If it be slightly lowered or raised, immediately the rings oscillate, at first slowly, then with such rapidity that they become invisible again. While they oscillate one may easily estimate their displacement; in one experiment, the *la* of the diapason being emitted into the transmitter with the vowel *u* (*ou*), and with moderate intensity, the displacement was nearly equal to the distance of two consecutive rings, and the amplitude of vibrations of the receiving plate would thus be 2 to 3 ten-thousandths of a millimetre.

If there be sent into the telephone currents of different intensities, but very weak, and each of which, e.g., does not cause displacement of the rings beyond half the distance separating them, one may, by considering a point of the glass disc, infer from its brightness the intensity of the current. This singular galvanometric process, says M. Salet, might undoubtedly be utilised in the telectroscopic receiver.

In connection with the foregoing, we will here proceed to notice an interesting device for augmenting the dynamic effect of the vibrations of diaphragms, recently described by Mr. W. B. Cooper to the Franklin Institute.

When a cord is passed over a revolving pulley it is well known that there is a pull on one side proportioned to the character of the surfaces in contact and the pressure on them. This pull is due to the friction of the surfaces on each other, and increases in nearly, if not exactly, the same ratio as the pressure. Now, if the pulley is loose on the shaft, and we pull a cord passing over it, we have the same force exerted at the other end minus the friction of the shaft; if, however, the pulley is attached to the shaft and rotating towards the end pulled, then the result at the other end is the force applied *plus* the amount derived from friction on the surface of the pulley. This is the principle of the device, which, in its simple form, Mr. Cooper calls a phonodynamograph. To one end of a wire or band he attaches a diaphragm or other pulsating body, then he gives a half-turn or several turns round a drum or pulley, which is rotated in one direction. To the other end may be attached a lever, having a point adapted to indentations of sheet-metal passed under it at uniform speed by suitable mechanism. Mr. Cooper has thus embossed brass of the thickness of writing paper by the impact of the voice on a diaphragm of the size used in the phonograph.

The principle, he points out, is applicable to the telephone, both for the purpose of increasing the intensity of the electric impulses transmitted, and augmenting their effects at the receiving station. At the transmitting station, *e.g.*, the same, or by means of leverage a greater, amplitude of vibration may be given to a stouter diaphragm; or an armature, controlled by a spring, playing before the poles of a magnet. It is manifestly applicable, however, to any form of transmitter in which increased power is advantageous; and by it the telephone may be rendered available for greater distances. For increase of power in the receiver, Mr. Cooper has devised a plan in which he applies the principle somewhat differently. A number of horseshoe electro-magnets are set rapidly in a drum, and their draft upon an armature on the face of the drum is increased by the agency of friction of a wire or band passing round the drum, and connected with the armature and with a diaphragm. For details of the working we must refer to the original paper.

IMPROVEMENTS IN THE SODA PROCESSES.

SOME important improvements in the manufacture of soda and potash, introducing a method of combining the Leblanc and the ammonia processes, have been recently invented by Dr. Max Schaffner and W. Helbig, of Aussig, Austria. In the Leblanc process sulphur is used, which is thrown away in combination with calcium as "tank waste." In the ammonia process the residue is chloride of ammonium, from which ammonia is regenerated by distillation with lime. The present invention consists in combining the Leblanc process with the ammonia process, by employing for the regeneration of ammonia in the latter process hydrated magnesia, precipitated by the reaction upon chloride of magnesium of the calcium sulphide contained in the tank waste, which is the residue of the Leblanc process, and then employing the magnesium chloride resulting from the reaction of the magnesia upon the ammonium chloride for the decomposition of a further quantity of tank waste from the Leblanc process. The first-mentioned reaction takes place according to the equation:

$$2(NH_4\,Cl) + Mg\,H_2O_2 = 2\,NH_4O + Mg\,Cl_2 + H_2O,$$

and the second reaction takes place according to the equation:

$$Mg\,Cl_2 + Ca\,S + 2\,H_2\,O = Ca\,Cl_2 + Mg\,H_2\,O_2 + H_2\,S.$$

By combining these two reactions there is obtained a new industrial result of great importance. For the lime hitherto used in the ammonia process is substituted perpetually-regenerated hydrate of magnesia, obtained as a by-product of the operation of decomposing the tank-waste of the Leblanc process; and the whole of that part of the sulphur used in the Leblanc process which exists in the residue in the state of sulphide of calcium is liberated as sulphuretted hydrogen, which sulphuretted hydrogen can either be wholly burnt into sulphurous acid, which can be then converted into sulphuric acid, as will be well understood, or can be treated for the obtainment of its sulphur in the free state, or can be utilised in any other manner which may be preferred. It will be desirable, in order to diminish loss of chloride of magnesium, to divide the operation into two stages. The first stage should consist in heating the tank-waste with an excess of solution of chloride of magnesium, and then, when the calcium sulphide in the tank-waste has been completely decomposed, separating the resulting magnesia, either by subsidence and decantation, or by filtration. The magnesia so separated will then be ready for use for decomposing an equivalent of chloride of ammonium from the ammonia process. The liquor separated from the magnesia will be a mixed solution of calcium and magnesium chlorides, and this should now be heated with a quantity of tank-waste containing more calcium-sulphide than the quantity equivalent to the magnesium chloride in the mixed solution. When the whole of the magnesium chloride in the mixed solution has been decomposed by a portion of the calcium sulphide in the excess of tank-waste with which it has thus been heated, a second filtration, or a second operation of subsidence and decantation, should be performed. The solution separated by this second operation will contain only chloride of calcium, and may be thrown away, or otherwise disposed of. The solid matter separated from the solution of calcium chloride will consist partly of hydrate of magnesia and partly of excess of undecomposed tank-waste, and should now be treated, with or without more tank-waste, by an excess of solution of chloride of calcium.

The manner of employing the hydrated magnesia, obtained as aforesaid, for the decomposition of the chloride of ammonium of the ammonia process, may be the same as that which is at present followed. The present invention is so far applicable to the manufacture of potash that the tank-waste may be the residue of the manufacture of potash by the Leblanc process. Between the present invention and all preceding proposals for the use of magnesia for the decomposition of the chloride of ammonium of the ammonia process, there are essential differences, alike of object, of method, and of results. All former proposals to decompose by magnesia the chloride of ammonium of the ammonia process have had for their object the obtainment as hydrochloric acid of the chlorine of the chloride of sodium converted by that process into soda; but the object of the present inventors is to obtain, not hydrochloric acid, but sulphuretted hydrogen. All preceding proposals to use magnesia instead of lime for decomposing the chloride of ammonium of the ammonia process have been based on the idea (which has never yet proved capable of practical realisation) of evaporating to dryness the resulting solution of chloride of magnesium, and then heating the dry salt in a current of steam, so as to obtain on the one hand hydrochloric acid and on the other hand anhydrous oxide of magnesium; but by the present invention the chloride of magnesium is decomposed by treatment of the solution itself with the tank-waste of the Leblanc process, and the products obtained, instead of being anhydrous oxide of magnesium and vapour of hydrochloric acid, are sulphuretted hydrogen, hydrate of magnesia, and solution of chloride of calcium. Lastly, while to decompose the chloride of ammonium of the ammonia process by magnesia obtained by decomposing magnesium chloride by heating it in a current of steam would be to decompose it by anhydrous oxide of magnesium got by reacting upon solid chloride of magnesium by heat and a current of vapour, under the present invention the agent used for the decomposition of the chloride of ammonium is hydrate of magnesia, obtained by treating a solution of chloride of magnesium by solid sulphide of calcium.

STRAIGHTENING CROOKED CASTINGS.*

WHICH way will my casting go? is a question that the foreman of a foundry is often asked. To answer this question correctly every time would be a very hard task. The foreman may be well versed in the cooling and contraction of castings, but some time a complicated piece will come along that will puzzle him. In some castings the sooner some of the parts are cooled the less liability there is of the casting being crooked, while again there are others that require to be cooled from some certain temperature. There are two reasons for castings warping. The first is ill-proportioned thickness: the second, the allowing of some parts to cool before others. To these a third reason might be added, viz., the quality of the iron. Bad proportion is, perhaps, the chief cause for warped castings.

The two sketches illustrate the straightening of a crooked casting (Fig. 1), and also how gates and runners often make castings crooked (Fig. 2).

FIG. 1

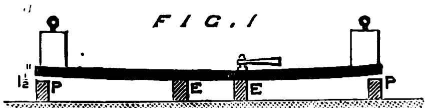


FIG. 2

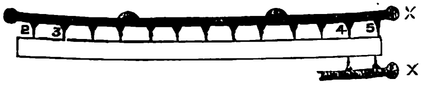

Castings for house work give trouble from warping, as they are generally light and long. When the thickness of metal in a column is not equal, the thin side will cool first and draw the thicker side towards it, thereby making the thin side of the column concave and the thick side convex. A variation of 1-16in. in thickness is often enough to make a column crooked. When care is not taken to have the thickness equal and the core well anchored, crooked columns may be looked for. Cores that are made in half-core boxes, and then pasted together, should always be calipered before setting the bottom chaplets, to see if they are round. Should the core be found to be flat or out of round, the difference should be divided between the top and bottom chaplets.

Moulders will sometimes set a flat core by measuring the prints, and allowing for the variation there, but making no other allowance; and when the cope is set on there will be, perhaps, more thickness of iron on the cope than on the bottom side. If questioned about this by the foreman, they will answer that the core-maker should have made his core round instead of flat. This is all true enough; but as it is a well-known fact that very few cores are pasted together so as to be exactly round, like a core that is swept up with loam or green sand, the moulder should always caliper them and then the pattern, and set the chaplets accordingly.

There are also many house castings, such as lintels and ornamental work, that are troublesome from having flanges and ribs, for the purpose of strengthening them, and saving iron in the main casting. The flanges or ribs are usually either thinner or thicker than the main casting. It can only be told how a flange or rib will draw a casting in the case of a special pattern; that is, no general rule can be given. The same shaped flange or rib attached to different proportioned castings will not make the castings all draw in the same direction. Although it is mainly flanges and ribs that are the cause of many castings bending into all kinds of shapes, we must not lose sight of the fact that the main casting is just as much responsible. Either the flanges and ribs or the main casting could generally be cast separately and come straight. When the main casting is the thickest, then we must give our attention to the cooling of that; but when it is the reverse, the flanges or ribs will require especial attention in the cooling.

About all that can be said as regards the cooling of ill-proportioned castings to keep them straight is, *cool the thick part and keep the thin part hot.* Try to keep all parts of the same temperature so that their contraction will be equal. There are castings that it is almost impossible to cool so as to keep straight, on account of their ill-proportions, and should we by good management do so, we run the risk of having them crack sooner or later, as there is sure to be a strain somewhere, because a thin body of iron will contract in cooling more than a thick body.

With castings in which a strong artificial cooling treatment has to be resorted to to make them come straight, it is best when possible to have the pattern made crooked to compensate for the warping when cooling. This is very often done in the case of castings that always warp one way. But there are castings in which this would be impossible, because they twist into all kind of shapes, one day being one way and the next day some other shape, and so on. About the best thing that can be done with such castings is to make them of iron, of the least possible contraction. If iron could be had that had had no shrinkage qualities, we would not be troubled much with crooked castings.

Weighting down the ends or the middle of long, heavy, or light castings is very often done to keep them straight. Sometimes the weights are sufficient to hold the casting straight without having to resort to any cooling process, and again it is necessary to weight them down and to cool them as well. It is sometimes better, when possible, to weight a casting down than to try to straighten it by cooling. I have seen long awning castings go so crooked that it was necessary to take them out of the mould, lay each end on some pig iron and weight down the middle so as to bend it down more than an inch below a straight line, the bending being done the reverse of the way that it naturally crooked or warped. This should be done as soon as possible after the casting is poured, so as to bend it while red hot. When the castings had cooled and the weights were taken off they come up straight.

Often moulders will weight down the ends of a casting, and shovel the sand from the top in the middle in order to keep the ends of the casting from coming up. This is wrong, for by cooling the middle on the top side, this part is contracted quicker than the under side, which will naturally cause the ends to come up if the weights are not heavy enough to hold them down. If the moulder is trying to hold down the ends of his casting, it would look more as if he understood what he was doing to dig underneath the middle of the casting so as to cool it, which, by causing the casting to contract there, will help the weights instead of working against them.

If the under side cannot be got at, it would be better to put on more weights, and instead of coolin the middle on top, leave it well covered over with sand, so as to keep it hot. It should always be remembered that removing the sand or brick from any part of a hot casting cools it; that cooling any portion of a hot casting causes a contraction, and that the side that contracts the fastest becomes the shortest. Also that before one side can become shorter than another, there must be a crook or a bend in the casting, this bend being made while some part of the casting is hotter than another. The part that cools first will generally keep the casting in the shape it was bent when hot.

It is not always that a moulder will succeed in straightening a casting before it is cold. He may, when he gets it out of the sand, see that it is crooked, and while there is yet a little heat in it, by dampening the rounding side or surface with cold water, straighten it. This treatment requires care, especially if the casting is so hot that you cannot bear your hands on it. The action of the water is sometimes visible as soon as it is applied, and if care is not taken, the casting will be bent the other way, in which case, if there is heat enough left, it may be wet on the other side to bring it back.

After castings are entirely cold and are then found to be crooked, they may often be straightened by pening with a hammer, or by heating the middle with a wood and charcoal fire, and weighting down the ends. Fig. 1 shows how this is generally done. The crooked casting is rested on two iron bearings, E E, high enough to give a good chance to build a wood fire underneath. There are then wooden or iron guide-blocks, P P, set to allow the ends of the casting, when it is being straightened, to be bent down the proper distance, so that, after the weights are taken off, the ends will spring up, leaving the casting straight. It will generally be necessary, if the middle is made red-hot, to bend it down about twice as much as it is crooked; that is, if it is ¾in. crooked, it should be bent 1½in., and after it is cold and the weights are taken off it will be straight. This is done by adjusting the blocks, P P, so that the weights will bend the ends down just as far as required.

---

* By Thos. D. West, in *American Machinist.*

In straightening castings in this way there is no cooling or contraction involved; the casting is simply bent, while red-hot in the centre, by the weights. The casting must be red-hot and be bent more than sufficient to straighten it, as explained. A wood fire is kept underneath, and a charcoal fire is made on top of the casting, so as to have it surrounded entirely by a strong fire. Often castings can be made straight by pening the hollow side with a hammer as shown. The hammering compresses and lengthens the part that is hammered, expanding the surface of the iron, which lowers the ends. A solid iron block should always be used to rest the portion of the casting under the hammer, and the hammer should have a good flat pene. The hammering should be done gradually over the surface. Steady hammering on one spot and then on another breaks the skin or surface of the iron, or perhaps worse, will break the casting in pieces. Fig. 2 shows how gates and runners sometimes draw casting crooked. This casting was a long toothed rack, the teeth being small. The casting was gated as shown, and when it was taken out of the sand it was bent sideways. This was caused by the gates and runner being lighter than the casting, and in cooling and contracting the quickest, they drew the casting crooked. To remedy this in the next casting, gates were made on both sides as at X X, instead of on one side only. This caused an equal pull on each side, thereby making a straight casting. The small gates 2, 3, 4 and 5, at the ends, would generally be broken from the castings by their rapid contraction. There is hardly a foundry that has not been at some time troubled by castings breaking or warping, and it is frequently troublesome to find the cause, and a remedy.

ANALYSIS OF JAPANESE BRONZES.

An examination of some specimens of Japanese bronze by Mr. J. Tadnari Matsdaira, B.Sc., a student of Rutgers College, N.J., gave the results recorded in the following short paper, contributed to the "Transactions" of the college. Bronze, as is well know, is an alloy of copper and tin. The relative amounts of its constituents vary according to the purpose for which it is intended; sometimes lead, zinc, gold, and silver are added, with the intention of giving it greater brilliancy or fusibility. Modern bronzes differ from the antique ones in composition and manner of manufacture. The bronze coin of Alexander the Great (335 B.C.) contained 86·72 per cent. of copper, and 13·14 per cent. of tin. A Roman bronze coin (500 B.C.) contained 66·04 per cent. of copper, 7·66 per cent. of tin, and 29·32 per cent. of lead. Many of the modern French bronzes are composed of—Copper, 91 parts; tin, 2 parts; zinc, 6 parts; lead, 1 part. The Japanese word corresponding to bronze is "karakane," meaning Chinese metal. Brass is called "shin-chu." The bronze industry in Japan is very ancient. Copper has been produced in Japan since the eighth century, but even before that period the manufacture of bronze had reached a certain stage of perfection, the copper or its alloys having been imported from China. Giyoka, a priest, and the introducer of the potter's wheel, planned the erection of monster statues to the god Buddha, and the plan was carried into execution by the Emperor Shomw, in 724-749 A.D. Three of these statues still exist. They are about fifty feet in height, and are said to contain a small percentage of gold. The modern bronze castings are employed for many ufeful and ornamental purposes, such as statues, bells, vases, knife-sheaths, candle-sticks, &c., and are generally made in the simple and curious style of the old and celebrated Chinese bronzes, or are embellished with the characteristically grotesque vagaries of Japanese art. The bronze objects are cast in clay moulds, formed upon models made of a mixture of wax and rosin, which is melted and poured out of the mould previous to running the metal in. The melting furnaces are generally of small dimensions, and consist of an iron pot lined with clay. The surface of the casting is then finished, and the design corrected by chiselling. Frequently gold and silver are inlaid to produce artistic effects. This work is known as "zogan," and is principally carried on in the provinces of Kagan and Techin. Frequently the surface of the bronze is deadened and darkened by the application of a solution of sulphate of iron and other chemicals. I have examined two of the best known kinds of bronze. One is called "shibuich." Its surface is of a light, brilliant gray colour, but a scratch reveals a red metal. The object from which I took the sample for analysis was a knife-sheath. The analysis gave—

Copper	74·11	per cent.
Silver	25·81	,,
	99·92	,,

The other sample was also from a knife-sheath, and was the metal known as "shakudo." The surface was a dark rich brown. It contained—

Copper	98·95	per cent.
Silver	·63	,,
Iron	·05	,,
	99·63	,,

THE METALLURGY OF NICKEL AND COBALT.

At the annual meeting of the Society of Chemical Industry, Prof. Huntington read a paper on the manufacture of nickel and cobalt. An important feature in the recent progress of this branch of metallurgy is the rendering of these metals malleable. In dealing with arsenical ores, Louyet's method is largely employed. For ores which do not contain arsenic the following method is said to be used. The ore is first fused with iron pyrites, by which means the nickel is separated in the form of a sulphide. The regulus of mixed sulphides is next treated for the separation of iron and sulphur, much in the same way as in the Swansea method of copper smelting—i.e., by a series of calcinations and smeltings, the "metal" in some cases being finally roasted in a fused state or treated with nitre to remove the last traces of iron. The remaining sulphur is then easily got rid of, and the more or less pure oxide of nickel thus obtained is reduced to the metallic state in the same way as in the wet process. The foregoing method is sometimes applied to the treatment of the New Caledonian ore, a silicate of nickel and magnesia, containing on the average 7 to 10 per cent. of nickel. This ore, which is very plentiful, is now, however, for the most part, smelted on the spot, much in the same way that iron is treated, and the metal exported to this and other countries in the form of pigs, containing about 5 per cent. of carbon and silicon, and occasionally a little antimony. The difference in cost for carriage between the ore and the pig amounts to about 20 per cent. The pig is refined without expense for arsenic by mixing with it a suitable proportion of arsenical ore. Hitherto nickel has only been used in alloy with other metals as a whitening agent. The reason of this is that it could not be obtained in a workable form. The metal resulting from the fusion of grain nickel is always wanting in malleability and ductility, behaving in a similar way to wrought iron which has undergone fusion, and probably for a similar reason.

Dr. Fleitmann, in the year 1879, succeeded in rendering nickel malleable by adding to it, whilst in a state of fusion, ⅛ per cent. of magnesium, introduced through a hole in the top of the crucible, a few lumps of charcoal having been previously added. In this way it is possible to produce malleable nickel which can be welded to iron or steel at a white heat, and rolled into thin sheets without separation. Fleitmann failed to get the same results by the use of manganese, aluminium, or calcium. Mr. Alfred Smeaton Johnstone, of the firm of Messrs. Wiggin and Co., who had previously been experimenting with manganese, has, however, succeeded perfectly in rendering both nickel and cobalt malleable by means of manganese. Commercial manganese (about 95 per cent.) or any ferro-manganese may be used for this purpose, the presence of iron not destroying the malleability of the nickel or cobalt. Thus the analogy between the treatment of nickel and cobalt and of iron which has undergone fusion is perfect. The manganese is added at a little a time to the fused nickel or cobalt, which is kept well stirred during the time, and finally poured out into moulds when tranquil. The metal is considerably agitated by the escape of gas during the addition of the manganese. For most purposes the addition of 2 per cent. of metallic manganese is sufficient, but when the maximum degree of malleability and ductility is required the quantity added may be increased to as much as 5 per cent., beyond which there is no gain under ordinary circumstances. The manganese left in the nickel need not exceed about ·2 per cent. Zinc can be successfully alloyed with nickel by reducing their oxides in a state of admixture. By rapidly fusing the alloy thus obtained a tough, malleable and ductile metal can be made. The melting point of nickel is too high to admit of zinc being introduced into it after the nickel is molten. The addition of ·1 per cent. of magnesium is said to improve the working properties of this alloy.

It is not likely that important applications will be long wanting for a metal possessing such valuable properties as malleable nickel, the price (about 4s. a pound) being comparatively low. Malleable nickel anodes are already being substituted for the old cast anodes. The former certainly have a great advantage in their uniformity of structure, which not only prevents to a great extent their being eaten away irregularly, but also avoids loss through secondary currents. The greater rarity and consequent higher price of cobalt precludes its general use in the metal state. It is, however, said to be used for electro-plating, the articles coated with it being sold as superior nickel plate.

COMETS' TAILS.

All who can should read Dr. William Huggins' interesting paper on "Comets" in the current number of the *Nineteenth Century*. He enters at length into the composition and nature of these bodies, points out what is to be learnt about them from the spectroscope, and from the information afforded by the observation of meteors and meteoric stones, and concludes with the following *résumé* of two or three of the most important of the many hypotheses which have been put forward to explain the formation and the phenomena of the tails of comets.

It is scarcely necessary to say that the enormous tails of bright comets, many millions of miles in length, cannot be considered as one and the same material object, brandished round like a great flaming sword, as the comet moves about the sun. It is but little less difficult to suppose that the cometary mass is of so large an extent as to include all the space successively occupied by the sweep of the tail at perihelion, the enormous stretch of tail maintaining a position always opposite to the sun, as the comet moves round the sun. Therefore, on the theory that material cometary matter is present throughout the entire extent of the tail, we seem shut up to the view that this appendage, often of stupendous magnitude, is constantly being renewed and reformed, either by matter streaming from the nucleus, or in some other way. But such a view involves velocities of transportation of matter far greater than the force of gravitation could account for, and indeed in the opposite direction, for we need a force of repulsion of some kind from the sun, and not of attraction towards it.

Consider a little closely the order of the apparent phenomena. As a comet approaches the sun, luminous jets issue from the matter of the nucleus on the side exposed to the sun's heat. These are seen to be almost immediately arrested in their motion sunwards, and to form themselves into a luminous cap; the matter of this cap then appears to stream out into the tail as if by a violent wind of some kind setting against it. Now one hypothesis supposes these appearances to correspond to the real state of things in the comet, and that there does exist a repulsive force of some kind acting between the sun and the gaseous matter which has been emitted from the nucleus. On this hypothesis the forms of the tails of comets, which are usually curved, and denser on the convex side, admit of the following explanation. Each separate particle of matter of the tail is moving in a curved course, under the influence of the motion it originally possessed, combined with that of this hypothetical repulsive force. But in the form which the tail assumes for spectators on the earth, we have to consider not only the effect of perspective, but also the circumstance that the comet itself is rapidly advancing in its course, so that the tail visible at any moment is due to the portion of space which at the time contains all the repelled matter, of which each particle describes its own independent orbit, and reflects to the eye the solar light, or gives out its own light as the case may be.

As a rule the tails of comets appear to be luminous by reflecting solar light, but at times the light-emitting stuff which gives a spectrum of bright lines or a continuous spectrum is carried into the tail, and retains this power of giving out light to a greater or less distance from the head. The value of the repulsive force which would be necessary on this theory has been investigated by Bessel, Peirce, Faye, and others. Recently Bredichin, of the Observatory of Moscow, by a series of investigations, has shown that the curvatures of a large number of comets fall into three distinct classes, each type of curve depending upon a different assumed value of the repulsive force. In this connection come in the secondary tails which are often present. On the hypothesis under consideration, these would appear to be darted off under an energy of repulsion so enormously great that the original motion of the nucleus tells for very little, and hence these secondary tails or rays are but slightly curved or even appear sensibly straight. It has been suggested that if this repulsive force, of whatever nature it may be, varies as the surface, and not like gravity as the mass, substances of different specific gravity would be very differently affected by it, and consequently separated from each other. On this view these secondary straight, or nearly straight, tails would consist of the lightest matter winnowed out from the other constituents of the cometary stuff. Of course, on this view a comet would suffer a waste of material at each return to perihelion, as the nucleus would not be able by the force of gravity to gather up again to itself the widely-scattered matter of the tail. It is certainly in accordance with this view that no comet of short period has a tail of any considerable magnitude.

A different view of the whole matter has been suggested by Professor Tait, which it is worth while to give as succinctly as possible, and in nearly his own words. He supposes not the nucleus only but the whole comet to consist of an enormous swarm of minute meteoroids, which becomes self-luminous at and about the nucleus in consequence of the impacts of the various meteoric masses against each other, giving rise to incandescence, melting, and the development of glowing gas, and the crushing and breaking up of the bodies into fragments of different sizes, and endowed with a great variety of velocities. The tail he conceives to be a portion of the less dense part of the train illuminated by sunlight, and visible or invisible to us according not only to circumstances of density, illumination, and nearness, but also of tactic arrangement, as of a flock of birds under different conditions of perspective, or the edge of a cloud of tobacco smoke. If on this hypothesis we are to suppose the glowing gas to arise from the decomposition of the meteoric matter, we should expect to have a more complicated spectrum from comets, and their spectra to differ from each other more than is the case, the comet of the present year standing alone in possessing a spectrum different from the type of spectrum common to all the other comets—about twenty—observed since 1864.

There seems to be a rapidly growing feeling amongst physicists that both the self-light of comets and the phenomena of their tails belong to the order of electrical phenomena. One of the most distinguished American astronomers recently wrote to the writer:—"As to American views of the self-light of comets, I cannot speak with authority for anyone but myself; still I think the prevailing impression amongst us is that the light is due to an electric, or, if I may coin the word, electric-oid action of some kind." The spectroscopic results fail to give conclusive evidence on this point; still, perhaps, upon the whole, especially if we consider the photographs of last year, the teachings of the spectroscope are in favour of the view that the self-light of comets is due to electric discharges. Those who are disposed to believe that the truth lies in this direction differ from each other in the precise modes in which they would apply the known laws of electric action to the phenomena of comets. Broadly the different applications of the principle of electricity which have been suggested group themselves about the common idea that great electrical disturbances are set up by the sun's action in connection with the vaporisation of some of the matter of the nucleus, and that the tail is probably matter carried away, possibly in connection with electric discharges, under an electrical influence of repulsion exerted by the sun. This view necessitates the supposition that the sun is strongly electrified, either negatively or positively, and, further, that in the processes taking place in the comet, either of vaporisation or of some other kind, the mattor thrown out by the nucleus has become strongly electrified in the same way as the sun, *i.e.*, negatively if the sun's electricity is negative, or positively if the sun's is positive. The enormous disturbances which the spectroscope shows to be always at work in the sun must be accompanied by electrical changes of equal magnitude; but we know nothing as to how far these are all, or the great majority of them, in one direction, so as to cause the sun to maintain permanently a high electrical state, whether positive or negative. Unless some such state of things exists, Sir John Herschel's statement, "that this force cannot be of the nature of electric or magnetic forces," must be accepted, for, as he points out, "the centre of gravity (of each particle) would not be affected. The attraction on one of its sides would precisely equal the repulsion on the other."* Repulsion of the cometary matter could only take place if this matter, after it has been driven off from the nucleus, and the sun have both high electric potentials of the same kind. Further, it is suggested that the luminous jets, streams, halos, and envelopes belong to the same order of phenomena as the aurora, the electrical brush, and the stratified discharges of exhausted tubes. Views resting more or less on this basis have been put forward by several physicists, and in particular by the late Professor Zöllner, who endeavoured to show that on certain assumed data, which appeared to him to be highly probable, the known laws of electricity are fully adequate to explain the phenomena of comets.*

RECENT ADVANCES IN PHOTOGRAPHY.—IV.†

By Capt. Abney, R.E., F.R.S.

In a collodion emulsion process, we have a process which is admirably adapted, at all events, for landscape work. The collodion emulsion was originated, I believe, in September, 1864, by Messrs. Bolton and Sayce, and a new era was opened out when they made their first emulsion. Now, an emulsion is very simply formed, particularly a silver bromide or chloride emulsion; but, as far to I know, it has been rather a crux amongst photographers to make an emulsion with silver iodide. However, this is a very easy thing to do, and I propose roughly to show those who are initiated in emulsion-making how an emulsion can be made, and further, how iodide of silver can be made amenable to treatment. The point in emulsion making seems to be, to get the precipitate in as fine particles as possible, and it is said that this can only be obtained, except at very great cost of time and trouble, by first adding the soluble bromide, or iodide, to the collodion. If you take the trouble to add the silver to the collodion, first of all the aspect of emulsion making is entirely changed, and you can get any amount of fineness by adding the iodide or bromide to the silver contained in the collodion so long as you keep the silver nitrate in excess. In this bottle is some ether, and some gun cotton which is not dissolved up. In this test tube I have some nitrate of silver dissolved in alcohol containing a very little water. I simply pour this solution into the mixture of ether and gun cotton, shake it, and I find an *emulsion* of nitrate of silver in collodion, since the alcohol and ether dissolve up the cotton. In the old days, emulsion makers would have said there is something wrong in having an emulsion of silver nitrate, but I think I shall soon demonstrate to you that in reality it is all right. Now I will add an iodide to this silvered collodion. I pour a solution of potassium iodide into it, not drop by drop, but somewhat carelessly, and shake it up in the bottle at intervals, and as a result, we get a very fine emulsion. You would find if you reversed the operation, and put the iodide into the collodion first, and then added silver nitrate, you would have precipitated the iodide of silver at the bottom of the bottle, and in a form which would not emulsify at all. My advise to those who wish to make collodion emulsion (not gelatine emulsion) is to add the silver to the collodion (or gelatine), and then add the haloid salts afterwards, and you will get as perfect an as you choose.

I have already shown you the colours of different haloid salts of silver under different conditions. I showed you two bromides, two iodides and two chlorides, one of each of which had been boiled in gelatine, and the other unmodified, and you saw the different colours they transmitted. To-night I wish to show you a new form of emulsion, which is adapted to certain purposes, and which is sensitive to the red and the ultra-red rays of the spectrum. If I had time I could show you that green is the most likely colour to absorb all above the red, and it was for this reason that I worked, till I obtained a green-blue colour for the purpose I had in view. I propose to try and take a photograph with the dark rays of the spectrum which lie below the red. These rays, which were discovered by Sir W. Herschel, and whose properties were examined by Tyndall, by means of the thermopile, we can analyse by means of photography. I will first, however, show you how very sensitive this form of bromide is to the ultra-red rays. There is what looks a very uninteresting picture on the screen, but still, it is sufficiently interesting for me to explain it to you. There are now, apparently, four black smudges, and these smudges were produced as follows:—A film of green bromide was prepared, and over it was put a card, punctured with holes of the same shape as the smudges, one-eight of an inch away from it. Above the card, and about half an inch away, was placed a kettle of hot water, having a blackened surface. After considerable exposure on development, I got the image of those holes in the card developed on the plate, and the result is the photograph on the screen. So you see that the dark rays of the kettle, or rather the energy of radiation from the kettle, was able to produce an image. This particular kind of bromide is very difficult to manipulate in a lecture, but I am going to be so bold as to make an experiment. I dare say some of you here who had the satisfaction of hearing Professor Graham Bell in his late visit, heard him discourse about the photophone; that is, as you know, an instrument which produces sound in a telephone connected to a selenium cell acted on by light. In one form of this instrument the light is intercepted by a revolving disc with alternate opaque and transparent sectors, which is traversed by a beam of light impinging on the selenium. He found, when he introduced between the source and the rotating disc a piece of ebonite, he still got the same effect, which was a matter of some interest. There were all kinds of explanations given about this remarkable fact. Some people supposed the ebonite took up the radiation, and gave it out on the other side, but I hope to show you that ebonite is transparent to the dark rays of the spectrum. I have some of this green bromide as a film on a plate. In front of that I have a piece of moderately thick ebonite. I propose to let the image of the carbon points forming the electric arc fall on the plate through the ebonite, by means of a lens. If the ebonite be permeable by the dark rays, we ought to get an image of the points on the bromide film when it is developed. As the rays have to penetrate through a mass of ebonite, I propose to give an exposure of about thirty seconds, and I dare say we shall then find we get the points fairly delineated.

For the sake of those who are uninitiated, I will show how very easy it is to develop an ordinary collodion emulsion plate. I am going to develop it with ferrous oxalate by means of a brush. Behind a negative is a plate coated with a collodio-bromide emulsion, and I will illuminate it by the magnesium wire. On taking it away from the negative, I place it in a little water, in order to make the developer flow, and then I brush the developer on the surface. It is rather a bold proceeding to manipulate a collodion film with a brush, but still I dare say it will answer. [The image was developed and shown.] The usual plan of developing these plates is to place them in a dish and pour the developer over them. They can also be developed in the hand in the same way as a wet plate. Now there is a great comfort in the collodio-bromide process, in that you are able to give local intensity to the image; and I hold that, for real artistic work, the great object is to be able to give local intensity to any part which the manipulator may judge expedient, so as to give that tone and that vigour which an artist may think necessary. In the next process which I shall describe you are at the mercy of your plate, and you must let come what will. The process which I refer to is the gelatine process, which may be described as silver bromide, held in suspension in gelatine, in the same way that it is in collodion.

What is the reason of the sensitiveness in the gelatine emulsion, for pictures can be taken in a tenth of the time necessary for a wet plate, and perhaps a thousandth that necessary for an ordinary dry plate? First of all we have seen on the screen in the last lecture that it has a blue form. But you must not run away with the idea that because anything is blue therefore the molecules composing that emulsion are blue. It may be an agglomeration of red molecules, agglomerated together in such a way that when light is scattered by it, it gives you the effect of blue light; and I believe I am right in stating that the most sensitive emulsion is that in which the agglomeration is in a red state, that is to say, the molecules themselves are red, and the agglomeration appears blue—the blue is there by accident, if I may say so. One reason why the gelatine emulsion appears so much more sensitive than the collodion emulsion is that you can use a more powerful developer. If you separate bromide of silver which has been emulsified in gelatine, and which gives very rapid plates from the gelatine—and there is an easy way of getting bromide of silver out of gelatine—and place it in collodion, the extreme rapidity will be found to be gone, simply because you cannot use as strong a developer as you can with the gelatine emulsion; in fact, the property that gelatine possesses of acting as a physical restrainer comes into play; each little particle, or aggregation of particles, is surrounded by gelatine, which prevents the developer acting rapidly on them.

Again, the fact that by boiling, or by the ammonia process, you get a coarser deposit of bromide of silver, also points to increased sensitiveness, for the reason that I tried to give point to in my first lecture. For when sub-bromide of silver is acted on by the developer, you have bromine, the last atom of bromine being taken away from the silver; and the moment you have freshly reduced silver in the presence of bromide of silver, and in contact with it, the bromide of silver can no longer exist, and therefore, you have fresh sub-bromide formed, thus:—$Ag_2 + Ag_2 Br_2 = 2 Ag_2 Br$, and this, in its turn, is reduced, and so on, until the whole of the bromide is reduced. The faintest action of light on one of these particles will therefore show itself, which it would not do were this aggregation not so marked as it is seen when looked at under the microscope. Another reason of the increased sensitiveness is this (and I have no doubt it aids it very materially), that if you boil or heat bromide of silver, or any haloid salt of silver, with an organic substance, it has a tendency to separate into the metallic state. So by boiling, for instance, a gelatine emulsion of silver bromide, the silver has a tendency to separate into a metallic state; in fact, the bromide of silver then is in the state of very tottering equilibrium; the bromine is ready to be given off at the very slightest disturbance of the molecule, much more so than before it is boiled. I think the fact that you so often get fogged emulsion when you over-boil, is proof of the statement that I am making. Now, if you were to ask me to illustrate the sensitiveness of a gelatine plate, I should take you down to the exhibition below, and I should point to you first, not some of those marvellously instantaneous photographs which you see, but I should just point out two, one by Mr. Henderson, which is a photograph by moonlight, and another by Mr. William Brooks, which is a photograph of some underground cellars at Reigate, taken by lamplight. I think, if anything can show what gelatine plates can do, it is the fact that candlelight and moonlight can be utilised for impressing the gelatine surface with an image. I have here another proof, perhaps, which will interest you as showing how rapidly a gelatine plate can act. I propose to take an image of a rotating disc, having alternate transparent and opaque sectors, when illuminated by the light of a single small spark. I have here an ordinary plate electric machine, and six small Leyden jars, together with a discharging machine, the knobs of which are placed five millimetres apart. If the Leyden jars are charged to a certain point, the spark will leap across between these two knobs. The light from that feeble spark will illuminate the rapidly rotating disc which I hold in my hand, behind which is placed a gelatine plate. The image, you see, of the rotating disc is perfectly sharp. I dare say it will interest you to know with what speed that photograph was taken. The duration of the electric spark, for a distance such as I have here, has been measured, and found to be 42-millionths of a second. You have now some idea of the immense velocity with which the spark travels, and the extreme sensitiveness of the plate which I employ. This recalls to my mind a very early experiment, made in the daguerreotype days, where a piece of newspaper was placed on a rotating wheel, and by the light of a spark obtained from a battery of fifty large Leyden jars, a photograph was taken of the rotating newspaper. I believe the words were tolerably well defined. The time of passage of the spark was greatly longer than that which I showed you first, and immensely thicker and more luminous. I should suppose the spark from the large battery at the Royal Institution would take not less than a thousandth part of a second to travel, so that you see they were labouring under better circumstances than we are here. I have taken a photograph of this rotating disc in the camera, with only a spark from one jar, but it was rather a ticklish thing, so I preferred to carry out the experiment in the way I have done, rather than to risk a failure. But you may take my word for it, that if you had fifty Leyden jars, you could take a portrait of our Chairman with the greatest ease, by a flash from the spark, in about a thousandth part of a second.

(*To be continued.*)

A Coloured Reaction of Atropine and Daturine.—If a specimen of either of these alkaloids or of their salts is covered with a little fuming nitric acid, let dry up on the water-bath, and when cold moistened with a drop of potassa dissolved in absolute alcohol, a violet colour is instantly produced, and soon passes into a fine red. Only the violet colour is characteristic, as strychnine also gives a beautiful red colour if similarly treated. According to the author, 0·000001grm. of atropine sulphate can thus be detected. None of the other important alkaloids give a similar reaction.—*D. Vitali.*

An Injector Worked by Exhaust Steam.—Referring to the article under the above head, p. 467, quoted from the *American Machinist*, the Patent Exhaust Steam Injector Company, St. Ann's-square, Manchester, inform us that the injector mentioned was made for them by Sharp, Stewart, and Co., under the Hamer-Metcalfe-Davies patent. The injector reported on by our Transatlantic contemporary was specially proportioned for taking feed at a higher temperature than is usual in this country, and the results are not quite equal to those obtained here—viz., temperature of delivery, 190° Fahr., against a boiler pressure of 70lb. The company inform us that they have these injectors fitted on all kinds of engines, and in every case they give satisfaction—as, in fact, they are bound to do, for if the feed can be forced into the boiler without using live steam, and without increasing the back pressure, there can be no question as to the economy to be obtained by the use of the invention.

SCIENTIFIC NEWS.

THE deaths are announced of two men well known in the world of mechanical science. Mr. Robert Wilson was the managing partner of the firm of Nasmyth, Wilson, and Co., was the constructor of the great combination hammer in Woolwich Arsenal, and a few years ago received a grant of £500 from the Government for his improvements in the fish torpedo. The deceased was seventy-nine. Mr. Robert Charles May, who died in the fifty-fourth year of his age, was well known at the Institution of Civil Engineers, and had a large practice as consulting engineer.

The *Science Observer* (No 37-38) contains a couple of diagrams showing the method of indicating the systematic work done in sweeping for comets. The diagram is divided into a number of squares which are occupied by nine types of peculiar form, the effect of which is to indicate by the depth of shade the work done. A closer inspection gives the actual number of sweepings. The horizontal lines represent parallels of declination, the spaces between being zones of 15° each. The vertical lines represent the hours of R A.; so that each square represents 1 hour R.A. and 15° Dec., and is further divided into nine squares which are empty or filled with types indicating the number of times that region has been swept over. Mr. Chandler has an interesting paper on Sawyer's Variable.

The autumn meeting of the Iron and Steel Institute will this year be held in Vienna, and the preliminary programme will doubtless attract a considerable number of members. The special train (Chatham and Dover) will leave on Sept. 16th, and the party will be conveyed viâ Flushing, Cologne, and Hanover to Dresden, where they will stop until the 18th, and arrive at Vienna on the 19th. The business of the meeting will then proceed with the usual excursions, the conversazione, and on the 21st the Institute will be entertained by the City of Vienna; the dinner will be followed by a concert and dance. Excursions will be made on the next and following days to Styria and Hungary, in the one case to visit the mines and large ironworks, in the other to inspect the mills and millwrights' shops.

We mentioned last week Mr. North's estimate of the coal in Natal We hear now that Prof. Green, of the Yorkshire College, has accepted the invitation of the Natal Government to go out and report.

In addition to the international expeditions to the Arctic regions mentioned last week, there is another which will attempt to winter either near Cape Chelyuskin or on the south coast of Franz Joseph Land. One of the principal objects of the expedition is to determine whether that land extends in a south-easterly direction towards Cape Chelyuskin, and whether a basis for further exploration can be reached without too great risk. Lieut. Hovgaard's vessel is an auxiliary steamship of 150 tons, and is provisioned for 27 months, but he hopes to return within 16 months. Observations will be made throughout the winter in accordance with the programme of the international congress.

The London and North Western have put on some new saloons for the fast service between Liverpool and London. The new type is 76ft. long, with a gangway throughout, the centre of the length being occupied by a luggage-box and an attendants' room, in which tea, coffee, &c. are prepared. This latter serves to separate the saloon into two compartments, one for ladies the other for gentlemen. The light is compressed gas, and the heating is accomplished by hot-water pipes arranged under the seats. The saloon is fitted with every convenience for comfortable travelling.

Electrical exhibitions are multiplying. Besides the combined international exhibition of gas and electrical appliances to be held at the Crystal Palace during the autumn and winter, a purely electrical show is to be held at the Westminster Aquarium from the beginning of November until the end of February, with the attraction of £1,000 in prizes. The Aquarium is in a central position, and the exhibition, of which Mr. W. D. Gooch is engineer, will doubtless attract both exhibitors and visitors. The exhibition at Munich is making progress, and the Bavarian Kunstgewerbe Verein has announced a prize for fittings suited for use with the electric light. Edison will again have a very prominent position; but the special feature will be the attempt to utilise the water-power of the Hirschau, and transmit the current over three miles to work a lift and a thrashing-machine during the day, and to light up the palace garden and the Königplatz in the evening.

A watchmaker in the Palais Royal, Paris, lights his shop with 24 Swan lamps, worked by as many Faure accumulators, each of which weighs 60 kilogrammes (say 132lb.) The accumulators work the lamps for eight consecutive hours, and the temperature of the shop is said to be 10 degrees less than when gas-lamps are used.

Mr. Henderson, an engineer employed by the Pennsylvania Steel Company at Steelton, has patented an improvement in converters which facilitates the work of lining them for the basic process. He converts the ordinary pillow blocks, in which the converter trunnions revolve, into wheels about 30in. in diameter, by means of which the converter may be run in and out of working position for use and for repairs, the track consisting of the girders usually provided. It is said that a 10-ton converter empty of metal, with the bottom removed, and weighing about 30 tons, can be wheeled away by two men, at the rate of about 25ft. per minute, for which purpose a power truck is provided, geared five to one, with winch handles. The invention has been secured by patent in the United States as well as in England, France, Belgium, and Germany. It dispenses with the necessity of having an intermediate ladle and crane between the converter and the ingot ladle to get the charge down to the working level. A special hydraulic lift for raising and lowering the shells is superfluous, and room is provided underneath the converters for the introduction of the gas main and pipes to rapidly dry the converters after re-lining.

The Mills Building, a collection of offices on Wall and Broad Streets, New York, has been wired for 5,588 Edison lamps. The conductors consist of 1,650ft. of patent electric tubes, 628ft. of lead pipe containing the taped leads, 23,658ft. of zinc tubes, 75,909 ft. of wire, and 24,162ft. of wooden troughs. The weight of the wire was 3,774lb., besides 48 vertical cut-outs and 213 division cut-outs. Full details of this installation would be useful, as there seems some difference of opinion in this country as to the precautions needed to avoid the fire-risks of electric lighting.

Mr. Edison's electromotograph drew attention to a new fact—viz., the variation of friction between two rubbing surfaces, produced by voltaic polarisation. Herr Koch found oxygen-polarisation to increase the friction of platinum or palladium; but he got no effect from the other kind. From recent experiments M. Krouchkoll infers that while polarisation by oxygen increases, polarisation by hydrogen diminishes friction. His apparatus consisted of a crystallising pan with polished glass bottom, rotated about a vertical axis. A series of small brushes of platinum, fixed in ebonite and connected with one battery pole, rubbed against the glass during rotation, and tended to affect the needle of a sensitive balance attached. The pan held a little water acidulated with sulphuric acid. The other electrode was a copper rod placed in sulphate of copper in a porous vessel, which stood in a second porous vessel holding water, and immersed in the liquid of the pan. By the movements of the balance, the effects above indicated were observed. Half a Daniell suffices to show them. The increase and diminution grow with the electromotive force.

A recent investigation by Professor Fischer, of Dresden, of the behaviour of phosphor-bronze wire with reference to tractive force, shows what a considerable influence the working of the wire has on its strength; and so, how uncertain experimental results are when this is not considered. On thinning the wire to about 0·4 of the original thickness, the force required for rupture was increased threefold, and it is thought certain that the same wire, by further condensation in the wire-drawing mill, and without annealing, could be made still stronger. In the case of telephone lines, less regard is generally had to flexibility and more to tenacity, as it is desired to span as great intervals with as thin wires as possible. Thus, with a view to strength and small sagging of the stretched wire, it is advisable to use as hard-drawn wire as possible, provided the conductivity is not hereby compromised. (For details of Professor Fischer's work see *Dingler's Journal*, July 12)

A safety buffer of simple construction has lately been devised by a German engineer, Herr Heydrich, and is being tried on several of the Government railways in Prussia. Its action is comparable to that of a brake, and takes place after full compression of the ordinary buffer-springs. On the buffer-rod, before the springs, there is a bush or socket (*Hülse*) with triple worm, and between the spring and the bush a shearing ring of hard steel. In the case of a collision, the latter is pushed forward, shearing the worm, and thereby so much mechanical work is absorbed, that the shock is greatly weakened. Thus, with four buffers per carriage (bush about 4in. long), a work of 7,200 kilogrammetres is consumed; and adding the work of the buffer-springs and that of the spring-frame, &c., transformed into heat before the carriage can be damaged, we have a total of 10,000kgm. per carriage. This corresponds to the kinetic energy of a carriage of 10,000kg. weight, at a velocity of about 16km. an hour, liberated by collision. This insures great safety, as in the case of shocks in or near stations, the velocity is mostly not over 10 to 15km. In new carriages, to avoid premature shearing of the screw, the cutting edge of the ring is applied not directly to the latter, but to a ring of certain width; and only after this has been sheared off does the continuous shearing of the screw begin.

Metals, it is known, can be volatilised at temperatures generally high, the use of the electric arc being often necessary. M. Demarçay has recently proved, however, that if the pressure be diminished, the volatilisation will go on at comparatively low temperatures. All the metals examined hitherto (the most volatile indeed), showed this effect. The metals were heated in a crystal tube by vapours of sulphur, mercury, &c., the tube being connected with a Sprengel pump, and having a U-tube, traversed by a current of cold water, inserted a little way in the metal. On this latter the metallic vapour was condensed. Cadmium was thus proved to have volatility at 160° C, zinc at 184°, antimony and bismuth at 292°, lead and tin at 360°. The deposits in 24 to 48 hours were sufficient to allow of weighing (5 to 15mgr.). M. Demarçay hopes soon to show that even metals like iron and platinum may thus be vaporised at temperatures much lower than commonly specified.

For ascertaining the water-level of steam boilers in the dark, Herren Schlag and Berend, of Berlin, place a small luminous float in the water gauge and make luminous marks near the glass. The float consists of a small cylindrical glass capsule, filled in the upper part with a mixture of Balmain's paint and phosphate of alkali salt. This mixture has the property of becoming luminous at temperatures of over 80°, without previous exposure to light. A grain of shot in the lower end of the float keeps it vertical.

During the first six months of 1882 the weather has greatly favoured Signor Tacchini's observations of sunspots and other solar phenomena. Thus there were 25 days of observations in January, 25 in February, 26 in March, &c. Spots were seen each day of observation. The solar activity has been increasing, and the maximum, it is thought, will probably be reached this year. There was a secondary minimum of spots in January; the size and number increased till April, then fell off again. There were most faculæ when there were fewest spots. With regard to latitude of spots last year, Signor Ricco has reported that there were 132 groups between + 7° and + 29°, with maximum at + 20°; and 120 groups between – 3° and – 33°, with maximum at — 18°. The northern spots seem to have more duration than the southern. Groups below 15° are displaced towards the equator, groups above 15° towards the poles.

In accordance with a recent State law of Massachusetts, special inspectors are now visiting the freight and passenger elevators used in Boston, to see whether they are provided with proper appliances for preventing a fall in case of breaking a rope. While all the safety catches tested on the first day checked the fall successfully, there were wide differences in their operation; thus, while in one case the platform was brought to a stand in about an inch, in another a weighted platform with cam catches fell 28¼in. before it was stopped. One platform was checked in a very smooth and gradual manner in 16½in. It is pointed out by the *American Architect* that the blow given to the guide posts by a platform weighted with one or two tons of goods, when brought up suddenly by a safety-catch after two or three feet of fall, would be terrific, and there are many buildings where the slender hard pine timbers would inevitably fail under such an impact, bringing down the whole structure in a heap. It would appear, further, that elevators depending for safety merely on the multiplication of the suspending ropes require thorough testing; for sometimes the parting of one involves that of the other.

Herr Noack, of Worms, has been making experiments on sounds from combined flames, with apparatus which allowed of moving the flames, either vertically or horizontally, towards each other. The burners were brass pipes 30mm. long and 6mm. wide, closed with a centrally perforated piece of platinum. The results were as follows: (1) When a horizontal flame burns against a vertical, the latter enters into vibrations; the pitch increases with diminishing aperture of burner. (2) The pitch is proportional to the distance of the horizontal flame from the mouth of the vertical burner, and inversely proportional to the distance of the vertical flame from the mouth of the horizontal burner. (3) The pitch increases with the pressure of gas in the horizontal burner, and falls in the same ratio with increased pressure in the vertical burner. With equal pressure in the two burners, the pitch is thus constant.

USEFUL AND SCIENTIFIC NOTES.

Testing Wine with Catgut.—The determination of the astringent matters contained in wine is a most delicate operation. The principal astringent is a tannic compound called *œnotannin.* The ordinary methods of determination are rather uncertain, especially where there is little astringent matter. M. Girard has lately devised a method of very simple nature, which has proved to be superior in precision to the others. It depends on the tendency of the matters in question to combine with animal tissues. Long ago Pelouze used skin to separate tannin from gallic acid; others have analysed bark by a process based on absorption of tannin by skin. Some chemists seem to have even tried ordinary skin in the analysis of wines, but it is not well-suited for this. M. Girard finds in catgut a pure animal tissue, of definite chemical species, a much better means of determination. He takes some of the fine, white violin cords prepared by M. Thibouville-Lamy, the last process of polishing with oil having been omitted. Four or five of these are put together. A certain quantity is soaked in water for four or five hours (one grain having previously been detached to ascertain the water in it); then these swollen portions are put in a known quantity of the wine to be analysed. This is quickly altered in consequence; in 24 hours generally, or 48 at most, all colour has disappeared. The tanned and dyed portions of cord are then dried, first in a flat dish, then in a closed vessel at higher temperature. A comparison then made of the original cord (free from water) with the same cord tanned, coloured, and dried, affords a correct estimate of the *œnotannin* and colouring matters of the wine.

An American paper says the New York Custom House records furnish the following figures, which show the growth of arrivals of steam and sailing vessels at New York, during the years named:—1865, steamers, 455, sailing vessels, 4,291; 1866, 623 and 4,284; 1879, 1,591 and 6,486; 1880, 1,895 and 5,922; 1881,. 1,953 and 4,976. Although there has been a decrease of 1510 sailing vessels since 1879, and the number last year was only 683 more than in 1865, the increase in the arrival of steamers has been considerable. In commenting on these figures, an exchange says that the steamers, however, have not increased in number to this extent, as the majority of them arrive at short intervals.

An extensive deposit of bismuth in the form of metal and oxide has been discovered in the north-east of New South Wales. Hitherto the bismuth of commerce has chiefly been derived as a bye product in the treatment of zinc, cobalt, and silver ores, and has commanded a price quite out of proportion to the cost of production. From the new mine, the *Journal* of the Society of Chemical Industry says, the metal can be sent into the market at a cost which, if the present price—6s. 8d. per lb.—were maintained, would insure a profit of more than £500 per ton.

LETTERS TO THE EDITOR.

◆

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

A CURIOUS WEATHER SUPERSTITION—AGE OF STONEHENGE—MEASURING THE HEIGHT OF LUNAR MOUNTAINS.

[20357.]—The rule with reference to the "Saturday Moon" and St. Swithin, given by Mr. Oliver in letter 20322 (p. 477) has broken down conspicuously, at the station whence I write, at all events. We had rain on St. Swithin itself, on the 16th, 17th, and 18th; fine weather on the 19th and 20th; rain on the 21st, 22nd, 23rd, 24th, and 25th, and then eleven consecutive days beautifully fine, hot, and sunny, without a drop. The solitary one of what I may call day rules in connection with the weather to which I attach the smallest importance is, "A wet Friday, a wet Sunday:" because it is a very common thing in this country for two days' rain to be separated by an interval of one, during which no rain falls. But then, of course, it would be equally correct to say, "A wet Tuesday, a wet Thursday"—and so on.

If "Neo" (letter 20323, p. 477) will consult Sir John Lubbock's most interesting book, "Prehistoric Times," he will find that its distinguished author attributes Stonehenge to the Bronze Age.

I very willingly accede to the request preferred by "A Ten Years' Subscriber" (in query 47538, p. 485), to give him the modus operandi of measuring mountains in the Moon. I can only, however, furnish some notions of the method of measurement, and of the principles on which it depends. For the reductions of such measures I must refer him to Neison's standard work, "The Moon," in which the mere formulæ (with their explanation)

FIG. 1.

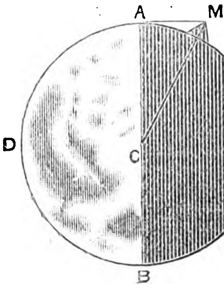

FIG. 2.

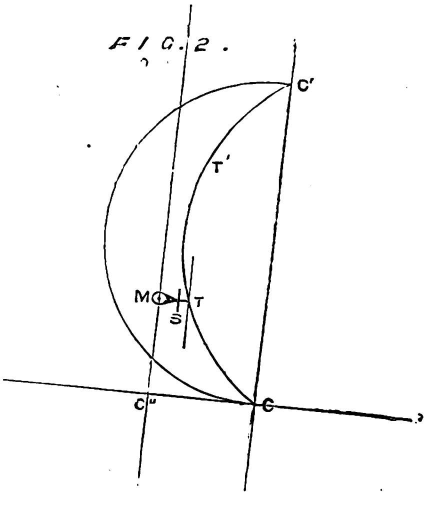

occupy pp. 554 to 560 inclusive. The older Selenographers proceeded on a principle which will be at once apprehensible from a study of Fig 1.

Suppose that A D B represents the Moon when half full, or accurately in her First Quarter, and let M be a mountain, the extreme tip of which only is illuminated, the Sun not yet having risen on the lower part of it; then, with a micrometer, measure the distance A M. Now, C A M is a right angle; C A (the Moon's semi-diameter) is known, and hence (Euclid I., 47) the hypothenuse C M is at once found. Take C A from this, and the remainder is obviously the height of the Mountain. As the Moon is a globe, a very little reflection will show that the point M may be anywhere to the right of the line A B, as long as such line is a straight one. Mädler adopted, and modern Astronomers generally use, a different mode of determining Lunar Altitude altogether—his method consisting in the measurement of the length of the shadow cast by the object whose height he was endeavouring to ascertain; then computing the altitude of the Sun above its Lunar horizon at a given instant, the remainder of the operation resolved itself into the solution of an ordinary right-angled triangle. It is the determination of the Sun's position with reference to the object at the instant of observation, which involves so much tedious calculation. The way in which the actual observations are made is indicated in Fig. 2. Here, C C′ are the horns or cusps of the Moon; C T T′ C′ the terminator, or boundary of light and darkness: M the Mountain to be measured, and M S its shadow. First, then, we measure the exact length of the shadow in a direction at right angles to the line joining the Cusps C C′; next, with all possible accuracy, in the same direction, the angle M T between the summit of the mountain and the terminator; and, lastly, turning the micrometer round 90°, we measure the distance M C″, or that between the Mountain and the Moon's Cusp. For the operose and most wearisome mass of calculation necessary to deduce the height of the given mountain from these data, I must, as I have previously said, refer my querist to Neison's great book. I may add that, having thus obtained the heights of certain standard objects, Mädler compared the lengths of the shadows cast by them with those of others in their immediate neighbourhood; thence deducing, very approximately indeed, the heights of the latter.

A Fellow of the Royal Astronomical Society.

δ EQUULEI—β LEPORIS—β DELPHINI.

[20358.]—The close pair (OΣ 535) of the triple star δ Equulei (Σ 2777) is probably the most rapid binary at present known. Whether a period of 6½ or 13 years (OΣ inclines to the shorter one) is the more probable is at present uncertain, owing to the small number of observations, and the almost perfect equality of the two compenents. It was discovered by OΣ, with the Pulkova refractor, on August 19th, 1852. The definition being extraordinarily fine, he saw the two stars just separated, with a power of 858; the next year he could only see an oblong disc, and in 1854 the star was absolutely single. It is a system resembling 42 Comæ, the elongations being from 0°–30° and 190°—220°. As far as I am aware, it has only been seen double at the observatories of Chicago, Lund, and Pulkova. The principal observations during the last twelve years are—

Du.	8°. Oblong, nearly certain ..	1870·73 (1ⁿ)
OΣ.	210·6°. Oblong, separated at intervals, distance 0·29″....	1874·71 (3ⁿ)
β.	[156·4°?]. 0·2″. A slight elongation (probably illusive)....	1877·76 (1ⁿ)
,,	No certain elongation	1878·65 (2ⁿ)
Hall.	Not certainly double, powers 888 and 1,300	1879·76 (2ⁿ)
β.	22·1°. 0·38″. (Unpublished)	1881·46 (4ⁿ)

Possibly Mr. Perry would be able to measure it this year; next year it will presumably be single again. The change in C is due to the proper motion of A-B. The distance was 19·5″ in 1781, it is 39″ now. The exceedingly pretty pair, β Leporis (β 320) has been supposed to be a binary in rapid motion, owing to large errors in the earlier measures. Hall's measures at Washington, and the Cincinnati observations, show that no change has really occurred. Hall's are as follows:—

281°·0	3″·12	1876·11	(3ⁿ)
284·9	3·16	7·12	(3ⁿ)
281·3	3·05	9·98	(2ⁿ)
282·4	2·70	82·10	(3ⁿ)

H. measured a 13ᵐ companion at the Cape (*h* 3761) 145·9° Δ A.R. 2·5s. 1835·9, but he missed the close star, though it is now easily seen with a 6½in. Calver; there is a much fainter star near H.'s comes. Smyth observed a very distant star in 67·5° 210″ 1832; β 75·0° 206·4 1879.

The wonderful binary β Delphini is opening out again. When Mr. Burnham discovered it, in 1873, it was a comparatively easy object with his 6in. refractor, and the next year I saw it with my 6½in. Calver. In 1879 it was absolutely single with a power of 925 on the 18½in. refractor at Chicago. The next year β. measured it 133·6° 0·2″ ± 1880·7, and the measures (unpublished) of last year give 149·2° 0·26″ 1881·50; this season it should be considerably easier. The arc described in seven years is not less than 135°.

MARKINGS ON JUPITER.

[20360.]—The red spot has been seen recently on Jupiter's central meridian at the following times:—

1882.	July	26, *p.* end	16h.	23m.
	,,	29, centre	14	22
	,,	29, *f.* end	14	53
	Aug.	5, *p.* end	14	50
	,,	5, centre	15	15
	,,	5, *f.* end	15	37

These times cannot be relied on as being very accurate, because of the extremely unfavourable conditions then prevailing, except those of Aug. 5, which are probably fairly accurate. The spot appears the same as it did last winter; but is perhaps a little paler.

The equatorial white spot was seen to be a little preceding the *f.* end of the red spot on Aug. 5, being estimated on the centre at 15h. 35m. It was bright, small, and very white. Closely following it was one of the dark spots seen by Mr. Denning (letter 20335, p. 498), to the east of the red and white spots, which has evidently gained not only on the red spot, but also on the white one.

The other features of the planet seem much the same as last winter, but the north equatorial dark belt is of very irregular breadth; in some places being scarcely visible, and in others nearly as broad and prominent as the conspicuous S. equatorial belt. Advantage might be taken of this to ascertain its rotation period. The colour of this belt is rather paler. The south equatorial belt now appears of a beautiful deep reddish brown, except in some places, where it approaches black.

On Aug. 2, at 16h. 0m., two singular larger nearly round white spots were observed between the north equatorial belt and the belt further to the north. Their appearance was rather striking, and bore much resemblance to some of those white spots seen in the equatorial zone for some years past. The whole of the interval between these two belts appeared unusually white.

A. Stanley Williams.

West Brighton, Aug. 7.

[20361.]—During the past three years the great red spot seen on the disc of Jupiter has been an object of unusual interest to astronomers. As the planet for the past three months has been too near the sun for observation, it was a matter of considerable interest to ascertain as early as possible whether the spot was still visible, because it was alleged last year by some observers that it was fading in colour and distinctness.

On the morning of the 14th inst. the great refractor was directed on this planet, and the spot was distinctly visible, and its approximate longitude ascertained by micrometer measurement.

The rotation of the planet, from observations on the red spot, made at the Dearborn Observatory in 1879, was found to be 9h. 55m. 34·2s. The observations made at the same place, in 1880 and 1881, showed that the rotation period was slowly increasing; or, in other words, the spot was retrograding with an accelerated velocity. The mean increase in the time of rotation amounts to about one five-hundredth of a second daily.

All our observations from September 25, 1879, up to the present time are fairly represented by the formula:—9h. 55m. 34sec. + t × 0·00209sec., in which t is the number of days after Sept. 25, 1879.

According to the formulæ, the "mean" period is now 9h. 55m. 35·9sec., and the actual period about two seconds more, so that the apparent rotation of the planet is four seconds slower than in 1879.

The observation of July 14th made the passage of the spot over the central meridian July 13d. 15h. 22·3m. M.T., and the formulæ gave 15h. 28·8m. M.T.

An approximate measure of its length gave 11·9″; the mean from last year's observations being 11·3″. The oval outline of the spot appeared as formerly, and the colour reddish. This remarkable object, which is 30,000 miles in length and 8,000 in breadth, has not perceptibly changed in shape, size, or latitude during three years. It has, however, apparently drifted in longitude about 40,000 miles, or one and one-third times its length. A number of astronomers have imagined it to be the solid portion of the planet; but the drift in longitude disproves this supposition. It appears to us that it is more probably an immense floating island of semi-cool matter resting in a liquid incandescent ocean surrounding the planet. Such a condition of the surface would give great permanency, and still allow slow and gradual changes in both the position and outlines of objects.

G. W. Hough,
Director of the Dearborn Observatory.
Chicago, U.S., July 25.

REFLECTED RAINBOWS.

[20362.]—Some time ago, I remember a discussion in your pages (see Index to Vol. XXVI.), as to the possibility of seeing reflected rainbows, and the Rev. T. W. Webb gave an account of one he had seen reflected in the Lake of Lucerne (p. 469, Vol. XXVII.)

In the *Field Naturalist* for August (a monthly, published by Abel Heywood, Manchester), is a paper by Prof. Stanley Jevons, the substance of which I beg leave to introduce to those of your readers who have not seen it:—"But though a reflected rainbow is to be seen, there are comparatively few people," says Prof. Jevons, "who have seen one. I have all my life looked out for any curious phenomenon of the sort, and have on several occasions seen beautiful lunar rainbows, which are considered rare appearances. Only two years ago did I for the first time notice a reflected solar rainbow. The rarity of the occurrence is no doubt due to the fact that it needs the combination of three independent conditions to allow of the observation. In the first place there must be a bright bow, which is not seen many times in the year; secondly, he who sees the bow must happen to be in the neighbourhood of a piece of water suitable in extent and position to reflect the bow; thirdly, the water must be tranquil enough to allow of reflection. The last condition will usually be wanting, because rain-clouds will in most cases be accompanied by wind.

"About two years ago, however, I saw a bright reflected rainbow, and what struck me much was that it assumed a form and character which I could not possibly have foreseen. I was on a steamboat, steaming up one of the lower and broader reaches of the lovely Hardanger Fyord. The water happened to be almost perfectly tranquil, and yet at the same time a brilliant bow appeared upon a heavy shower of rain, which was falling at the further side of the fyord. The brilliant colours of the bow were finely contrasted against the darkness of the cloud and of the surrounding fyelds; and as the boat advanced through the glassy water, it was easy, from the head of the vessel, to see a bright reflection. Instead, however, of the perfect segment of a circle, with all the seven colours clearly distinguished, I was surprised to see something entirely different—namely, a broad and nearly straight streak of confused whitish light, extending from the base of one side of the bow to within 10 or 20 yards of the steamer, where the light rather suddenly curved off in an awkward, sickle-form, and was soon abruptly lost. The fact is, that the water, although so placid and glassy, was affected by a ripple almost imperceptible except by its disfiguring effect upon the bow. Now, as we see in the case of the sun or moon settling over a placid sea, the effect of such a ripple is to spread out the reflection into a long streak, each wave, within certain limits of distance, having some part of its surface disposed at a suitable angle to produce reflection. A complete rainbow springs perpendicularly at the sides, and approaches the horizontal at the summit. If we imagine the bow cut up into nearly square segments, it follows that many of these segments in the legs of the bow will be reflected into streaks, and these streaks will be superimposed upon each other. Thus the full light of the bow will there be seen reflected undiminished by the scattering effect of the ripple, and as different coloured rays, derived from different parts of the bow, will be mixed together, they will, in accordance with the Newtonian theory of light, be fused together into white light. As regards the summit of the bow, however, there would be no superposition of reflected streaks, and the one thickness of the bow would give insufficient light to be perceptible.

Without in the least denying that a person may casually, and still more probably by intention, witness a rainbow reflected in all its beauty of form and colour, I have no hesitation in saying that nine times out of ten the reflected bow will be no bow at all, but only a whitish streak. Artists will doubtless continue to paint reflected rainbows as they are seldom or never seen, rather than as they are seen.

It should be added that since I began to write this little article, I have happened to see a rainbow almost perfectly reflected, both as regards form and colour, upon the flat wet sands of the sea-shore. The watery surface being unaffected by the moderate breeze which was blowing, acted as a nearly perfect mirror. Although persons walking upon flat wet sands see the clouds fully reflected therein, I cannot call to mind that I ever saw this effect represented in landscape paintings. I am, of course, far from denying that it may have been often so represented."

T. F. N.

ON THE CONSERVATION OF SOLAR ENERGY.

[20363.]—If Mr. C. H. Romanes (letter 20287, page 450) thinks the concluding paragraph in his letter so very sublime, his opinion on Dr. W. Siemens's theory cannot be worth much. Supposing the energy produced by the shrinking of the sun's body is required to assist its rotation, surely there must come an end of it. We would gain nothing by it excepting a few millions of years longer existence. It is against the laws of nature, and against logic, thinking that anything in nature should be constant, excepting change. That aqueous vapour and carbon compounds may be in the stellar and interplanetary space is most likely, but if the oxygen can be dissociated by radiant solar energy while in a state of extreme attenuation I cannot conceive how they can come back to the sun's photosphere without combining. This theory has been brought under my notice since the last four years by a Mr. Gether. He, however, differs, inasmuch as he thinks that the aqueous vapours and carbon compounds leave our solar system, and then are drawn into enormous forests where they are dissociated in the same way as on our globe. Then they are brought back by a stroke, similar to the blood in the lungs by the beat of the heart, every ten or eleven years, which he calls a sun year, and by that means accounts for the varying solar energy within that time. He was therefore in high glee when we had that severe winter three years ago, and the children in our house used to say "Mr. Gether has thrown coals on the sun, and before they burn properly we shall have a good deal more skating." Speaking from memory only, I think it best to make some inquiry to see whether I have made a correct statement, or whether Mr. Gether has improved his theory, and why he has not made it public.

J. H. Schucht.

GRINDING AND POLISHING GLASS SPECULA.

[20364.]—I think we can now rest satisfied that we have got at the true rule to find the ratio of the zonal foci for testing at the so-called centre of curvature. We all owe our thanks to "Orderic Vital," and all the other friends that have helped on the mathematical side of the question. The second paragraph of "O. V.'s" letter (20298) is very useful, and shows that the moving of the shutter an inch or so from the radiant point cannot make an appreciable difference in the ratio of the zones' foci. "Prismatique," as quoted by "O.V.," is quite right.

I have no doubt that our practical amateur friends who are waiting for information as to the actual grinding, polishing, and figuring of specula, have had their patience considerably put to the test by the time the investigation of the testing of specula has taken; but they must remember that perhaps we are writing on the subject for the help of the amateurs of the next 10 or 20 years, and, therefore, it is better that one subject be treated of at a time, and thus appear in one place in the future vols. of the "E. M." This will make reference much easier to those who have to refer to the vols. in the future, and this is my reason for thoroughly exhausting each subject as we go on.

I feel I should not be doing justice to our friends if I did not try to help them to understand the shadow test, at least as far as it can be depended upon; this shadow test is what may be properly called the Foucault test; it is the judging from the way the shadows come on the whole face of the speculum (*i.e.*, without stops), how far it is corrected, or, in other words, how near it is to the parabola. Now, I must warn the amateur that, unlike the zonal test, the shadow test is a matter of guess from the beginning to the end; that absolute certainty, even to the most experienced, is impossible, while the beginner may be fearfully mistaken; but still, as there is some benefit in understanding the shadow test in conjunction with the zonal test, and, above all, since the simple zone focus measuring apparatus that I have already described, enables the amateur to learn the shadow test in one-tenth the time he could without it, I will try to describe it. That moving the shutter by hand across the cone of rays is very trying to the beginner will be easily understood, when we consider that the image of the radiant point, or pinhole as it is sometimes called, is, perhaps, less than 1-200in. in diameter; this the beginner has to pass the edge of the shutter across by hand in the old way, and all the shadows from which he has to judge are produced in a moment, while he passes the edge of the shutter over this 1-200in.; then he must have the edge of the shutter exactly at a certain point along the cone of rays, at least to the 100th in., or else the shadows come on in a different way, and are, therefore, of no use; these difficulties have been too much for some (as well they might), who have made specula even up to 12in. diameter, while others, whose work I have had to test, who thought they understood the shadow test, and were masters of it, have been deceived, and specula that they thought correct were utterly wrong; and, to crown all, I know it as a fact that those who have had large experience in the shadow test, can at best only guess at what is the right amount of correction by it. Now this is not to be wondered at. If we understand the principle of the shadow test, it is a necessity of the case, and cannot be otherwise. The fact is this—The shadows from the ellipse approaching the parabola are exactly the same as the shadows from the parabola, and the shadows from the hyperbola just beyond the parabola are the same as from the parabola, the only difference being in their intensity, which intensity, to make matters more difficult for the beginner, varies with the proportion of the diameter to the focal length of each speculum. The shorter the focus in proportion to the diameter the more intense the shadows, so that not only has the amateur to get the right place to within the 100th inch along the cone of rays, and then by hand, while keeping the shutter in its right place pass it steadily across the 1-200in., but he has to judge, or rather guess, from the intensity of the shadows, whether the proper amount of correction has been reached, even when the proper kind of shadows are produced, the intensity he has to allow for, according to the proportionate focal length to the diameter. All I can say is—Poor amateur! Now, with the measuring apparatus a great deal of this difficulty is done away with, and the test becomes a pleasant one, though it can never (from the nature of the case) be a certain one; but as it is a help to the zonal test as to the judging of the regularity of the curve, I will attempt to describe it. But let me again warn the amateur not to depend upon it, for he can only (nor can the most experienced do more) tell from the shadow test that some correction has been obtained; whether it is just enough or too much or too little, no one can tell with certainty; the best can only guess from long experience better than the beginner.

I will now attempt to describe the shadows as produced by the shutter passing over the cone of rays from a parabola; of course I have had to greatly exaggerate the figure where the rays cross one another to make the indications perceptible to the eye. Of course, the amateur knows that the outside rays from the ellipse, parabola, and hyperbola are longer than the inside rays, the difference being that the parabola's outside rays are longer than the ellipse's, and the hyperbola's are still longer than the parabola's; the rule of dividing the square of the semidiameter by the radius of curvature (double the focal length for parallel rays) gives us the true amount of lengthening for the parabola; therefore, it is, that the zonal test is the only certain way of testing at the centre of curvature. Now, let S P in Fig. 1 be the speculum divided into 6 zones, and the rays 1 to 6 proceeding from the middle of these zones to their respective foci. I have drawn the rays alternately plain and dotted lines, so that their course can be more readily traced where they cross one another about their foci. The positions of the shutter opposite the focus of each zone are seen at 1 to 6 B. The circle, F C, with the markings on it, represents the face of the speculum as the shadows pass over it. Now, to commence, let the amateur put stop No. 1 on—i.e., leaving only the outside zone exposed (of course, I suppose the amateur has made himself master of my previous letters describing the measuring apparatus and zonal testing, &c.); he now puts the index to the number of hundredths of an inch that the focus of the outside zone is longer than the focus of the centre zone No. 6, as shown by the rule; he now passes the shutter across the cone of rays, and alters the position of the shutter along the cone of rays by the adjusting screw, till the shadow comes on alike on both sides of the zone and at the same time. He has now the shutter at the focus of the zone No. 1; he can now commence to test with the shadow test; but, before he does this, he had better see that his centre rays are shorter than his outside; for, if they are not, it is no use testing with the shadow test, for the proper shadows will not be produced; so he had better put on No. 5 stop and carefully find its focus by the measuring screw; if it is shorter than No. 1 zone (as our supposed parabola would be), then he can commence the shadow testing by placing the shutter back to the focus of the zone No. 1, by putting on stop No. 1 and testing for its focus by the measuring-screw; then, if the index points to the same number of hundredths as before, he will be doubly sure that he has got the right place to test at by the shadow test. Now, he has got the shutter at No. 1, B, position—*i.e.*, at the focus of zone No. 1. He must now remove the stop and pass the shutter across the cone of rays by the shutter-screw. This will be from left to right, in the order of the figures, 1 to 7 A. Now, let him observe on the figure that the first ray intercepted is No. 4 P; then No. 3, so that when the shutter has advanced as far as 1 A, it will have shut off or darkened the spot between 4 and 3 P on the speculum S P, which is represented on F C by the dark spot 1; thus it will be observed that the first dark spot on the face of the speculum will be exactly midway between the outside and centre of the speculum. Here the shadows commence from in the ellipse, the parabola, and the hyperbola, so that this test does not tell the amateur which figure he has got; but we will proceed to suppose the shutter to be made to advance to 2 A, and oh, the ease and pleasure this can be done with by the shutter-screw, as compared with the hand, the distance being only perhaps 1-500in. or less; well, now it will be observed that the rays 5 and 2 P are cut off; in other words, the shadow 1 C has enlarged so as to be represented by the shaded part 2 2 C; now this enlargement has been gradual as the shutter was passed from 1 to 2 A. The shutter is still further passed over the cone of rays to 3 A, and now it will be seen that the left-hand ray 1 S is intercepted, and so the space frem S to 1 is darkened, and thus the shadow 3 F will be produced while the shaded part 2 2 C will be enlarged till when the shutter has reached 4 A it has increased so as to include the shaded part 4 4 C, but having the right-hand edge 5 C still light, while the 3 F has got fully darkened; with the shutter's advance to 5 A, the bright part 5 F will be darkened, and now the whole of the right-hand half of the speculum will be in darkness, with the darkened edge 3 F increasing in darkness and size; now advance the shutter to 6 A, and the shade on the right has crept out to the left-hand half, and the shade 3 F has crept to the right till the part 6 6 F is now covered with shade, and we have only the space 7 7 and 8 F left light; pass the shutter still further to the right to 7 A, and the part 7 7 F is cut off, and it becomes shaded, leaving now only 8 F light, and now a little more advance of the shutter, and all is darkness. It will be observed that the numbers at A and F C correspond to the order in which the shadows come on, so that by tracing the advance of the shutter from 1 to 7 A, and as it meets with a number looking for that number on F C, the part shaded by the shutter in that position is at once seen. Let it be remembered that a part once shaded never becomes light again, so that if we want to see what parts are shaded when the shutter gets, say, to 5 A position, we have only to look for 5 on F C, and that part and all parts numbered with figures under 5 will be likewise darkened with the shutter at 5 A. And, further, let it be remembered that the shadings gradually creep from one part to the next: thus the shade 1 C gradually enlarges till it covers the whole of 2 2 C by the time the shutter has reached 2 A. This, then, is the Foucault, or shadow test proper, and all that it tells is that the centre rays are shorter than the outside, but this we proved with the zonal test before we commenced the shadow test, so we have gained nothing so far. Of course, I suppose the speculum is pretty free from rings, regular in curve, and not turned down at the edge.

FIG. 1.

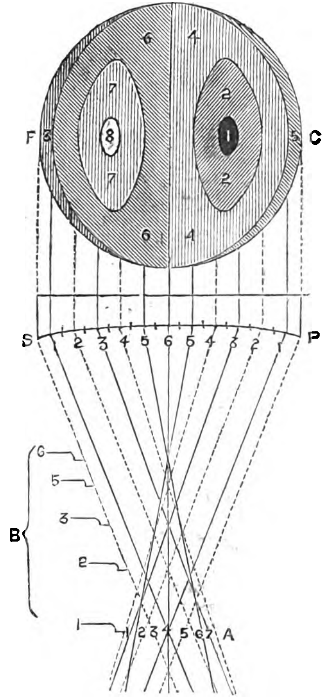

FIG. 2

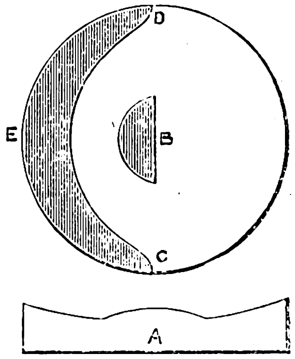

FIG. 3.

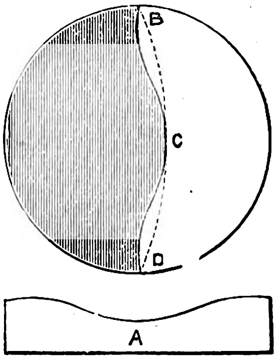


But now we will proceed a step forward to a really useful application of the shadow test, and that is, to see by its aid, if the curve is absolutely regular or not. To do this we must put the shutter in another part of the cone of rays, and this must be at the focus of the centre rays. To do this put stop No. 5 on, and find the focus for this zone. See whether it is the same number of hundredths that it was found to be when we at first tested to see if the centre rays were shorter than the outside, to see if it was any use to go on with the shadow test; if the reading is the same we can be doubly sure that we have the right place; this will be No. 5 or 6 B. Now let the amateur pass the shutter across the cone of rays, from left to right with the shutter screw, and he will observe that the shadow will gradually pass from left to right to the centre of F C, and will in succession cut off the rays from S to 6, so that when the shutter gets to the ray 6, just half of the face of the spec. F C will be in the darkness. This is the way the shadow comes on in the ellipse, parabola, and hyperbola; but now, suppose the curve is not regular, although the centre rays are shorter than the outside, such a speculum with a surface as seen in section at Fig. 2 A will present the appearance as at B E, when the shutter is halfway across, which is always known by the shadow at the top and bottom—D, C being half-way across the face of the speculum; then the centre part, B, will be shaded as shown, and a half zone of light will be between it and the outside shading E; the face of the speculum is really formed of two curves. Now suppose, in another speculum, when the shadow formed by the passing of the shutter across the cone of rays, at the focus of the centre rays and a little beyond the centre, as at C, Fig, 3, the curve of the outline of the shadow is not a regular curve, as marked by the dotted line, B, C, D, but as represented by the shaded portion, then the curve of the speculum is as seen in section at A, the opposite of Fig. 2. Thus the passing of the shutter across the cone of rays, at the focus of the centre rays, shows whether the curve is regular or not; thus, if in turning the shutter-screw at a regular rate, while the shadow is passing across the face of the speculum, the shadow does not move at a regular rate, but jumps forward every now and then, and its right-hand edge does not keep a regular curve, first concave, gradually decreasing in concavity till it reaches the centre, when it ought to be straight from top to bottom; then convex with a regular increase of its convexity, till it reaches the right-hand edge of the speculum. If all this is not seen, then the curve of the speculum is not regular. In all I have now said I have supposed the absence of rings, and the turning down of the edge. These ought to be seen, if present, at once by any one who has had the slightest experience with the shadow test, especially with the aid of the perfect control the measuring apparatus gives over the motions of the shutter, and its place along the cone of rays. The following experiment I should advise the amateur to perform, as practice in the shadow test. First ascertain the position of the foci of the various zones by the index, as before described for the zonal testing; now put the index to the number of hundredths that corresponds to the shutter being at the focus of zone No. 1, pass the shutter across the cone of rays, and carefully study how the shadings come on, by repeatedly passing the shutter from left to right with the shutter-screw; he may stop the shutter at any point, and draw the shadings on paper. All this is possible with the measuring apparatus, but next to impossible by hand in the old way. Now put the index to the focus of zone No. 2, and pass the shutter across the cone of rays as before, studying the shadings where they differ from the former position of the shutter; then put the shutter to the focus of No. 3 zone, and proceed as before, studying the difference of the shadings, and how the difference is gradually progressing; thus proceed through all the zone foci. When at the last zone, or with the index a little in front, which may be easily guessed from the ratio of the other foci, so as to pass the shutter over the focus of No. 6 zone, the regularity of the surface may be studied. All this will be to the earnest amateur a pleasant task; the certainty and ease with which it can be done, and the time allowed for study, which the control the apparatus has over the motion gives, will be the means of learning more in one day than possibly could be learned in twelve months in the old way of moving the shutter by hand. And further, if the amateur has time, and will for it, he cannot do better than make a drawing like Fig. 1, and make the distance between the foci 1 to 6 B 1in., as I have done, and putting the other foci in between at their respective positions and drawing the rays from the zones on S P to their respective foci, he can then, by watching the order in which the rays are intercepted, explain the shadows produced by the shutter, when it passes over the cone of rays at the corresponding zone focus of the actual speculum; no more interesting experiment I know than thus to master the principles and laws we are at work under in our testings. It will perhaps take a little time to get thoroughly master of all this; but once accomplished it is worth all the time, and will make the amateur discontented with anything short of perfection in his speculum.

H. A. Wassell.

Addenbrook Villa, Love-lane, Stourbridge.

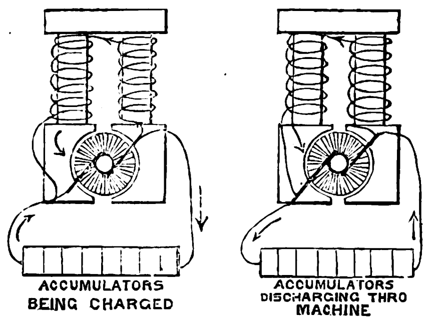
NOTES ON DYNAMO-MACHINES—VII.

[20365.]—54. In all dynamo-machines the current generated tends to cause rotation in a direction opposed to that in which the machine is being driven. Consequently, if a current is sent through an ordinary dynamo-machine in the same direction as the current flows when worked as a generator, the machine will go as a motor *backwards*. Changing the direction of the current will not alter the direction of rotation, since the polarity of the field-magnets is changed at the same time as the direction of the current in the armature.

55. To reverse an electro-motor the direction of the current through the armature must be changed by a switch in connection with the brushes and field-magnets; the current always flows in the same direction as regards the terminals of the motor.

56. It is impossible to say in which direction the current will flow in a new dynamo-machine, and it is easy to change the direction of the current in a dynamo by an accidental discharge through it in a direction opposite to that in which the current has hitherto flowed. This is a serious consideration in charging accumulators, for should the engine be stopped or the belt slip off when charging, the accumulators will at once discharge themselves through the machine, sending a current in the opposite direction. On starting again the current will continue to flow in this direction, and so discharge the accumulators; moreover, the combined strength of current from accumulators and machine will very probably burn the latter up.

57. To avoid this, accumulators are always charged by a dynamo arranged as a shunt, or by a dynamo excited by another machine. It will be understood from Fig. 16 that although the current may be reversed in the main circuit and armature by an accidental discharge, the current round the field-magnets flows in the same direction as when charging; consequently the polarity is not reversed. On starting the machine after an interruption the current will become reversed in the main circuit, when the E.M.F. of the machine is sufficient to overcome the E.M.F. of the accumulators, and the charging will continue.



58. Since a current in an opposite direction through the shunt-dynamo alters the direction of current in the armature without altering that of field-magnets, it follows that the shunt-dynamo, when driven as a motor, always runs *forwards*, and not backwards, like the ordinary dynamo. This fact is sometimes taken advantage of when employing a gas-engine as the motive power in charging accumulators, by making the accumulators start the gas-engine.

It is a matter of inconvenience to drag the flywheel of the engine round two or three times by hand, so the accumulators are discharged through the machine; and since the machine runs forward it starts the gas-engine without any trouble. It is very easy to arrange any ordinary dynamo-machine as a shunt, by putting a convenient resistance in the field-magnet circuit.

59. The E.M.F. of a Faure accumulator is two volts. The mean resistance in charging (large size, about 28 to a ton) is ·04 ohm, and the resistance in discharging ·01 ohm each. The charging takes about twelve hours with a current of 30 ampères, and a fairly constant current of about this magnitude will be given off continuously for ten hours. Since the E.M.F. required for a Swan incandescent lamp is 45 volts, about two dozen accumulators are required to light one lamp. The minimum number for an Edison incandescent lamp is 50. Incandescent lamps of two-candle power are now being manufactured, requiring an E.M.F. of six volts.

E.

SMALL DYNAMO-MACHINES.

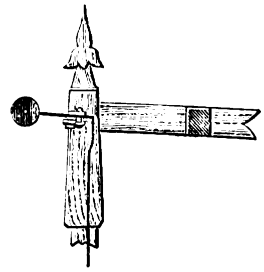
[20366.]—Notwithstanding all that has been said of the impracticability of small dynamo-machines, there has not, in my opinion, been a single scientifically valid reason shown why successful current generators of this class cannot be constructed. In many cases, no doubt, failures result from ill-proportion of the various parts, owing to the designer's ignorance of the physical laws involved. But the chief cause of failure appears to be the absence of a sufficient quantity of residual magnetism in the field-magnets to originate current in the armature when it is revolved. tl to remedy this, I should propose that one or alothin steel magnets be placed longitudinally son e-a cores of the field-magnets. Let no perpends o. too much from his machine. If he ex- n power upon it, he cannot reasonably hope that it will give out in electricity the full equivalent of that power, because some of it will be absorbed by friction, some in heating the coils, and some will be wasted through the mechanical imperfection of the apparatus. The most successful of the large dynamos driven by power do not, on an average, give out in electricity more than three-fourths of the power expended on them. Their efficiency will therefore be represented by this fraction. In all calculations regarding the capabilities of dynamo machines, large and small, the work is much facilitated by expressing the current produced in mechanical equivalents, such as foot-pounds, horse-powers, &c. To find the horse-power of a current, multiply the square of the current in ampères by the resistance of the circuit in ohms, and divide the product by 746; or, which is the same thing, multiply the current in ampères by its electro-motive force in volts, and divide the product by 746. Thus, if we desire to know the maximum current and electro-motive force that can be produced by a hand-driven dynamo, we proceed as follows: Assuming the efficiency of the machine to be represented by the fraction two-thirds, and that one man-power is equivalent to one-twelfth one horse-power, then $746 \times 1\text{-}12 \times \frac{2}{3} = 41$. Therefore the number of ampères of electricity that can be produced, multiplied by its electro-motive force in volts, cannot exceed 41; consequently when the number of ampères is 4, the electro-motive force will be 10·2, and when the number of ampères is 3, the number of volts will be 13·6, and so on. Let us now see what candle-power we might expect in an incandescent lamp from a hand-driven dynamo. The maximum candle-power in an incandescent lamp has been found to be 300 per horse-power of current. One horse-power of current is equivalent to 746 volt-ampères, and; our hand-dynamo gives 41 volt-ampères, therefore we obtain the following proportion: 746 : 41 : : 300 : 16, from which we find we can expect only a 16 candle light from the energy of one man-power.

Hosein Ibrahim.

RAILWAY SIGNALS.

[20367.]—Thanks are due to those correspondents who have so rapidly responded to my letter in your issue of July 14th (20267), and I will now, with your condescension, reply to the several suggestions which have been made.

I do not see any practical utility in weighting the back of the arm (letter 20295), so that if the connecting-rod between the arm and the weighted lever at the bottom gave way it would fall back to danger, for so few of these accidents have occurred that the extra expense (slight as it is) would not be warranted. We might, perhaps, shift the weight from the bottom of the post to a point level with the arm, but this necessitates putting the lamp lower down, unless we perch it up behind the arm, but that would not very much matter. The weight in the position shown (see figure) would, however, look rather unsightly, and, should it require regulating, it is not so easily got at as below, seeing that they are sometimes of considerable size. and the man would have to stand on the ladder. A compensation for strained backs might frequently have to be paid. The specs are usually affixed to the arm itself on bridge signals and all places where they are suspended from the roof, but sometimes the specs are inserted in the arms of other signals. Of course the hole necessary for the insertion of the latter materially weakens the arm, and, for this reason alone I think it desirable to have the spec separate. When the arms and spec were fixed on an axle, which was round throughout, they frequently used to slip after a little wear, but this is avoided by making the portion of the axle which bears them square. The wear under the latter condition must be very great, for them to slip out of position. I do not see that there is a greater impetus to fly to danger at 85° than at 45°, because the nearer to the perpendicular the weight is, the greater the weight sustained by the axle itself, and the less the said impetus to go to danger. Of course, as long as the weight does not reach the perpendicular, and is heavier than the arm, it is bound to fall to danger when the lever is taken off, when the wire breaks. I have not heard of connecting-rods breaking by ordinary wear, as used in our present locking arrangements; but they are liable to decay, like all other worldly matter. The "home" and "starting" signals should not throw different angles; it was this very discrepancy between the various signals which caused me to start this correspondence. "G." makes a good suggestion when he asks, "Would it be any practical use to coat the arms with luminous paint?" But the question arises as to how far this luminosity would be visible.



The reason for allowing the 5° above zero—condemned by Mr. Manock—is this—viz., axles wear, as do also axle bearings; but they may not be so far worn as to require renewing, although they may allow the arm to go a little above the horizontal position. However, a limit must be fixed to this upward inclination, and when the axle has gone so far as to let the arm go up to 5°, it must be renewed; or perhaps the hole through the arm may have given way a little; then that must be seen to. Thin pieces of board are liable to split; so are, consequently, signal-arms; and one or two bands of iron, or other metal, have to be put round to prevent this defect, as, should such an accident occur, it is more than probable that it will be near the axle, and allow the arm to shift. The bands prevent this. There is not likely to be any confusion, or misunderstanding of any kind whatever, if a rule of strict uniformity is established, never mind what the angles determined on may be. Mr. Manock's angles I cannot agree to, and in confuting them, it would be well for me to state the reasons why the angles given in letter 20267 were fixed on. A true "danger"-signal is the horizontal position, in which the weight should rigidly keep it; but owing to the decay and other causes previously enumerated, an allowance of 5° on either side of zero is made, and more than this on either side opens up a "doubtful" signal, and is to be, and must be, emphatically condemned. As all our readers are aware, iron is capable of expanding 1-820th to 1-888th of its length when subjected to heat, and stranded iron wire is soon penetrated by the heat, and expansion ensues. Now, let a wire be 500 yards long, and let temperature be 53°; this is one-fourth of heat required to give expansion of 1-820th, and let us see what the result is. We shall find that the expansion is about 5¼in. for 500 yards at 53°, and this is no mean figure.

The point at which no expansion would occur is 32°, or freezing-point, and as our temperature is not always so low as that, we must make a little allowance for it; and even then we see that the lineal extension of the wire must be great. As the heat varies, so varies the degree of expansion, and the signal arm is affected accordingly. Hence, we see the difficulty of defining to a nicety the "clear" signal; and from 45° to 85° is allowed for that signal, so that the error caused by expansion will not affect what the driver has to comprehend. If the signal fall from 85° to 90°, the driver *has* instructions to treat the condition as a "danger" signal. Between 5° and 45° is treated as a "doubtful signal," and acted on accordingly. These are the reasons for proposing what I have done; and this controversy can but lead to a good result in the end.

I congratulate Mr. Harrison on his invention. It is a good one, provided its action is as good as its purpose. May I ask if the signal is returned to "danger" mechanically or electrically?

"A Fellow of the R.A.S." seems rather inclined to hypercriticism in his remarks concerning angles, and I may say that other correspondents have described things apart from my direct question, instead of endeavouring to assist me. I do not for one moment assume, or for one moment expect, that an engine-driver would be able to detect *to a nicety* how a signal stood. What I wished to arrive at was a "hard and fast" rule whereby all signals might be made uniform, or as nearly so as possible, in the *fixing*.

"Danger" and "clear" are of course the only two *true* signals; but suppose the specs to be in such a position as to show *half green and half red*, what is the engine-driver to make of that? Must he not treat it as "wrong," and act on it as danger? Again, when the curve is entirely hidden from view through having fallen within the post, must not he see something is "wrong"? And if he has a *doubt*, is he not bound to treat that "doubt" as "danger"? Virtually there are only two signals: but provision must be made to insure decisive action when the arm does not fall far enough, or, through a disconnection, falls too far.

H. Stooke.

[20368.]—I have read the remarks of "Nun Dor.," p. 501, letter 20344, but I really cannot see that any advantages would accrue from making the changes suggested by him. It is quite true that the G.W.R. Co. did, and may still, use a form of disc signal, but in my opinion a semaphore is much the best. If there were not great advantages one may be sure that the M.R. Co. would not at the present moment be going to the enormous expense of cutting down every disc signal upon their enormous system and replacing them by semaphore signals with "swallow-tail" arms. "A Driver" is quite right in stating that the arms should not go lower than 45°, and that every post should be placed upon the left-hand side of the line; in my opinion this is a most important point. I would even go a step further, and insist that as all signals and platforms are on the left-hand side, that the driver's situation on the foot-plate should be on the left-hand side. Before I conclude I should like to express one opinion which I hold most strongly with regard to signals at night. As far as signals go, white lights should be abolished. "Green" should be the "all right," "white" being "no signal," or "signal out of order," to be treated as "danger." What say my brother-drivers to the suggestion?

A. S. H.

THE WERRINGTON JUNCTION AND ELY ACCIDENTS. — AUTOMATIC v. NON-AUTOMATIC BRAKES.

[20369.]—The recent accidents upon the Great Northern and Great Eastern railways furnish most conclusive evidence in favour of efficient continuous brakes, and against those which are inefficient.

Upon the 26th of June, an express train, consisting of an engine, tender, and eight vehicles, fitted throughout with Smith's vacuum brake, was running near Werrington Junction, upon the Great Northern Railway, at a speed of about 45 miles an hour, when one of the side-rods broke and tore down the adjusting-rod of the vacuum brake upon the engine; this latter rod falling on the rails caused the tender and train to leave the line. The driver at once shut off steam, and opened the valve to apply the vacuum brake; this brake being non-automatic was, of course, rendered useless at the very moment when it was required. The engine broke loose from the tender and ran forward for about a mile before it could be stopped. The tender and train ran no fewer than 470 yards off the line, and finally came to rest with two of the carriages turned over on their sides. Considerable damage was done to rolling-stock, permanent-way, and signal materials, details of which occupy a page and a quarter of the official report, and from this it will be seen that the vacuum brake gear was more or less damaged on the vehicles throughout the train, and was of no use whatever.

On Friday, the 28th July, the Great Eastern Company's 5.15 p.m. express from London was thrown off the line near Ely in consequence of the balance weight of the engine of an up train falling off and getting under the down express.

The accident is very remarkable from the fact that the weight, which weighed about 3cwt., escaped between the wheels of its own train when running at a speed of 50 miles an hour.

Fortunately, the express was fitted with the Westinghouse automatic brake, and although the distance from the engine striking the obstruction to the point where it came to rest in the ditch was only 114 yards, the train was, by means of the brake, safely stopped, without any loss of life, or "telescoping" of the carriages.

The contrast between a train running 470 yards all off the rails, and another being pulled up in about 100 yards on the rails is, as the *Engineer* remarks, "sufficiently striking." Had the circumstances been reversed, and the Great Northern engine, instead of running away for a mile, been turned into a ditch at the end of 100 yards, the consequences must have been of the most fatal character.

Clement E. Stretton.

Glen Magna, Aug. 5.

HOW TO MAKE A FLAT FOR A NEWTONIAN REFLECTOR.

(*Continued from page* 430.)

[20370.]—The two discs should now be rounded on the "jigger," or bevelled to a circle on the faces; this will prevent chips from being detached from the edges, which would endanger the surfaces. Great care must be used in cleaning all grit from the surfaces before putting them together. I find the best way is to hold the plates vertically, and blow between them just as they are on the point of contact; if there is the slightest sensation of grit they must be recleaned. This method gives us the lesser of the two possible evils, for if the discs are slipped together there is no chance of scratching. In the former way a few pits or bruises may be got, which are not so unsightly as scratches, and do not interfere with the performance. It is well to place the discs horizontally together on a table, and let them stand an hour or so before looking for results. A sky reflection from between the surfaces must reach the eye in this test. Those who have seen Newton's rings produced in the usual way, will be prepared for the results. Now, if the surfaces are convex and spherical, Newton's rings, pure and simple, will be produced—broad in the centre, and narrowing as they reach the edges of the discs; the reverse of this if concave. If the rings are fairly uniform, a very near approach to flat has been produced; if a single colour covers the surfaces (I find green or red usually, and both colours, in testing the same plates by altering the position of the eye a very little), it is proof that a mechanically true flat, or, I should say, two flats, have been got —a result which I hope none of "ours" will get is absence of colour. This would prove that the surfaces are so hollow or concave as to be perfectly useless for our purpose. Of course, there is nothing for it but to start on another disc, and try again, carefully fitting tools, &c., as at first. Hoping that our operator has achieved a success with the surface, I will now describe how to finish the edges. The "shanks" come again into use to chip off the sides of the discs to form the minor axis of the flat. It is best for the amateur to leave plenty to grind off to insure neatness, so I would say leave the minor axis 1 3-16in., and do not shorten the major axis at all with the shanks. When chipped near enough heat both discs enough to melt a little fine sealing-wax on the polished surfaces; place them together, but do not press them too close. Leave the major axis standing out as shown Fig. 1, and let them cool down in that position. A wooden chuck is now wanted with the end cut off to 45° (Fig. 2), also a "jigger" with a plate for grinding 2½in. wide; the two flats are cemented on the wooden chuck with pitch, adjusted while warm, and when set, ground into shape on the jigger, screwing up very gently, until all lumps are ground off. It will be seen that the required shape must be got by these means; 90-hole emery should be used at first and a little No. 2 to finish with, when all chip marks are ground out. It then only remains to separate the flats by heating, and to soak off the wax with naphtha or methylated spirits. The sharp edges may be taken off with a very fine file or a strip of No. 1 emery paper glued on a stick. The method I have endeavoured to explain in these letters may be used for any size of flat by simple increase of proportion all through.

Prismatique.

STRING VIBRATIONS.

[20371.]—Page 197 contains my letter on this subject with what I thought some original conceptions based on simple analysis of a tuning-fork, represented by a hairpin. This seems to have stirred up the ire of Mr. Stocks, p. 238, who pins his faith on experiments with the tuning-fork proper, by Prof. Guthrie (an expensive and tedious process), but who, however, still believes in Chladni's theory, that a vibrating string is made up of ventroids instead of oscillating from side to side, the greatest impulse being in the middle of the string. I have stood alone for 10 years in this primary law, everyone contradicting me until they have taken the trouble to look for themselves, instead of believing the classbooks. And, moreover, professional men do not like to be disturbed, and will not listen till obliged; but their day will soon be past in the popular eagerness for knowledge. This month's *Musical Opinion* has a letter from Mr. Hermann Smith, which is worth perusal, showing Chladni's mistake. It is a pity this has only now been found out; but it infers a radical change in our ideas of the value of nodes, and, without offence let it be said, that if one part of a theory is wrong, the whole falls to the ground.

Mr. Smith writes: "As in all musical instruments, the communication of transversal vibrations from one solid to another is invariably through the nodes," &c.

Now this I do not agree with, although it is precisely on these ideas that the violin has been called the most perfect of all musical instruments—*vide* Mr. Schucht's letter on the Berliner violin, and his node formed between the leg of bridge and the soundpost, an interval of half an inch or so. I am very bold in saying that if the soundboard is moved or vibrated the right way, that no soundpost is required at all, and it will sound louder—consequently without a node. What does a node infer? Simply an harmonic formation, which by itself weakens the sound because it is only a part of the whole fundamental tone; hence one harmonic is scarcely heard, while the total harmonics joined in one diameter in the centre of the string sounds the loudest of all. Therefore, it must be the joint action of all parts of the string acting from the middle, that communication is made between bridge and soundboard. I don't expect old theories to be done away directly. Didn't our grandfathers make a living out of them, and can't I see the dealers in Houndsditch handling the precious relics and selling them for their weight in gold! This need not go on, for a useful instrument need not be expensive; it has only to be made the *right* way to vie with the finest expositions of the old masters. Time will show! The bass of our new violin is now perfected. But to return to this old idea of sound being imparted through a node or soundpost, or any other obstruction, would a drum sound better or at all with a soundpost? Here we have plenty of pressure, elasticity, and free motion to and from the centre to the edges round the head. I won't wait for an answer. Try it on with a harp, piano, or banjo. No; it won't do. None of these can be called the most scientific instrument. Then why have a post added to the violin? I answer because it is *not* a scientific instrument as usually constructed, requiring a post to return the vibrations, so that the soundboard may move the right way, and so unfortunately robbing the vibrations of their direct action. This is something like the Irishman's crooked gun, made to shoot round the corner. Now then jumps up my little critic, and says: Ah! I should like to see any violin come up to mine, my dear old Amati, Klotz, &c. Now, I never can but admire other people's babies, because they are so grateful for a little praise; but, in return, let them remember that I am a family man, and fully expect my fledgling to come up to and finally surpass all. It is reduced to 22in. in length and 8in. wide in the major width. A small ordinary violin is 23¼in. long. Some going over 2ft. having strings 14in. long, which is very bad form indeed. To end this letter, Why not put a series of soundposts and so make a number of nodes; but this might be like to the man who said, If one feather so hard to lie on, what must a large number be.

Fiddler.

COLOUR.

[20372.]—The reason for advising that the "blue glass" to be used in the experiment on mixing blue and yellow light should not be cobalt glass is not (as Mr. Calton suggests) that if cobalt glass were used —"in fact, something approximating pure blue—the unfortunate result may be green"; but that I wished to put in as marked contrast as possible the very different result of mixing blue and yellow *light*, and of superposing blue and yellow glass, or of mixing blue and yellow pigments. I, therefore, chose a blue glass, which, when placed together with the yellow glass, allowed green-coloured light to pass through, which was not the case when cobalt glass was used. The light transmitted by cobalt glass, though very far indeed from pure blue, does not contain sufficient green for our experiment; but the glass I used, the common blue glass, coloured with oxide of copper, does transmit light containing a considerable quantity of green. The yellow glass also transmits a considerable quantity of green, and when the two are superposed, green light alone passes through. But when the two coloured lights are added together, the resulting light is white, with perhaps a yellow tinge; and this light is of greater intensity than its yellow constituent, and not of less, as Mr. Calton supposes. Of course, the blue and yellow glasses are not pure blue and pure yellow; if they were, they would, when superposed, produce a black or opaque combination. Each contains green, and the same is the case with any blue and yellow pigments which, when mixed, give a green pigment. If Mr. Calton can find a blue pigment which, when tested by the prism, is found to contain no green, and a yellow pigment also containing no green, then I venture to predict that on mixing them he will obtain a black colour. So in Mr. Calton's "much simpler and certain test" experiment of throwing light, coloured by passing through blue glass on to yellow paper, or that which has passed through yellow glass on to blue paper; the yellow light contains green, and the blue paper is able to reflect green (does not absorb green in fact), though it absorbs yellow and red; therefore the light reflected from the paper is green. If, instead of using yellow light containing green, Mr. Calton will illuminate his blue paper by monochromatic yellow light, obtained from a (really) non-luminous flame—e.g., of a good Bunsen lamp—in a dark room, by sprinkling sodium carbonate into the flame, he will find the paper does not appear green at all.

Mr. Calton objects to the method I suggested (as the easiest) of mixing blue light and yellow light, as "dodgery"—I really do not know why; but there are several other methods of experimenting which all lead to the same conclusion.

If we want to use pure colours we must employ a spectrum, and if we combine (for example, by reflection from strips of looking-glass upon a white card, or by allowing the required colours to pass through holes in a screen, and then combining them by means of mirrors, or lenses, or prisms) blue and yellow light so obtained, we do not obtain green, as I can testify; probably Mr. Calton has never seen the experiment. There is another way of combining blue and yellow light, which does not require a dark room, and which ought to satisfy Mr. Calton, but that, as I suspect, no amount of evidence would satisfy him. I mean the experime
in which two discs of blue and yellow (if requi
light are caused to overlap, and it is seen th are
overlapping portion is colourless. The ough
obtained by viewing a small round apertu

a doubly refracting prism of Iceland spar, the aperture being illuminated by polarised light which has passed through a film of selenite. The overlapping portions of the discs are as colourless as if the selenite and prism were simply colourless glass. On turning round the prism a large number of pairs of colours are obtained, each pair giving white light. Amongst these pairs might be obtained blue and a particular shade of yellow.

X. N. X.

[20373.]—Before categorically replying to the letters on this subject in the "E.M." of 28th July, 1882, I wish to state that both my business and my inclinations have induced me to study the doctrine of light. I write occasionally for the photographic journals on photographic and lantern optics, and have, therefore, a reputation to make or lose. I have devoted all the time I could spare to the study of the phenomena of light, with the view of satisfying myself step by step, and it is only after long and careful thought and research that I have come to the conclusion that the modern theory is still incomplete and unsatisfactory. I therefore claim a patient hearing, and while allowing that I may err, will not allow anything else except it is self-evident or mathematically proven.

It were presumptuous on my part to propound a theory of colour. The one propounded by Brewster was generally accepted until Helmholtz succeeded in causing it to be rejected. I do not affirm that Brewster is right or that Helmholtz is wrong; but I do say that the proofs produced by Helmholtz, and now currently adopted, are fallacious, and that the phenomena which he pointed out in connection with the commingling of blue and yellow light do not amount to proof that the theory of Brewster is wrong. I say this with the fervent hope that others, more capable than myself, will re-investigate the subject and clear away all error wherever it may lie. Indeed, I have no theory to propound. I incline towards that of Brewster because I find that some of the phenomena relied upon to upset his hypothesis can be intelligibly explained in accordance with them, and because I believe that painters, whose whole lifetime is devoted to the study of colour, fail to reconcile the modern theory with their experience. It is but a short time since that a lecturer on Modern Chromatics—reported in these pages—announced that he had never been able to make a painter agree with him on the theory of colour. Can this be right? It is the pride of modern science that it is true religion, the immutable laws of God as learnt from established facts. Science, therefore, is ever progressing; conditions previously overlooked are carefully examined, till, by degrees, hypothesis is strengthened into theory, and theory, when found to agree with all observed facts, is accepted as a law. No philosopher, however, is justified in saying that any law is absolutely settled, but he is justified in holding to it until it is proved to be based, either on incorrect premises or erroneous deductions. Such a case, I believe, we have here—erroneous deductions from causes overlooked in the premises.

In reply to "Sigma's" courteous letter, I quite agree with all the main points of the theory of the production of colour. The doctrine is so clearly laid down in Tyndall's "Notes on Light" that I repeat them here. The italics in all quotations are Tyndall's.

"255. Natural bodies possess the power of extinguishing, or, as it is called, *absorbing* the light that enters them. This power of absorption is selective, and hence, for the most part, arise the phenomena of colour.

"256. When the light which enters a body is *wholly* absorbed, the body is black; a body which absorbs all the waves equally, but not totally, is grey; while a body which absorbs the various waves unequally is *coloured*. Colour is due to the extinction of certain constituents of the white light within the body, the remaining constituents which return to the eye imparting to the body its colour.

"257. It is to be borne in mind that bodies of all colours, illuminated by white light, reflect white light *from their exterior surfaces*. It is the light which has plunged to a certain depth within the body, which has been *sifted* there by elective absorption, and then discharged from the body by interior reflexion that, in general, gives the body its colour."

"258. A pure red glass interposed in the path of a beam decomposed by a prism, either before or after the act of decomposition, cuts off all the colours of the spectrum except the red. A glass of any other pure colour similarly interposed would cut off all the spectrum except that particular portion which gives the glass its colour."

So far, by substituting the word "rays" for "waves," which in no way alters the real meaning, this definition might have been written by Sir Isaac Newton himself? and, as far as I know, is absolutely correct. Tyndall, however, continues:—

"It is, however, extremely difficult, if not impossible, to obtain pure pigments of any kind. Thus, a yellow glass not only allows the yellow light of the spectrum to pass, but also a portion of the adjacent green and orange; while a blue glass not only allows the blue to pass, but a portion of the adjacent green and indigo."

Here, I would ask, what is the yellow which cuts off all rays except yellow and a portion of the adjacent green and orange? But to continue:—

"259. Hence, if a beam of white light be caused to pass through a yellow glass and a blue glass at the same time, the only transmissible colour common to both is green. This explains why blue and yellow powders, when mixed together, produce green. The white light plunges into the powder to a certain depth, and is discharged by external reflection *minus* its yellow and its blue. The green alone remains.

"260. The effect is quite different when, instead of mixing blue and yellow *pigments*, we mix blue and yellow *lights* together. Here the mixture is a pure *white*. Blue and yellow are complementary colours.

"261. Any two colours whose mixture produces white are called *complementary colours*. In the spectrum we have the following pairs of such colours:

Red and greenish blue,
Orange and cyanogen blue,
Yellow and indigo blue,
Greenish yellow and violet."

It is with No. 260 that we have to deal. I do not think I at all misunderstand the bearing of Tyndall's experiments in considering that they are intended to prove the position he there lays down. To my mind, they fail to prove it, and if so, it still remains an open question whether the law is true or not, unless there are other proofs to be brought forward.

To *prove* anything we must have clear definitions, axioms, and postulates from which we can argue step by step. It will be best to avoid such terms as "wave-length," "rate of vibration," &c., —in fact, to treat the question as if the theory were yet to be established.

For definitions let us represent *pure* colours as red, blue, &c., and natural colours, all of which are impure, as red, blue, &c. Our axioms shall be the production of colour by absorption from white light, and my only postulate that the eye alone is not infallible in the matter of colour. This is easily demonstrated, but will at once be allowed on reference to "Notes on Light," 278.

In Tyndall's experiment, No. 1, he professes to produce white by the overlapping of blue and yellow discs. At the best it can be but white, for even allowing that blue and yellow produce white, it is clear that as the blue and yellow pigments employed are *each* capable of allowing green to pass—besides other colours—although the impression on the eye is that of white, it is not really so. This experiment, then, does not prove the position laid down in 260, while, as I showed in my last letter, it is quite easily explained in accordance with the Brewsterian theory.

As to Tyndall's experiment No. 2, Mr. Holmes asks: Where does Tyndall show that "what he (Tyndall) here calls the blue and yellow contain between them all the colours of the spectrum?"

I reply, In his "Lectures on Light," pp. 29, 30, 31, and subjoin the full quotation:—

"The synthesis of white light may be effected in three ways, which are now worthy of attention. Here, in the first instance, we have a rich spectrum produced from the decomposition of the beam. One face of the prism is protected by a diaphragm, with a longitudinal slit, through which the beam passes into the prism. It emerges decomposed at the other side. I permit the colours to pass through a cylindrical lens, which so squeezes them together as to produce upon the screen a sharply-defined rectangular image of the longitudinal slit (now upright). In that image the colours are reblended, and you see it perfectly white. Between the prism and the cylindrical lens may be seen the colours tracking themselves through the dust of the room. Cutting off the more refrangible fringe by a card, the rectangle is seen red; cutting off the less refrangible fringe, the rectangle is seen blue. By means of a thin glass prism, I deflect one portion of the colours, and leave the residual portion. On the screen are now 10 coloured rectangles, produced in this way. These are *complementary* colours—colours which, by their union, produce white. Note that, by judicious management, one of these colours is rendered *yellow*, and the other *blue*. I withdraw the thin prism; yellow and blue immediately commingle, and we have *white* as the result of their union. On our way, then, we remove the fallacy, first exposed by Helmholtz, that the mixture of blue and yellow light produces green."

If Mr. Holmes will read this carefully, he will see that no stopping-off screens are employed. The words are clear: "I deflect one portion of the colours, and leave the residual portion." The card is used as a stopping-off screen in a preliminary experiment. I, therefore, repeat that in this experiment, what Tyndall calls "blue and yellow," are the whole of the colours of the spectrum, so divided that they appear to the eye blue and yellow, but, as a matter of fact, contain red.

Mr. Holmes proposes a test experiment: that I should "cut off from the solar spectrum all but the pure blue and yellow, and then recombine these." Precisely. If Mr. Holmes will tell me how this is to be done, how I can get blue and yellow, he will solve the great problem.

Next, if Mr. Holmes will advertise his address, I will send him an apparatus, which I have had constructed for the purpose of rapidly revolving coloured discs in the lantern, and trust to his honour to report to the readers of the English Mechanic whether he was justified in asserting that I have said "the thing which is not." I repeat, that if an aperture of one-tenth the circumference be cut in a coloured disc, and that disc be made to revolve rapidly in the lantern, the effect, *to the eye*, will be a white ring on a coloured ground, the nine-tenths colour actually present being apparently destroyed by the one-tenth of white light.

"Sigma" allows that in the overlapping experiment there is an excess of green on the screen, which is apparently destroyed by the white light present. My postulate, therefore, is proved.

I do not affirm that blue and yellow make green, though I incline to that belief. I simply deny that it is proved that they make white. I deny that they are complementary colours, though blue and yellow may be.

Take a blue film—a solution of ammonio-sulphate of copper is a very good one—and look at the fire through it. The flames, which are tolerably white, are clearly visible while the live coals are invisible. This is exactly what should be expected. The blue cannot allow yellow, red, or orange rays to pass. Now take a purple film, one which confessedly allows the red and blue rays to pass. The coals glow with a gorgeous crimson. As I write I have before me in the garden bright yellow calceolarias, and scarlet geraniums almost side by side: through the purple film both are a brilliant red—almost indistinguishable in hue. I turn to the gravel path, to a stray piece of orange peel to every place where the eye sees yellow, and find red. We have agreed that the light coming from these objects is sifted by the film. The red, therefore, is not produced by the purple film: it *must* be existent in the yellow. Yet, if I look at the spectrum through this same film, the yellow is entirely cut off.

Clearly, then, every natural yellow contains also red, and, therefore, the phenomenon of blue and yellow producing white is quite consistent with the Brewsterian theory.

Of course, I admit the theory of complementary colours. Imagine a disc on which the colours are arranged round the centre in segments — first broadly with three segments of 60° each, red, yellow, blue, the intermediate spaces with orange, green, and purple, or still more elaborately with the colours blending by slower degrees. Each opposite pair will be complementary colours and agree with either theory, as well as every-day experience.

Geo. Smith.

FORECAST OF STORMS.

[20374.]—"The atmosphere travels with us at an enormous velocity, through a void and airless region; yet no particle of it leaves us. Why is this? The earth exerts upon the atmosphere the attraction of gravitation. As we travel it travels with us. As we revolve it revolves with us. Could the globe for the space of one hour continue its revolution on its own axis while the air stood still, the resistance offered by the air to the passage of the earth would be such as to produce to all appearance such a tremendous blast as would not only level trees and houses, but would lift men and animals and every movable thing into the air, hurling them in common destruction against the first mountain range that might present itself." ("Chemistry of Creation," by Robert Ellis, F.L.S., M.R.C.S., &c., Edition 1870 A.D.) "There are tides in the air as in the sea. The hourly observations of the barometer made for some years past at the Meteorological and Magnetical Observatory at St. Helena have now placed beyond a doubt the existence of a lunar atmospheric tide. On each day the barometer at St. Helena stands on an average four-thousandth of an inch higher at the two periods when the moon is on the meridian above or below the pole than when she is six hours' distant from the meridian on either side, the progress being continuous and uninterrupted between this maximum and minimum" (Sir R. H. Ingliss, at the meeting of the British Association, 1847). "A vast air-wave has for several years been observed about the middle of the month of November. It begins, rises higher, reaches its highest point, then subsides again to its usual condition in the space of a fortnight or sixteen days. Sometimes it has been observed to set in with a gale of wind, and end with one also." ("Chemistry of Creation," page 181.) Now, it is highly probable that closer investigation would have shown that this so-called atmospheric wave in November was only one of an ever-recurring series. Let us take another period of the year, and see how the matter stands. Thanks to Mr. Westwood Oliver for information, of which I was deficient. (See letter 20322, ENGLISH MECHANIC, p. 477), in which he asserts that "a gentleman examined records covering a period of about 80 years, and as the result asserted that 19 times out of 20 a Saturday moon was followed by 20 days of wind and rain. He announced his discovery to the Royal Astronomical Society in 1848.")

One gentleman finds out a periodical storm-wave in November for years past, another gentleman finds out periodicity at St. Swithin, and the records extend over years past. And I have already pointed out that the normal period of time from one set of atmospheric depressions to another set is 20 days. Is not this tolerably conclusive evidence of the operation of a natural law, and as the 20-days period of storms is not an exceptional phenomenon, may we not expect this periodicity to continue?

The balance of atmospheric pressure is restored by periodical storms, which come over us when the moon has lost its hold on the atmosphere and the sea. It is for those who have the means of information to follow out the inquiry here indicated, not by theorising, but by the examination of barometrical and magnetical records of the past. There seems to be a paucity of information on this question of storm periods. One gentleman says you must continue your observations for twelve months, another says observations must extend over several years, yet another says I have long been aware of this periodicity; but the period is not perfect, and therefore of little practical use. Now, one would have thought that a scientist would not have spoken thus, but would have endeavoured to trace the cause of this imperfection. Must it not be sought for in the maximum and minimum sunspot periods, and in the ever-shifting orbit of the moon?

I beg to thank "F.R.A.S." for his kind reply to my query.

The books containing the above quotations were not known to me when I wrote letter 20305, p. 453, ENGLISH MECHANIC, No. 904.

W. M. Gardner.

OPEN-FRONTED MACHINES—TRICYCLE BRAKES.

[20375.]—To have a good brake and know how to use it is of great importance to tricyclists. In my experiments I find the hindwheel-brake very defective, as it not only allows the machine to slip and tumble, but causes it to swerve out of the path by affecting the steering; often makes the machine run across the road, and before you know what is the matter the rider and machine are wrestling together; but the machine generally throws the rider.

I have fitted a double-spoon brake to my machine, which is a decided improvement, which allows the spoons to grip the wheels instantaneously, and has great power over the machine without stopping it too suddenly. **Ex.**

LEGAL REPLIES.

[20376.]—(47568.)—WITHOUT seeing this agreement, I cannot advise with certainty. It is necessary that a lease for more than three years from the making thereof, should be under seal, which, I understand, this is not. But it may be that the document amounts to an agreement to grant a lease for longer than three years, at the tenant's option, and this the Chancery Division would compel the landlord to do, presuming the agreement is clear. Whether or not the writing is for three years or more does not affect the stamp required; and either as a lease or as an agreement, it must be stamped according to a scale which is fixed by the yearly rent payable. If, as seems likely, there is only a sixpenny stamp, this is useless. Additional stamps cannot be added after the two months allowed, except on the payment of the penalty. I may add, that in answering this question I am much hampered by the want of a fuller statement of the case.

(47596).—I cannot understand how any office insured a life without asking the usual questions as to health. But even though no questions were asked, if the insurer knew that the insured suffered from an illness and said nothing about it, this is a suppression of a material fact which would certainly void the policy. It is true that the agent's conduct in making no examination is strange and remarkable: but still, presuming the office to have acted *bonâ fide* in taking the life, and to have had no reason to suspect such an illness as is mentioned, they would undoubtedly succeed in their defence to an action for the amount insured if they could prove that the insurer concealed this fact of disease, which was within his knowledge.

(47618).—It is quite certain that any documents, such as a lease and policy, deposited with the holder of a bill of sale, as collateral security, must be handed over to the grantor when the sum secured is paid off. With regard to the bill of sale itself, I believe the same rule would apply; because I am unable to see what good ground the grantee can have for its detention. The way to proceed is, after having made a demand, which might as well be in writing, for the delivery up of the bill of sale, to bring an action in the County Court for its wrongful detention. This would, I think, prove successful, unless, indeed, there is anything in the bill of sale itself, or perhaps the rule of the society, to the contrary.

MEDICAL REPLIES.

[20377.]—VEGETARIANISM.—This subject, on which I am asked by several correspondents to say something, is one which needs defining. Persons there are who object to wearing leather shoes; others who object to milk, eggs, &c.; while the majority go only so far as to eliminate from their use the flesh and other parts of animals which involve their slaughter. Some adopt vegetarianism because they object to the slaying of animals; others take purely economical grounds, and point out that one acre of ground will support five vegetarians, but only one flesh-eater. Others again say that men are healthier, longer-lived, and happier as vegetarians, than as eaters of a diet containing flesh meat. It is difficult to set a practical limit to the consequences of a purely humanitarian basis—much as one denounces anything like cruelty to animals. Admitting, for the sake of argument, that a man has no more right to murder a horse or an elephant than to murder another man; yet, upon the balance of the greatest happiness to the greatest number (say of oxen or sheep), I think it could easily be shown that flesh-eaters provide more happiness to these animals than vegetarians would; and that the quick and painless death by which their lives may be terminated constitutes but a small set-off against the pleasant and untroubled life which is conferred upon animals reared for the purposes of food. I speak now not necessarily of our present methods of killing animals, which includes the bleeding to death of calves, &c., but of a refined and sensible system of slaughter. The economists would arrive at a somewhat modified vegetarianism. They would still slaughter the beautiful salmon which multiplies in our rivers, where no other food could be grown, and which, descending to the sea as large as one's finger, browses around the coast upon materials still less accessible to us, and comes back as large as one's lower limb. Thus, in various ways, the practical outcome of the economist vegetarian differs from that of the humanitarian. Now, if the mere multiplication of human beings be the end of civilisation, it is clear that the economists have the argument. It can be shown abundantly that several times as many people who take their vegetables—say, as oatmeal porridge and fruit—can live upon the land as those who like their "vegetables, after they have been converted into beef and mutton," as is suggested by an anti-vegetarian, which simply comes to the substitution of animal life for that of man. Here, again, the question rises, Is the object of civilisation to multiply human beings? Or is it, rather, to develop a comfortable number of human beings of the highest possible type? For myself, I confess that the mere multiplication of human units would have no more interest for me than the multiplication of rabbits. I go for *quality*, at the sacrifice, if necessary, of quantity. Just as I would prefer a few small paintings that I could name to acres of vulgar canvases, so I would rather see a community of 500 of the grander types of men than of 5,000,000 of mere animals in human form. It follows, therefore, that I see nothing in mere humanitarian vegetarianism, nor in mere economical vegetarianism; and that, in my eyes, the question turns solely upon what food is most likely to develop the grandest type of men. There is, however, in the economy argument another aspect than that of an increased multiplication of human units. The life of an individual man is mortgaged, first, for that amount of labour which will provide the man with the means of existence; and only after these are provided does the man begin to have leisure for enjoyment and personal culture. Now, the simpler the food upon which he can exist, the larger the margin will he have, and the more profitable and perfect will he be as a mere machine for all purposes beyond those of mere animal existence, and the man eats to live, instead of merely living to eat.

In attempting to say how one would shape one's own life, if one could unroll half a century, and, with one's present knowledge, begin again as a plastic and developable infant, what one first sees is that one would like to select one's own parents. Almost the entire value of any eminent horse that is now before the public depends upon his *pedigree*, upon his *stock*. Most of our present eminent horses trace their pedigree back to one great horse of the last generation, i.e., Eclipse. Often in the shafts of a London cab one sees a horse with a Bay Middleton head on his shoulders—a head that once seen, even in engravings, is never forgotten. But here the body of the cabhorse tells of some fine progenitor having been mated, but not matched, and the horse is no more the Bay Middleton than a common stock upon which a beautiful rose has been grafted will reproduce the rose which it bears upon its trunk.

If we take eminent greyhounds, eminent cattle, in all cases we find their value to depend upon their pedigree again, and no amount of feeding or of training will produce a racehorse out of a cart-colt. We cannot choose our own pedigree; but if when marrying we marry wisely, we shall do for those who come after them as much as a single generation of wise selection of one parent can do. Taking the physical make of the man's mouth and digestive apparatus, the indication is that he was constructed to live upon grain and fruit rather than flesh. But the mere structure, notwithstanding the habits of progenitors for many generations, must be taken into account in considering what is fittest as food for the individual. Assuming that 100 men, accustomed always to live upon grain and fruit, were suddenly transferred to flesh food, what would happen is this. Some of these men would perish from their inability to live upon a purely flesh diet. Some would do indifferently well; some would take rapidly to flesh, and would flourish admirably upon it. Confine these people to an island, and in each generation the same result would take place; and thus, after many generations, we should have, in the survivors, a race of pure flesh-eating men, just as, in the Amazon, there are races of fruit-eating fish, and, in Norway, the cows live upon fish and offal. Now, were these carnivorous men suddenly moved to another island, where, instead of living entirely upon flesh, they had to live entirely upon fruit and grain, the result would be a gradual reversion of the previous modifications. Those who had flourished most perfectly upon flesh would probably do worst upon grain and fruit, and would perish from dyspepsia and various consequential diseases. Those who did worst upon flesh would probably take most readily to grain and fruit, and such reversion and natural selection going on, the tribe would have become pure vegetarians again after many generations. Therefore the adaptability or elasticity of the digestive organs would in each case be a measure of capacity to survive, and the law of the "survival of the fittest" would govern the result. It must be noted that the "survival of the fittest" is one thing, and depends upon the conditions of existence. The "survival of the best" is another, and depends upon abstract ideas of the ultimate object for which the men or animals are designed, and upon the extent to which the conditions of existence can be varied so as to subserve these ideas. If, for instance, we want horses to ride we aim at one ideal, horses to draw brewers' drays another, horses to run one-mile races another, horses to run four-mile races quite another, and so on. I shall not attempt to define an ideal man. In an ideal community we should need as many types of ideal men as we now have of horses and of dogs, and differing, perhaps, as widely as the King Charles spaniel from the bloodhound. Considering also that Byron had a club foot, that Pope was a hunchback, that Milton and Homer were blind, that Napoleon had epileptic fits, and that the Shakesperian strain of blood is dissipated, the subject is one upon which it would be very difficult to lay down any general principles. But, to multiply people who are blind, or deaf, or otherwise physically defective, would be bad policy, unless such defective persons have other qualities which clearly outweigh these defects. One querist (47615), for instance, asks:—"I am engaged to a young lady, aged 33 years. I have recently been told that 13 or 14 years ago she lost her reason through a bereavement, but soon regained it, and has ailed nothing since. I desire to know is it wise to marry her or to break off the engagement?" Here is a most important question, most intelligently put; and there is no doubt that if querist discovers that there is marked insanity in the family, he would be wise to break off the engagement, and especially so if he himself also has insane relatives. But there are few families in which some mental or physical defects would not be discovered by a careful investigation of two or three generations. And in this case, if the parents are healthy, moral, well-conducted people, without eccentricity; if the lady is in good health, and of an equable mind and good temper; if her brothers and sisters are all right, the incident may be looked upon as a mere temporary attack of mental illness, like an attack of bronchitis or of pneumonia not at all dependent upon a consumptive tendency. In the latter case it would be wrong to disturb an important engagement such as this, and to do so would be to inflict a great cruelty upon the lady, inasmuch as the cause of the rupture would be sure to break out, and give lasting pain to herself and all her family. But in such a case as this, the personal judgment of a skilled physician is what should be relied upon.

The causes of death of parents and of brothers and sisters may always be obtained by searching at Somerset House and getting copies of the certificates of death, and these facts would be important as materials for judging in such a case.

Returning to the question of vegetarianism, it will be seen that while fruit and grain are the food for which man's mouth and digestive system are constructed, man yet has a most elastic digestive system, and that those whose parents for many generations did well on a mixed diet will probably continue to do well on a diet largely consisting of flesh. As to the nutritive properties of a sound practical vegetarian diet, there can be no question that among Englishmen of my own acquaintance, some of the very finest specimens of physical and mental developments have been vegetarians, and some of them also the children of vegetarians. Pythagoras, probably the greatest of the Greek sages, was a vegetarian. I believe that we poison ourselves with nitrogen in the large proportion of flesh food that we now take. The one difficulty that I have been consulted about by vegetarians of very active turn of mind is *sleeplessness*, and in more than one instance vegetarianism has had to be abandoned on that account. But some persons, undoubtedly, derive vast benefit from vegetarianism. Those who desire to consider this subject more fully, and in detail—and the subject is one of great interest and importance—should get the "Dietetic Reformer" (post-free 2½d. Pitman, Paternoster-row), of which this present number now lying upon my table is a most able and scholarly one. Pitman also publishes some little pamphlets and cookery-books on vegetarianism which are sound and useful. My own conviction is, that I should do my own work better, and live longer, as a vegetarian; or, at any rate, with almost no flesh food. For years I have taken no alcohol, and have rather limited the amount of flesh I eat. Fortunately, also, I never could persuade myself to use tobacco; and I am of opinion that the use of tobacco lessens one's freshness of memory and one's mental endurance. The only reason why I have never tried vegetarianism is because I never yet have had indigestion, or, indeed, any other illness, and being apparently in excellent health, I drift along on the principle of leaving well alone. In dining out, also, it is a great infliction upon friends to have to eat up all their vegetables.

NIGHTMARE (47580). — If stout, the patient should starve down at the rate of one pound a week, till at the fair weight for his height and make. Heavy suppers should never be taken. Less flesh-meat should be used, if that be now freely used. Lying upon the left side, and upon a horsehair mattress, and not covered up with an impermeable coverlid, is good.

James Edmunds, M.D., &c.

Grafton-street, Bond-street.

P.S.—Being about to go to Norway for my annual holiday, I shall see no more papers till the middle of September.

SCIENCE AT SOUTH KENSINGTON AND THE CITY AND GUILDS INSTITUTE.

[20378.]—WHEN the "gentlemen who live at home at ease" at South Kensington read the letter of Mr. E. Jackson, p. 498, they no doubt exclaimed "Save us from our would-be friends!" for, unlike Balaam, he came to praise, and has passed a scathing condemnation, obviously an honest one, for he does not see the effect of his statements. The pith of Mr. Jackson's letter is stated in the following sentences:—"While at South Kensington, I received instruction and gained information which has enabled me to take such a position as would have been impossible from private study only. And this was not peculiar to me. I know a number of men now holding important (*sic*) positions in both pure and applied science who could not have hoped to have attained such positions had they not have been fortunate enough to get to South Kensington." From these sentences it seems clear that the persons referred to were students at South Kensington, not merely members of science classes and candidates for science certificates. Now we follow on. "One is a teacher of science under a school-board, another is in a corporation surveyor's office, a third chemist in a large chemical works, a fourth science master in a grammar-school," and so on. Mr. Jackson does not say what he is himself, but he shows that one-half of the instances he quotes have actually gone astray from the very objects of the Science Department, especially if, as I assume, they were students of South Kensington itself; for no sooner did these men get a little scientific training than they departed from their trades, and never acted as leaven at all—although Mr. Jackson assures us that the majority would still have been earning their living in a workshop but for the Department at South Kensington. Permit me to ask, is there any lack of science teachers of the usual type—any lack of chemists, or of suitable persons for the duties of a corporation surveyor's office? for if not, it seems to me that the public is being taxed for the benefit of individuals. Had these gentlemen remained in their workshops, without the benefit of South Kensington, they would, no doubt, by their native nous have made intelligent workmen; had they remained there, with the knowledge gained at South Kensington, they might, or they ought to, have been of great benefit to their particular workshop. I do not mean that of necessity they ought to have stuck to the bench; but you may depend upon it that if South Kensington is to be utilised for educating or fitting persons for occupations which are supposed to be higher in the social scale or better paid, the British taxpayer will begin to howl loudly. By all means spread a knowledge of science—if you can reach them, down even to the lowest ranks of the labourers; but don't inculcate the notion that it is worth studying merely with a view of bettering oneself. It should be distinctly understood that science students selected for the special course at South Kensington are not educated for their own especial benefit, but for the good of the country at large. Mr. Jackson's letter deals, however, only with the fringe of the subject; for the question really is, what amount of good is done amongst the many candidates for the examinations? Undoubtedly many of the teachers who have graduated at South Kensington are up to their work; but it is incontestable that many more are only schoolmasters tempted by the extra grant to qualify in certain subjects—such subjects, moreover, being those of but little value to their pupils, even supposing the masters were competent to teach them thoroughly, which they are not. I speak from experience. Mr. Jackson says that "not even the teachers themselves, much less the Department, can be held responsible for these answers" (that is, those quoted on p. 463). If the teachers are not responsible, permit me to ask who is? Candidates do not attend examinations unless they have been prepared somewhere, and with all deference to Mr. Jackson's opinion, I think he will find that the majority of people will say that the teachers (save the mark) are responsible for sending such crammed birds to the plucking, and the department is responsible for such "teachers."

In your "Scientific News" (p. 496) you quote the energetic denunciation of Prof. Graham referring to the examinations of the City and Guilds Institute, but if you look at the figures given in Table III., you will see that the case is as bad as bad can be. There were 41 candidates in "breadmaking," and only one passed! Of these 38 were taught in classes the teachers of which receive payment by results, and three were from other institutions or were private students. The solitary candidate who passed belonged to the latter category, so that for candidates trained in classes under the rules of the Institute, or connected to it, Prof. Graham returns the percentage of failures as 100! In brewing there were five candidates from the science classes, and 80 per cent. failed; 21 from other sources, and only 9·5 per cent. failed. To take larger numbers—in mechanical engineering, there were 397 candidates from science classes, and 51·3 per cent. failed; 126 from other sources, and 31·7 per cent. failed In mine surveying, of 87 science class students 55·1 per cent. failed; of 12 candidates from other sources all passed. It is worthy of note that the solitary pass in breadmaking was a pass in honours, and yet one would think that that is an industry of which, at least, something ought to be known by the candidates sent up by so-called teachers.

If your readers will refer to *Whitaker's Almanac* they can see the large sums paid as salaries to the officials at South Kensington, and it will not be surprising if, with a falling revenue and increased taxation, the British public shortly demands to know what they do for their money. A careful digest of the Tables shows that what I may call private students are by a long chalk far in advance of the students of science classes. The summary does not show that fact, because in many subjects there were no candidates from science classes at all. I recommend a perusal of the Report to those interested in the subject—especially the Pass List.

Nun. Dor.

PRESSURE OF WIND.

[20379.]—As I did not read the paragraph on page 143, but only the version of it given in the query on page 461, this accounts for my remark that "the figure in the 'E.M.' is evidently a misstatement." I did not therefore deny that with an hourly velocity of 50 miles the pressure was 49½lb., but that with a velocity of 50 miles an hour the pressure on the square foot was 49½lb. This "F.M.S." might have seen had he read my letter carefully.

It is quite true that mere contradiction or statement is of little value unless supported by confirmatory evidence, and when I said that such a velocity as 53lb. on the square foot, was unknown in this country, and spoke of the erroneousness in the registration of such high pressures, I did not do so without the support of such evidence.

Are we to believe that every structure that is now errected, including even those which are "jerry-built," is calculated to resist such a pressure as even 40lb. per square foot? If we are to trust our anemometers, such must be the case; otherwise, far more damage would be caused, than what we now observe, which does not often exceed broken windows and loss of slates. That buildings are not subjected to such a high pressure as this, we conclude from the fact, that tall factory chimneys, and other structures of a more or less fragile nature, which are certainly not calculated to resist a pressure of 40lb. on the square foot, have remained intact, notwithstanding many a storm and in spite of the anemometers. Again, railway carriages, it has been ascertained, are overthrown by a pressure of from 30 to 40lb. per square foot. [Vide Report of Committee appointed to consider the Question of Wind Pressure on Railway Structures, on July 29th, 1880] Now if such pressures as these were as common as the anemometers would lead us to suppose, the upsetting of a railway carriage would be no unusual occurrence, and it would not be necessary to have a pressure of 93lb. per square foot to overthrow a locomotive.

These remarks on the force of the wind do not apply to air-currents above a certain height from the earth, for it is known that as we ascend the wind can blow with much greater violence, owing to the absence of friction which terrestrial currents experience. Thus Mr. Simmons may easily have reached a velocity of 130 miles an hour in his recent balloon voyage. But I would venture to assert, from the considerations before mentioned, that we never have such a storm as that on the surface of the earth.

I do not consider that "F.M.S." proves in at all a conclusive way, that Mr. Hawksley's formula and table are "worse than useless," and the only apparent ground upon which that conclusion is founded, is, that the connection between velocity and pressure as illustrated in the formula does not coincide with what the anemometers give, and it does not seem to strike him that the latter might be at fault, for he remarks that "the only trustworthy data are the actual pressures registered." Now as there must be some connection between the velocity and pressure, perhaps "F.M.S." can suggest a better formula than that given by Daubuisson ($P = \frac{wv^2}{g}$, which applies not only to atmospheric air, but to any liquid) or point out where the error lies. With regard to the pressure of wind on a structure, I think the opinion of such an eminent engineer as Mr. Hawksley should have some weight, as he speaks, not with the voice of a mere theorist, but as a practical man, and he considers, "that for structural calculations a pressure of 40lb. on the square foot may be safely adopted, notwithstanding some common anemometrical observations to the contrary." I quite agree with "F.M.S." when he remarks that "velocity per hour" is misleading when pressure applied for one second will destroy, still in a table it is of course useful to have the velocity in miles per hour, as well as in "feet per second."

Worthing, Aug. 7th. **C. H. Romanes.**

Errata.—Amateur Surgical Appliances, p. 499.—In letter on above subject, in line 2, first col., p. 499, for "cut" read "at;" and in next line for "½in." read "1in."—N. S. HEINEKEN.

Tracing on Cloth.—A correspondent of the *Moniteur Industriel* refers to the difficulties encountered in tracing upon cloth or calico, especially the difficulty of making it take the ink. In the first place, the tracing should be made in a warm room, or the cloth will expand and become flabby. The excess of glaze may be removed by rubbing the surface with a chamois leather, on which a little powdered chalk has been strewn; but this practice possesses the disadvantage of thickening the ink, besides, it might be added, of making scratches which detract from the effect of the tracing. The use of ox-gall, which makes the ink "take," has also the disadvantage of frequently making it "run," while it also changes the tint of the colours. The following is the process recommended:—Ox-gall is filtered through a filter paper arranged over a funnel, boiled and strained through fine linen, which arrests the scum and other impurities. It is then placed again on the fire, and powdered chalk is added. When the effervescence ceases the mixture is again filtered, affording a bright, colourless liquid, if the operation has been carefully performed. A drop or two must be mixed with the Indian ink; and it also has the property of effacing lead-pencil marks. When the cloth tracings have to be heliographed raw sienna is also added to the ink, as this colour unites with it the most intimately of any, besides intercepting the greatest amount of light.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45964.]—**Glass Transparencies (U.Q.)**—Many thanks to "M.I.C.E.," p. 64, but the transparencies he speaks of are an entirely different thing to those to which I refer. The latter are often as large as 20 by 24in., and have no film of any kind upon their surfaces. They are glazed into window sashes, and not acted upon by the weather. They have the appearance of roughly-ground glass.—An Old Fellow, Melbourne.

[46748.]—**Sharpening Carpenters' Saws.**—Will "Jack of All Trades" kindly say if he means that each of the teeth 5, 6, 7 in Fig. 3 should be sharpened on both sides when in the position so represented, or that the fronts of those set from you and the backs of those set to you should be sharpened when in the position so represented?—Tiro Tironum.

[46841.]—**Vacuum Pump.**—I expect, ere this reaches England, J. R. Edginton will have discovered or had his error pointed out by some readers of the "E.M." However, in the event of such not being the case, I supply the required information. "J.R.E.," in not constructing his pump particularly according to my description (p. 34), has completely nullified its action. For the pump to act with a reservoir of mercury raised above bulb A, it would require that the top of tube F should be full 30in. above the surface level of mercury in the reservoir when at its highest point. This was, in fact, the original design of my pump, but in order to make it more compact and prevent the necessity of raising a reservoir of mercury (a somewhat laborious matter), I designed the force pump at the base of the stand, the length of tube B being such that on production of vacuum in A the height between surface of mercury in cylinder C and junction of F with B is over 30in. This being the case, it is only necessary that the top of tube F be about 2in. or 2½in. above the bend between A and J. The length of vertical portion of F in mine is 11in, the upper angle being 3in. above the bend between A and J. The cylinder C must be made of iron, and by having plenty of leverage in handle E, the work is comparatively light. I notice one reader has failed to obtain a current from my secondary battery, although the sulphate of copper solution was all decomposed. This is evidently owing to his having deposited the copper on the amalgamated lead plate.—Henry Sutton.

[46859.]—**Indigo-Blue Dyeing.**—I am very sorry indeed that "Blackwater" should think that his friend, Mr. Simpson, was treated rather ungenerously. "Blackwater" says that a woad vat will dye 700 yards of serge navy blue with 12lb. of indigo, at 6s. per lb., and wishes to know what quantity Read-Holliday's process will produce. Of course, it is important to know the weight of the cloth, for navy blue serge, like other cloths, differs in weight. I have calculated it, however, at 12oz. per yard, which would give over 520lb. weight. Now, to dye that all indigo to the depth of colour that the writer of this is in the habit of doing daily, is simply an impossibility. I can assure him that if he can dye 700 yards of cloth, the weight that has been calculated at, with that amount of indigo, he need not trouble himself about any other process. Read-Holliday's process of indigo-blue dyeing is as expensive, perhaps more so; but the time to dye 700 yards of cloth in a woad vat, Read-Holliday's process will dye 1,200 yards a much better colour, less cost in the cleaning; so that, time being money, the new process is preferable to the old. I trust "Blackwater" will kindly state the weight of his 700 yards of serge, and give some idea of the depth of colour, and perhaps I shall be able to give him some practical information. Indigo-blue dyeing, in the manufacturing of woollen goods, is a large item, and it is important to manufacturers to ascertain the cheapest and most durable method.—J. Ormiston.

[46859.]—**Indigo-Blue Dyeing.**—I do trust J. Ormiston will not suppose I am answering his note—but to "Blackwater" I wish to explain that the mysterious preparation of indigo sent out by R. Holliday and Sons is merely that drug in a reduced state, so that the dyer has only to use zinc-powder, bisulphite, and lime in small quantities to get the vat into condition. (I do not know what term the dyer would use for this.) You are not obliged to buy indigo in this state, but can reduce your own by making an arrangement with the firm. You will, no doubt, understand that, manufacturing this bisulphite of soda, and being very large buyers of zinc-powder and indigo, and by the employment of special plant, they can supply small consumers at a lower rate than they could reduce the drug for themselves; another point which may be of advantage to the consumer is that they send the indigo out of uniform strength, which everyone knows cannot be obtained in the drug as imported. They do not use anything beside the chemical substances I have enumerated. A very fair idea of the manner in which reduction is accomplished is given in the little book on "Dyeing and Tissue Printing," by Crookes, lately published. There, however, it states, that scrap-zinc is employed, which is an error; zinc-dust is used in its stead. I am sorry I cannot tell the cost as against that of woad vats; but I believe the majority of users of the new process say it costs more than the old method; the extra cost, however, is more than counterbalanced by its being so much more expeditious, &c.; all this, however, you can find out for yourself by using it against the woad process. I wish to say, in conclusion, that the statement I make as to the reduction is not from hearsay nor book knowledge, but from personal knowledge. I am much obliged to "Blackwater" for his thanks.—S. J. Simpkin.

[47029.]—**Difficulty with Coil.**—To Mr. Lancaster.—Now satisfy yourself that the wire you have removed is good throughout its entire length, then commence re-winding, and leave out two coils from each end in every successive layer, carrying on the insulation from end to end as before. The middle will, of course, be even then thicker than the two ends. You ought to have a coil as nearly perfect as possible.—W. J. Lancaster.

[47219.]—**Textbook of Physiography.**—Thanks to "S. R.," I am acquainted with both Huxley's and Geikie's manuals, but neither goes over all the ground required for the advanced stage of the Science and Art Department.—A. J. Smith.

[47223.]—**Bird-Cage Making.**—"Querist" would require a pair of good wire nippers about 7in. long, two pair pliers (round and flat nosed), awls size of wire and brads used, and a true square is indispensable. He had better buy a common cage and work upon its principle as to posts, &c.; but if he will advertise his address, and communicate with me, saying what he requires, I will with pleasure assist him either with advice or drawings. —Handy Man.

[47228.]—**Telephone.**—I should advise you to put 1oz. of No. 36 silk-covered wire on each bobbin, the size of which should be ¾in. diameter (of ends), and 1¼in. long, made of cardboard, with wood ends.—Beetle Crushers.

[47239.]—**Biliousness—Bile.**—I think Mr. Nolan will find the following correct:—The bile is mixed with the blood in the process of digestion and blood manufacture. It is the duty of the liver to extract the bile from the blood and pour it into the bowel. If this duty is neglected the bile is carried with the blood through the system, reaching the delicate veins of the head, and producing severe bilious headaches. From which arrangement I think we may gather the following: certain materials require bile to pass them through the bowels, which bile they contain in the quantities required. If the liver does not perform its duties in secreting and excreting the bile, we not only have bilious headaches, &c., but also stoppages in the bowels, &c. Moral.—If the liver is out of order, don't take material containing too much bile.—John Alex. Ollard, F.R.M.S., Enfield.

[47261.]—**Arsenic in Wall-paper.**—When powdered arsenic is dropped into chlorine it immediately takes fire, producing arsenic trichloride $AsCl_3$. I should advise you to scrape the wall-paper and drop some of the powder into a jar of chlorine gas. I suppose, from your query, you understand something about chemistry. Another way is to mix with it some ammonium sulphide, NH_4HS, which gives a yellow precipitate.—Beetle Crushers.

[47267.]—**To Chemists.**—Thanks to "Video" for his reply, but quicklime slaked with water would not answer my purpose. I want a mixture of chemicals that in small quantities will produce considerable heat gradually. Would a mixture of iron-filings and sulphur answer, and if so, in what proportion? Surely any practical chemist could answer this query. "Video" says I appear to think, by asking twice, that I am entitled as of right to a reply. I think that all replies to queries in the "E. M." are obtained by courtesy. I have answered many on subjects I understand, and have felt a pleasure in doing so.—Caloric.

[47274.]—**Illuminating Clock.**—Why not dispense with reflectors, &c., and paint the hands and figures of the clock with Balmain's luminous paint? Then the time would be plainly seen in the dark, and the expense is trivial. If your clock has its hands and the figures gilded, probably you would not care to spoil the look of them in the daylight; therefore you could paint the face with the luminous colour, leaving the hands and figures gilded; then in the dark the figures and hands would appear black on a luminous ground.—Beetle Crushers.

[47277.]—**Engine.**—This is one of those queries which no one can possibly feel inclined to answer, except by referring the querist to previous replies. What does the querist mean by "the piston is cut off for a crosshead"? Undoubtedly such an engine might be made to work a sewing-machine, and probably a flywheel weighing 14lb. would suit it as well as anything else. Really, "T. B.," you should read up back volumes, or, at all events, learn sufficient to state explicitly what information it is you do want.—Essar.

[47281.]—**Tricycles.**—"Cherophus," whoever he may be, should, before he writes, be sure that he knows what he is about to write, and not make any erroneous statements. He may be—and most likely is—unconscious of having misrepresented me; but, at the same time, he ought to have been more careful before he deliberately puts one in the category of—well, people not to be believed. Now, anyone can refer to my answer on page 433, and they will find that I never once said I could ride 12 miles an hour all day, neither did I say that anyone could go 12 miles an hour all day; but what I did say was, "With such a machine you can go 12 miles an hour." Perhaps "can" should have been in italics to have made my meaning more distinct. I have on the road ridden a mile in five minutes, measured; only last evening I rode a mile and a half in seven and a half minutes, and could do it any time; but this is on a back-steerer, and I have never seen or used a machine that has given me greater pleasure. There are many reasons why I don't like a front-steerer, and although they may be coming to the front now, they will, I feel sure, soon go to the back again. With a back-steerer I can climb hills that I cannot possibly climb either on a front-steerer, rotary, or any of the other forms of machine now made. I have plans for a new machine that possesses advantages not in any machine now made, and I shall have a machine made up and then will describe it. Its great feature is throwing the continuous strain off one set of muscles and putting it alternately on to others. Of this machine, when I have tested its powers, I will write more.—W. J. Lancaster.

[47283.]—**Launch Tubular Boiler.**—The spec. grav. should never exceed 1,087, and, for a launch, better be kept down to 1,060. The quantity of water used as steam is an indication of the quantity that must be blown off, and as it is required to keep the water down to 2-33, and the normal contents is 1-33, the water to be blown off is to the water evaporated as 1 is to 1. Blow off in any usual way, and supply by feed, at any time that suits you.—Essar.

[47284.]—**Modelling in Plaster.**—Presumably you mean modelling in modeller's clay, for "plaster" is used for casting, not modelling. It is an art that cannot be taught by writing, beyond such simple directions as to how to keep the clay moist, and the special manipulation of the tools—mostly strips of box, or other hard wood. There are some handbooks on the subject—one by Vago, published by Simpkin and Co.; but if the whole of that were reproduced here, you would be very little the wiser. If you wish to go in for the art, you can obtain lessons at many of the science and art schools at a very cheap rate, and with just a few hints, you want no more than an artist in any branch can suggest. Perhaps some of your readers who may have gone through the elementary class will give an outline; but it is much like asking for directions to drive a locomotive: there is precious little that can be put into words, but a tremendous lot to learn by actual practice.—Nun. Dor.

[47286.]—**Chromograph.**—I have made very good "graphs" with the following "compo": ½lb. gelatine glue, 6d.; ¾lb. of glycerine, 1s. 6d.; ½lb. water, and a little prepared chalk in order to give an opaque surface. The ink I used to write with was Judson's aniline violet dye, 6d. per bottle, and I got, as near as I can remember, 40 distinct copies. I cannot say anything about HCl being useful for removing the old copy. I have always found hot water to answer as well as I could desire.—Beetle Crushers.

[47289.]—**Sulphur Casts.**—Are you sure the vermilion was good? The only method is to stir it in just before pouring, and to work at the lowest possible heat, because vermilion, being a sulphide of mercury, is liable to be decomposed in melted sulphur. I should try some other pigment, preferably one of the red earths.—E. G. M.

[47290.]—**Calculating Machine.**—For details of calculating machines, see p. 109, No. 811 (Babbage's); p. 611, No. 649; p. 563, No. 568; and p. 642, No. 571 (Thos. de Colmar's instrument illustrated). If the querist will look still further back in your volumes I have no doubt he will find much other information about them; but if he consults the pages mentioned he will obtain a good idea. De Colmar's machine is in use in several offices in London (the Railway Clearing House, for one, I believe), and querist should endeavour to see it, though the illustration in No. 571 makes everything clear.—F. I. A.

[47292.]—**Bunsen Battery Connections.**—The description I gave in No. 901 "E. M." will, I think, give all the necessary information you require.—BEETLE CRUSHERS.

[47293.]—**Pump Query.**—The clearance may be ¼in. for such a pump; but it may be practically very small. The speed should not be more than 500ft. per minute.—NOSCO.

[47307.]—**Mildew on Vines.**—I am sorry to find "Amateur Gardener" and others are troubled with the mildew; but I was once troubled in the same way, but found a most certain and effectual cure for it, as well as the insects which sometimes abound on the vine. I fear, by what "Amateur Gardener" says, that this year the grapes are too forward to do any good, because the remedy I used will make them taste; but in future it will be a sure cure if made and used as directed. Boil a small quantity of sulphur with some quicklime, quite fresh, in a glass flask, with some water. It will require to be boiled for, say, 10 minutes. Great care must be taken that it don't boil over, and the mouth of the flask should be slightly stopped with paper so as to form an obstruction to air entering. When the boiling ceases the sulphur and lime quickly settle, when the clear yellow liquor should be poured into a bottle tightly corked, and fresh water added, and the boiling again begun. This should go on till sufficient solution is obtained—say, nearly a pint. The sulphuret of lime solution should be kept well corked, as the air decomposes it very quickly. To use it add a wineglassful to a quart of water, and then brush the stem of the vine with it, doing it quickly, as it decomposes almost directly. When the stem has been well brushed don't be sparing with the solution; the whole of the leaves should be syringed, and the greenhouse shut up for a short time. This should be repeated three times, the last just when the grapes begin to form. If well done, it is a sure preventive for scale, mildew, &c. I don't say anything about the management of the vine, as I suppose that is properly understood. If the trouble is thought too great to make the sulphuret of lime, perhaps it may be bought; but I cannot say. A Florence flask is the best to use.—EDWD. THOS. SCOTT.

[47310.]—**Naturalisation.**—This question depends entirely on the laws of France. If a Frenchman has been naturalised here, he acquires all the rights and privileges of a Britisher. But I do not see how that can affect his status in his native country; and if it is the law that the property of those who run away to escape their duties as Frenchmen shall have their property confiscated, the mere fact that they have been naturalised here or elsewhere will avail them nothing.—PATRIOT.

[47311.] — **Cannon.** — Make it 3in. thick at breech end, and "prove" it, before you sell it.—E. G. M.

[47322.]—**Injured Thigh.**—To DR. EDMUNDS.—I have looked back all the numbers I have (34), and cannot see any of your former replies I would think suitable as you direct for treatment. I may say some days before I received your reply the abscess came to a suppuration of its own accord without pain. I then kept it poulticed with linseed-meal (now about five weeks). I kept it well pressed to assist the emptying of it, and there came at times about the size of a nut of pus, and occasionally twice the quantity, but no apparent lessening in size. For the last ten days I have discontinued pressing it, but nothing has come away since. The opening is about the size of a point of a lead-pencil, and the gathering has rather a solid or hard feeling. Will Dr. E. kindly say what would be the best treatment to continue? Should I follow poulticing, or when should I give it off, and if correct to put it on as warm as I can really bear it; or should I take any medicine or tonic at the present time or after? Since I received your reply I rested, but kept moving a little about. The warm poultices have made the flesh tender on the surface, and in a few places there is a slight oozing of serum. Any remarks as to mode of treatment will be thankfully and gratefully received by—S. J.

[47351.] — **Mathematical.** — I am much surprised to find, after the very lucid explanations by J. H. M. Jacoby and "Hemisus" of the illegitimate assumption made by "An Engineer's Son," that the latter still considers his solution satisfactory. "Hemisus" very truly points out that the fallacy lies in the fact that $(1 - x)^{-n}$ is not independent of x; and, to take the very instance proposed by "An Engineer's Son" in his last letter, the reason why the coefficients of x in $(1 + x + x^2)^3$ increase up to 7, and then decrease, is not at all because when written:—$(1 - x^3)^3 (1 - x)^{-3}$ (i.e., $1 (1 - x)^{-3} - 3x^3 (1 - x)^{-3} + 3x^6 (1 - x)^{-3} - {}^9 (1 - x)^{-3}$). The coefficients 1, 3, 3, 1, obey the rule and $(1 - x)^{-3}$ is then multiplied into each, which is the reason set forth in "An Engineer's Son's" first letter.—CANTAB.

[47423.]—**Diabetes.**—There is a work entitled, "The Skim-Milk Treatment of Diabetes and Bright's Disease, &c.," published by Longmans and Co., price 10s. 6d., in which, I should think, "E. F. C." may obtain the information he requires. There is, also, an American work, published in Philadelphia, under the title of, "How a Person afflicted with Bright's Disease ought to Live," by J. F. Edwards, price 4s. It is numbered 677 in the list of American publications in the *Publishers' Circular* of 15th February, 1881, and may be obtained through Sampson Low and Co., or any respectable bookseller.—G. TOMMY, Bristol.

[47434.]—**Lathes.**—In answer to Mr. J. H. Evans, what I wished to know is how to Babbitt the mandrel, and as it is a bar-lathe, I also wish to know how to Babbitt the two iron bars that form the shears or bed. How are the holes chambered in the standards to receive the metal? If J. H. Evans would inform me how to make and use Babbitt metal I shall be obliged. Does he think ordinary white metal would answer?—MINER.

[47441.]—**Minute Photography.**—You can have a lens of any focus made to photograph either the whole of the front of a newspaper or parts; then these can be read either with the table or the oxyhydrogen microscope. You cannot use ordinary collodion, as the film is more or less reticulated under a high power. The albumen process is one of the best for obtaining a structureless film.—W. J. LANCASTER.

[47450.]—**Measuring Flow of Water.**—Multiply the depth, breadth, and speed, in inches, together, and you will have the total amount in cubic inches passing over in any given time. It is then only a matter of simple calculation to bring it into gallons, pounds avoirdupois, or whatever you may require.—W. CLARKSON.

[47451.]—**Improving Definition of Telescope.**—I am sorry I cannot help you much in getting rid of haze. The only way to remove the difficulty, even in a slight degree, is by using an eyepiece of very large field and lower power than the one you have. I should have an eyepiece with its field-lens at least 1½in. to 1¾in. diameter, and mounted with the erector in the pancratic form, to give a power of 10 to 20 diameters. You might use a comet eyepiece, and a diagonal to reinvert the image. This would perhaps be the best thing you could do.—W. J. LANCASTER.

[47463.]—**Change-Wheels for Screw-Cutting.**—I am obliged to Mr. T. J. O'Connor for his attention, but he hardly answers my query. Let me put it this way. The change-wheels are the usual set, 20 to 25, and from 25 to 125 by fives; the leading-screw is four to the inch. Suppose, now, I require a screw 31 threads to the inch—you will say, perhaps, that with these wheels it is impossible to cut 31 to the inch exactly. But out of the thousands of screws which can be cut with these wheels and this leading-screw, I should expect to find one or more differing from 31 to the inch by so small an amount that in practice the error could be neglected. Now, what I want is a method of calculating this as directly as possible. What is the method in actual use? I don't want to be shown how to calculate for 31 specially, but for any number, and to find the screw with the least error.—TRY AGAIN.

[47465.] — **Faded Daguerreotype.** — The answers in last week's issue are good, with one exception, and that is, the pouring on to the plate. Don't pour at all, unless you wish to spoil the daguerreotype; but put the plate into a dish. I have restored many so-called faded daguerreotypes with cyanide of potassium solution. It, of course, requires a little care; and when the solution is done with, don't leave it for the youngsters to drink, but at once throw it away.—W. J. LANCASTER.

[47468.]—**Transit of Venus.**—I send the following, hoping it will be of service to "Jamaica:—

LATITUDE, 18° 5′ N. LONGITUDE, 77° 30′ W.

	Local meantime.				Sun's altitude.	
Dec. 6.	h.	m.	s.		°	′
First external contact	8	52	37	a.m.	30	15
,, internal ,,	9	13	23	a.m.	33	54
Last internal ,,	2	39	5	p.m.	32	17
,, external ,,	3	0	22	p.m.	28	29

The point of which lat. and long. is given above would be in the vicinity of the "Blue Mountains," Jamaica.—S. G.

[47468.]—**Transit of Venus.**—A three years' residence in the Southern Port Royal Mountains of Jamaica makes me think the atmosphere there for telescopic work is simply superb. In and about Kingston, however, which is situated on a plain, I think the radiation of heat during the day-time is so great that good definition would be out of the question; but in those mountains which surround this plain, and which rise very abruptly to elevations varying from 1ft. to nearly 4,000ft., the case is very different. I will give an experience or two out of many similar. Many times I have seen the horizon as a fine delicate line drawn between sea and sky, from the tops of the Flamsteed and Bloxburgh Mountains, whose elevations are over 3,000ft., and from the former with a 3in. telescope (not, by the way, a five-pounder), I have seen, with ease, the time by the town clock (Kingston) at 9 a.m. with the sun shining in its full strength, a distance of not less than 14 miles; and from the top of the latter mountain with a 1½in. or 1⅝in. telescope, I have seen the various splashes in the water from a cannon-shot (in target practice) off Port Royal, 20 miles away, at least. I have also seen one of the R. W. I. mail steamers with the same telescope, when five hours' sail off the port, the white foam from the paddles being plainly seen, and not until two hours after could a trace of the ship be seen with the unaided eye. I think these facts will give an idea of the rare excellence of the atmosphere for telescopic work. The finest time in this country cannot be in any way compared to it. My reasons for selecting the Southern Port Royal Mountain can be given if required, and December a good time.—S. B.

[47478.]—**Induction Coil.**—To MR. LANCASTER.—The core should be ⅜in. diameter for such a coil as you intend making, and should not be more than 6in. long for ½lb. secondary. If you are careful in winding and insulating you will be able to get a good ⅜in. spark or under very favourable conditions, ½in.—W. J. LANCASTER.

[47486.] — **Euclid's Axioms.** — What Euclid asserts in axiom (2) is: that if A and B are equal, then A + C = B + D; from this we can deduce that A − D = B − C, which is obviously the same as A − C = B − D, which is axiom (3). Axiom (4) can be demonstrated indirectly from (2). Suppose that when A and B are unequal, and C and D equal, that A + C = B + D. But this is clearly impossible, since it has been shown to be the case when A and B are equal; therefore, the sum of A and C is unequal to the sum of B and D. Axiom (5) may be deduced by a similar consideration. Axioms (6) and (7) are obviously merely cases of Axiom (1).—C. H. ROMANES.

[47490.]—**Loco. Engine with Broken Crank Shaft.**—W. Bradshaw, Derby, on p. 506, answers "Young Mechanic" re broken crank-shaft, but gives no information as to the modus operandi. Driving-wheels are often lifted clear of the rails by putting a couple of nuts or fish-plates on the rails, and drawing the driving-wheels on to them, the extra pressure forcing the axle-box up so as to allow packing to be placed on the keeps or bottom-stays, the pressure of springs tending to keep such packing firm. If the engine has outside axle-boxes, a screw-jack will answer if applied under them. "Young Mechanic" should ask some old driver, and not be ashamed of his ignorance, when he would get all the information he requires.—TAKAPUNA.

[47491.]—**Magic-lantern Slides.**—You cannot learn how to paint lantern slides from any description. You will have to work hard until you succeed. I have a lot of men who colour slides, and but few of them know how to put the colours on as they should be, and yet I often pay 10s. to 15s. for one slide. There are several handbooks, most of them written by men who never painted a slide in their whole lives. I once attempted to paint a few slides, and I put the colours on as the best books told me; but the success was indifferent, and I found it would take years to obtain the knowledge how to paint properly.—W. J. LANCASTER.

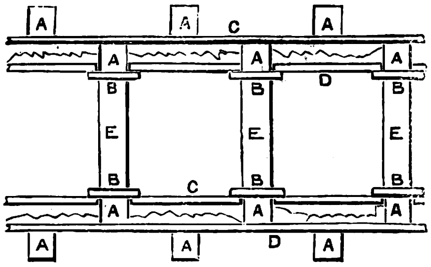
[47496.]—**Power of Batteries and Coils.**—There is no rule, but a safe plan is to use not more than four quart Bunsens to each 1in., and, to be absolutely safe, not more than three to each 1in. for coils giving 2in. and longer sparks.—W. J. LANCASTER.

[47498.]—**Indigestion.**—Having recommended cocoa from the nibs as a most valuable tonic for the stomach, the best receipt for making it is, I believe, to put 4oz. of the nibs into a kettle or large tea or coffee-pot, add 4 pints of water, and let it boil for about 4 hours; it is then reduced one-third (not more) if boiled slowly. A good drink of cold water, repeated if necessary, often removes uneasiness, and is excellent before meals. I find alcohol an injury instead of a benefit to stomach or nerves.—C. M. Y.

[47500.]—**Bichromate Battery.**—To "BEETLE CRUSHERS."—The number of plates in the battery depends upon what amount of power you wish to obtain from it; the more plates you have the stronger will be the battery. Supposing you used the battery four hours a day, on completion of the work remove all the solution, and allow a flow of water from a tap to pass through the battery, thus thoroughly cleansing the sawdust, plates, &c. This may be done for a week, when it is best to take the battery to pieces and reamalgamate the zincs, see to connections, &c. To attach the battery to an electric lamp, it is only necessary to connect the binding-screw that has the zinc wires to one wire of the lamp, and the binding-screw connected to the carbons to the other wire of the lamp. Any information further required I shall be most happy to supply.—Beetle Crushers.

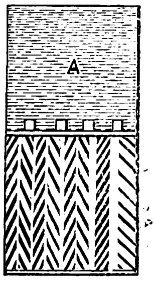
[47510.]—**Cistern.**—A cistern 6ft. diameter and 8ft. deep, clear dimensions, would be suitable for a house of the size given—i.e., 70ft. by 23ft., capacity 226 cubic feet = 1,380 gallons.—Ditton.

[47511.]—**Coffer-Dam.**—Get the shell of an old Cornish boiler, if for sinking well; or if for putting foundation in for wall, proceed as follows: Put piles in as Vandyke fashion shown in sketch;



main piles, A A, 5in. by 3in., and plank at back of B, 8in. by 1½in. Boards put down between, as A, and B, C, and D; puddle between with clay, and stay or strut from one point to the other, E E. Perhaps waleing A, B, C, and D put down, break joints with felt, will do without puddling.—Jack of All Trades.

[47513.]—**Water Filter.**—Make a cistern under ground, rectangular, 8ft. long, 5ft. wide, with a partition wall across the centre, one end 10ft. deep, the other for filter 7ft., and in the latter put bricks on edge, as shown in sketch, one course;



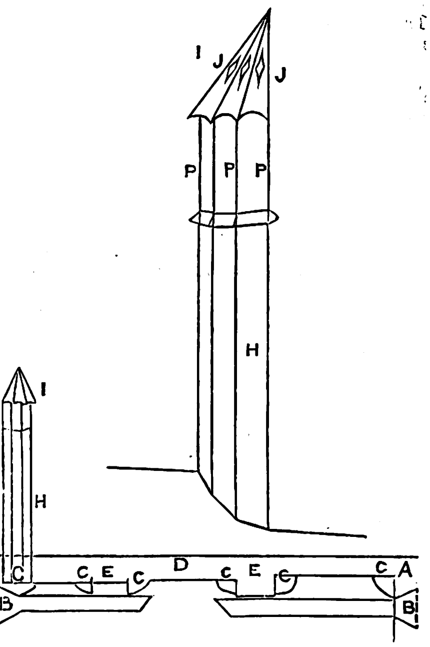
reverse the order, and lay another course; upon these lay another course of flat; upon this some washed shingle sifted through a ¾-mesh, about 8in.; upon this some finer, about 4in.; and upon this some (about 3in.) river sand washed; upon this 2in. of charcoal dust, and 2in. more sand. The bed or bottom of this should be inclined towards the receiver, A, and an opening, or four or five, about 4in. square, left in the parting-wall into it. When foul the top sand can be removed and the filter supplied with a fresh lot; thus the filter is renewed when choked, and, if thoroughly out of order, the whole can be taken out, washed, and replaced with little trouble.—Jack of All Trades.

[47515.]—**Dry Collodion.**—Presuming you have some acquaintance with the wet process, proceed as follows:—Coffee process: coat the plate with a substratum of sheet gelatine 15 grains to 12oz. of distilled water, with the addition of 24 minims of ammonia. When dry, coat with ordinary collodion, to which has been added 2 grains of cadmium bromide to each ounce; sensitise with a 40-grain bath, wash for about one minute under a stream of water from the tap, and flow over with a preservative as follows:—Solution of coffee ½oz., boiling distilled water 5½oz, and white sugar 90 grains; when cool, filter and mix with solution of gum-arabic (picked) 90 grains sugar-candy, 20 grains, and distilled water 5½oz. filtered. Flow this preservative over the plate in two applications of about a minute each, using the liquid from the first flowing as the first application to the succeeding plate. Drain the plate, and dry in a drying-box. The plates are very transparent, and so require a backing to prevent blurring; for this a non-actinic paper coated with gum may be used. The exposure required is from three to six times that for a wet plate. Before development, soak the plate in water for three minutes, and remove the backing. For developer make solutions of (1) pyro, 6 grains to the oz.; (2) Bromide potass, 20 grains to the oz.; and (3) ammonia (·880), 15 minims to the oz. Take two parts each of (1) and (2), and flow over plate and return into developing-cup, in which is one part of (3). If the plate shows over-exposure, return developer into cup and wash the plate; continue with more of No. (2) added. If under-exposed, add more of No. (3). The image may now be intensified by the ordinary pyro intensifier, first flowing over with solution of ammonio sulphate of iron 10 grains, sulphate of copper 10 grains, and citric acid 10 grains to an oz. of water; fix with hypo. The above process is that of M. de Constant.—Ditton.

[47518.]—**Balance-Wheel Cutting.**—I am sorry I cannot oblige this correspondent. I have not got a balance-wheel cutting-tool, and am not provided with drawings of one. It is an expensive and complicated tool, and by ordinary jobbers very little used, or even known. To give a drawing from memory would end in failure, so I will not attempt it. Small files, called balance-wheel files, may readily be bought, with which, by careful working, the teeth may be correctly recut if they are incorrect. The tips of the teeth may be trued up in the turns with slightly oiled Arkansas-stone. The ends of the teeth should be cut in a line with the pivot centre, and should be of equal thickness, and good clearance should be left in them for the swing of the pallets.—Alfojoe.

[47531.]—**Ventilation.**—Fix on roof two of Boyd's patent ventilators for outlets, and for inlets, tubes 7ft. high of any convenient size with grating to open air at bottom. These outlets should have a total area of about twice the total area of outlets to prevent draughts.—Ditton.

[47531.]—**Ventilation.**—If your floor-line lies above the general ground-line, remove bricks at each end, 12in.sq., and cover over with a perforated, ornamental, cast-iron panel. If the interior of walls are panelled, put an ornamental zinc piece across the angles, with perforated ornamental top. These should be 5ft. 6in. high; and at the bottom the angle of flooring should be removed, and these put over them. The air, if taken through the holes under the floor and up these shafts, will be somewhat noisome, and a zinc trunk, for the conveyance of the air to these shafts, would be better—say, opening at each end 18in.sq., tapering up to 12in. by 8in.; distance from end, 2ft. (See sketch.)



A, outer wall; B, ventilation trunk; C, angle; D, wall line; E, piers; F, floor line; G, joist; H, ventilating shafts; I, caps; J, perforations; P, perforated panels). The material need not be heavy.—Jack of All Trades.

[47548.]—**Industrial Company's Account.**—It is impracticable to answer this query, even in outline, within a reasonable space. The general principles are those of double entry, which can be found explained in books costing eighteenpence and upwards. The problem is solved by the best application of those principles to any one particular business. The practice, therefore, depends much on the detail and extent of the business—more on the number of items than the money amount of them—and other like considerations. The results which "Boss" wishes to see displayed are sometimes arrived at by dividing the business into departments, so far as the cost of production is concerned; but this course need not necessarily be followed. In a large concern, an exhaustive analysis of the wages, raw materials, and manufactured articles bought; of such costs as horses, stabling, and cartage hired or carriage both inward and outwards, of stocks or goods previously bought, when subsequently issued for use; wear and tear of plant; sub-contracts, &c., &c.; and the redistribution of such results when obtained among works contracted for, extras on the same, day-work, piece-work, jobbing, and many other heads—all this is often costly—to establish a good system as well as to carry it on. The most lucid accounts are those which show the financial facts of the business, in its earliest stages, in the most ample detail, and in its latest stages in the most complete condensation—so that a man may carry his balance-sheet written on the back of his calling-card. Such accounts are analogous to the "quantities" of the architect or engineer, and have quite as much or more work in them; the one, however, is based on estimate, and the other on accomplished financial facts; and any difference between parallel lines should be easily discernible on comparing the one with the other.—J. D.

[47540.]—**Measuring Flow of Water.**—To ascertain cubic feet of discharge per second, use the following formula:—$5{\cdot}35\, b\,.\, h^{3/2} = Q$. Where b = breadth of weir in feet, and h = height of water above weir in feet. To get the cube of the square root of height ($h^{3/2}$), look in a table of squares and cubes: in the column of squares for the nearest approach to h, and opposite, in the column of cubes, will be the approximate value of $h^{3/2}$. Example: Weir 6in. wide; depth of water over same, 3in. Here $Q = 5{\cdot}35\ ({\cdot}5 \times {\cdot}25^{3/2}) = {\cdot}33$ cubic feet per second = 2 gallons. This is supposing the discharge is from a still pond. See Rankine's Rules and Tables.—Ditton.

[47553.]—**Problem in Dynamics.**—The ball will acquire a velocity = ½v. The following consideration will make this clear, I think. Suppose the monkey to ascend to a height v above E, the point at which they are in equilibrium. The action of gravity will cause it to descend, drawing the rope over the pulley, and consequently raising the ball through v. Both will now be half v above the original point of equilibrium I. But the monkey will have ½v rope hanging below E. Thus, while the monkey has gone over a distance = v, the ball has only risen ½v in the same time.—C. H. Romanes.

[47556.]—**Calculating Sizes and Powers of Boilers.**—In reply to "Learner," 474 is the vol. of steam compared to 1 of water, and it means that 1 cub. ft. of water may be converted into 474 cub. ft. of steam at a pressure of 55lb.; so that having ascertained the quantity of steam required per hour, we can thus find the quantity of water required to produce it; and the boiler must be able to evaporate that quantity. The number corresponding to any pressure may be found in Molesworth, or any similar work, under the head of "Table of the Properties of Saturated Steam."—J. H.

[47562.]—**'Xtraordinary Challenge.**—I have ridden this make now over twelve months, previously having ridden "Timberlake," "Ariel," "D. H. F. Challenge." For safety and ease in mounting and dismounting, it is far beyond the old style, or, rather, the ordinary style. Speed is the same. There are some things you can do on ordinary make but not on 'Xtra., such as riding with hands in your pockets. With 'Xtra. you must keep hold with one hand or over you go. I do not find it any easier to mount hills, nor do I find it easier over rough roads. I may add I am 52 years old. I like the 'Xtra. My son does not, but likes his D. H. F. better.—B. N.

[47563.]—**'Xtraordinary Challenge.**—As one of the oldest riders of the bicycle—being just 80 years of age—and also a frequent user of both the ordinary and 'Xtraordinary machines, I may offer "Undergraduate" an opinion of the merits of the 'Xtraordinary. I began with a 50in. ordinary, but a smashing cropper over the handle warned me to look for something 'xtraordinary to avoid such an occurrence for the future, and I obtained a 52 'Xtraordinary. This I rode for some time with great confidence—alas! somewhat misplaced. Having been from early youth, and, in fact, being still, a first-flight rider with the foxhounds, I early learned the advantage of speed down-hill, and the swift rush through the air is a most enjoyable sensation. Now, this the bicycle affords you in perfection, and I fancied myself secure when on my 'Xtraordinary. There is, however, this disadvantage, when the speed becomes too fast for the feet to be kept on the pedals, the only method of keeping them out of the way of the pedals and levers of the 'Xtraordinary is to lift them above them; but this is a fearful risk, as I found to my cost about a month ago. Being out with a young companion, whose youth and strength enabled him to outride me going uphill, I rejoiced in the nerve and confidence in my machine which enabled me to overtake him ere he reached the bottom on the other side. This went on pleasantly for some time; but on coming to the bottom of a long and steep hill, I allowed my right foot to drop too low, owing to fatigue. The pedal struck it, knocking it into the wires of the wheel, and jamming it against the fork. Away we went—over on the left side first, and then bounding over to the right, the machine clinging to me like a rat-trap, and lying on me at last, of course a perfect smash, and with my foot so fixed in the wires that my companion appeared to me an hour in releasing me (I believe he was five minutes). I was badly knocked about, but no bones broken—the bicycle a perfect smash, and a cart brought it home for me; and I am now careful not to let my machine run away beyond the control of my feet, as unless the rider can hang his feet over the handle, he runs a fearful risk in doing otherwise. Now for the merits of the Xtraordinary—and they are: great safety from croppers, when used with care, as a brick may be ridden over with safety. Great ease in mounting, from the saddle being so much farther back and lower than on a common machine of equal size of wheel. Less jolting experienced in riding over rough roads, as the jolt is shared by both wheels. Any size wheel may be ridden without reference to the length of the rider's leg, as the pedals are made adjustable. Also, I think, an increase of power, from the feet being over the pedals. The disadvantages are: increase of weight, also more friction from the joints of the lever, and more of the weight also being put on the small wheel. But I consider the advantages are greater than the objection, if the machine is to be used for common road-riding. I can get ten miles an hour out of my machine, without any great fatigue, and I do not find much difference in mounting hills with one or other machine, for with either I walk up if at all steep, as the change of motion is pleasant and the fatigue much less. The steering is a little different at first; but this is soon overcome. On a smooth flat road, the common bicycle would have the advantage; but not on roads as they are commonly found to be. I will call the attention of my fellow bicyclists to a little addition I have to the Challenge wrench, as also to the four-holed spanner, neither of which are long enough to enable one to unscrew the nuts of the pedals, after they have been some time in use. This is, to the Challenge wrench, a piece of stout wire ⅜in. diameter, having a twist at the top to hook round the lower end of the wrench, and fall into the square nick at the end, and 6in. long, which will add 5in. to the length of the wrench, and give power enough to unscrew the nuts of pedals. In the four-holed spanner I have another and similar piece of sheet iron, with two bolts at one end, the heads of which fitting into the two smaller holes of the spanner, make that proportionally more powerful, and these pieces being only 6in. long, will go into the tool bag of the bicycle, and be often of great use. Such has been my experience. — PHILIP VALLANCE.

[47570.]—**Bronzing of Cardboard.**—The cards are, I believe, specially prepared with gum or isinglass, to prevent the absorption of the varnish or gold size; when covered with the varnish, they are passed through the powder, just tapped upon the edge to remove surplus until set; afterwards brush over with a hare or rabbit's tail, or foot.—JACK OF ALL TRADES.

[47571.]—**Polishing Bobbin Ends.**—This will be best done with a flat disc of wood in a lathe, covered with felt or stout cloth. Furnish yourself with some thin polishing cake, made of 2 parts of beeswax and 1 of gum sandrac melted together; pour out upon a glazed tile, plate, or marble slab, for use; when your chuck is running, touch the face with a piece of this; then apply your bobbins with both hands as fast as you like. You do not require much of it. If you have convenience, you can run your chuck, or polishing-wheel, horizontal. The least used the better they will polish. Put the compo. in centre, and finish outside.—JACK OF ALL TRADES.

[47572.]—**M.R. Tank Engines.**—The latest class of M.R. tank engines have cylinders 17in. by 24in., and leading and driving-wheels 5ft. 3in. diam. They are similar to the former class of tank-engines numbered 1252-1281, and built by Nelson & Co., 1876, with a few differences. The older class have leading and driving-wheels 5ft. 6in. diam., but the tanks and coal-bunkers of the new class are somewhat larger. Fifteen of the new class, numbered 1532-1546, were built for the local traffic at Manchester and Bradford. These were built at Derby in 1881. Nos. 1547-1561 are for the London traffic, and are now in the course of construction.—METEOR.

[47577.]—**Watch-Cleaning.**—Get a sixpenny bottle of refined benzine, or benzine collas, and pour a portion of it into a saucer or other shallow vessel. Put all the dirty parts of the watch into the benzine, and stir them gently about. Allow them to remain therein for a few minutes, then remove, and allow the spirit to evaporate. That which remains in the saucer may be thrown away or returned to the bottle. Do not mind the disagreeable smell; it will soon pass away. This will cleanse all the parts perfectly from oil, and no fear of rust need be entertained as regards the steel work. The most delicate hairspring may be laid in it without injury. I won't answer for common benzine, though, as it leaves a film upon the bright parts, which may or may not be detrimental. I habitually use the refined, so can speak of it from experience. On no account approach a naked light with it, as it gives off a highly inflammable vapour at a given temperature. Clean the watch in the usual way after this operation. Watch-cases may be cleaned in the same way that silver and gold in general are cleaned—i.e., by plate powders, rouge, common chalk, or whiting. The rims are easily cleaned with a blunt peg, on which is a little moist rouge or chalk. A chamois-leather should be used for the surfaces of the cases, or a buff made of wool and shaped up like a brush, the wool taking the place of bristles.—ALFOJOE.

[47579.]—**Deal Made to Imitate Maple.**—Your job will want well rubbing down; then give it one coat of pale priming—i.e., about 1 of red-lead to 6 of white, mixed with very little oil and plenty of turps: when well dry, give it a coat of body-colour, pale or warm, as you like it, with raw sienna and white-lead; when thoroughly dry, rub well down, and give another coat; when dry, wash with damp sponge and stale porter, into which put a little pumice-stone powder and ox-gall, and when dry, proceed to figure with a sponge raw sienna and beer; when dry, varnish with some good pale oil varnish.—JACK OF ALL TRADES.

[47580.]—**Nightmare.**—One source of nightmare lies in overloading the stomach late at night with hardly digested food, such as pork, pastry, crab, lobster, &c. I well remember having a distinct impression of a havy tree lying across my chest, which subsequent pondering resolved into pastry, taken at supper previously. But the most pregnant cause of the distress is lying on the back. This position in old people obstructs the breathing, goes on to snoring, and then (to persons subject to it) nightmare. And if "Nightmare" makes inquiry, he will probably find that his relative is in that position when the unpleasant occurrence happens. It is difficult to suggest a means of prevention; but, perhaps, some different arrangement of bedding, or a lump fastened on to the sleeper's back, might be of service.—FRED. DAVIS.

[47581.]—**Large Lathe.**—I believe the largest lathe in the world is at the St. Chamond Steel-works, in the Department of the Loire, France. It was constructed for turning 100-ton guns, by Sir Joseph Whitworth and Co., of Manchester, about two years ago. Perhaps some of our Manchester friends could give us some of the leading dimensions of this excellent workshop tool?—FITTER.

[47582.]—**Casting Small Articles.**—If your moulds are bright, blacken them, and you may keep them hot—about 180 or 200°—without the metal adhering to them. There are various alloys called Britannia metal, consisting of about 100 tin with from 4 to 8 per cent. of bismuth and antimony, and from 1 to 2 per cent. of copper, according to what it is wanted for.—JACK OF ALL TRADES.

[47583.]—**Glazing Sanitary Pipes.**—This is done with salt thrown into the fire when the firing is very near completed.—JACK OF ALL TRADES.

[47587.]—**Cross-Bow.** — Lancewood.—JACK OF ALL TRADES.

[47587.]—**Cross-Bow.**—The best wood is English yew, then lancewood; but better than either is steel, far more elastic and powerful.—FRED. DAVIS.

[47588.]—**Moss-Covered Steps.**—Clean down occasionally with water made acid with spirits of salts, and, in intervals, use hard broom to sweep. If whiteness is no object, flood them down with thin wash of Portland cement.—NUN. DOR.

[47588.]—**Moss-Covered Steps.**—Paint them over with a solution of potash, say at night time, and wash off with water next morning. If it is done carefully, and using a strong solution, you will not be troubled with the moss or green on your steps again this summer.—J. P., Aigburth.

[47591.]—**Indiarubber.**—Treat it to a vapour-bath of bisulphide of carbon, and masticate it. Some dissolved in the same will give you a cement.—JACK OF ALL TRADES.

[47595.]—**Copper-Plate.**—If the edges of the engraving are worn round and some fine lines very near obliterated, it is not of much account. It can be raised from the back side and recut, and deep scratches taken out by the same process.—JACK OF ALL TRADES.

[47595.]—**Copper-Plate.**—Perhaps your plate is not worn at all. Heat the plate, and clean out with turpentine, as the ink gets clogged sometimes. Printing ink won't do. You must use copper-plate ink, not too thin; don't rub much. Hand-pressure is not heavy enough; it must be passed through two rollers. Scratches can be taken out by burnishing with a steel burnisher, which must be well polished, as the plate is very easily scratched. After you burnish it, polish with charcoal and oil, then rottenstone and oil; or any engraver will do it cheaply for you.—R. MCBEAN, Edinburgh.

[47600.] —**Deodorising Paraffin.** — Without apparently knowing it, you are asking for something that would be of considerable commercial value. Many attempts have been made to disguise the odour of paraffin oil, with, however, only limited success; but such as they are, you will find them described in back numbers of the "E. M." There are several oils in the market which have but a slight odour, but they are too expensive for lubricating purposes. As you are "only" an "Amateur Mechanic," and presumably do not use many quarts of oil in a year, suppose you try almond.—G. H.

[47603.]—**Plating with Gold Inside and Silver Outside.**—Fill the cup with the gold solution, hot, attach the wire to the handle, and hang the piece of gold in the centre; do this after electro-plating the cup with silver.—J. P.

[47603.]—**Plating with Gold Inside and Silver Outside.**—No great difficulty in that. Gold solution inside, with gold anode; standing in silver bath, with silver anode. I guess you do not want to know how to couple them up.—JACK OF ALL TRADES.

[47603.]—**Plating with Gold Inside and Silver Outside.**—The cup must first be plated with silver inside and outside. When that is accomplished fill the cup with gold solution, and suspend the gold anode in it; twist the other wire of the battery round the stem of the cup; you will so gild the inside. It is as well to have the outside of the cup dry, so that the solution will not creep over the edge.—OS.

[47603.]—**Parcel Plating Gold and Silver.**—First electro-plate the whole cup, outside and in, with silver. Then dry, and carefully fill cup with gold solution, and reduce again. N.B.—The gold reduces very rapidly, one touch sufficing to give a deposit.—FRED. DAVIS.

[47606.]—**Brake Power on Goods Trains.**—About six years ago some interesting experiments were made on the L. and N. W. Railway with a goods engine, No. 1629, with a load of 45 waggons of coal. The result elicited the fact that one tender and one van hand-brake had but little control over such a train if on a gradient of any severity. The Midland Company also made some experiments, the results of which your correspondent will find in a book published by the company entitled "Midland Railway Train Brake experiments," in which every detail of all experiments relating to brake trials is fully set forth and ably explained. The said book also deals fully with the experiments made relating to the Kildwick Accident, in which, it will be remembered, an unfortunate driver was actually found guilty of manslaughter upon the statement that he had brake-power at his command wherewith to stop in 400 yards; whereas, when engines 815 and 892 were tried, it was found that the poor driver had not the necessary power in his hands.—A. S. H.

[47607.]—**Kitson's Steam Brake.**—I am able to state positively that Kitson's steam brake was not tried at Newark, for I was there, and if your correspondent will refer to Mr. Stretton's able and useful little book, which is now before me, he will find the following, page 8:—"The Midland company fitted an engine and tender with Kitson's steam brake, and the programme previously issued contained it in the list; but this engine did not arrive at the place of trial." As the engine was not tried, of course the official description does not appear in the report, and therefore, I am unable to give any reply to the part of the question relating to the water-jet. Two hydraulic brakes were tried—Barker's fitted to 135 engine, and Clarke's fitted to 891; but I am unable to remember or find in my notes any mention of a water-jet.—A. S. H.

[47611.]—**Silicate Cement.**—Rather a queer subject to deal with. If your varnish is too full of gum, a skin will form over it and prevent it drying. Precipitated silicate from silicate of soda, with salt or hydrochloric acid, well washed and fired, the highest rectified spirit, or better, naphtha, 1 pint, shellac 1oz. The shellac, when dissolved, should be allowed to settle perfectly clear, and poured off for use.—JACK OF ALL TRADES.

[47612.]—**Re-whitening Stucco Figures.**—Milk of lime, then hot lime-wash.—JACK OF ALL TRADES.

[47618.]—**Bills of Sale.**—How is it that no amount of exposure seems to prevent people from dealing with loan office swindling and bills of sales? The ruin of victims, the denunciations of judges, the adjurations of public writers, all, all, seem to have little effect. A new debate in Parliament upon bills of sale cannot repress the mania! The blood-sucking scoundrels of these loan offices are, with very few exceptions, *ad hostes homines*—enemies to the human race. The present immunity from legal consequences is on account of the state of the law, enabling them to scandalise English civilisation up to, or down to, madness. I could nearly fill our English Mechanic with examples, both from my own reading, and personal knowledge, that would disgrace the lowest race of savages in cruelty. Look at the case of the poor widow the other week, who, in the affliction of a recently buried husband, and a house full of young orphan children, applied—alas! in vain—to the magistrate to save her furniture against a bill of sale for £1 15s., the remains of usurious interest which the loan vampires were about to put into force, which bill her deceased husband had unfortunately signed just before his fatal illness. I never was in the clutches of these infernal fiends myself, nor anyone belonging to me; but my hatred arises solely from personal knowledge and what I have read. Several of the newspapers are powerful agents on the loan office side for the sake of the standing advertisements, as the 300 per cent. scoundrels can afford to pay well and promptly. In one very shocking case a prominent daily paper wrote a strong leader in confirmation of the exposure and severe indignation expressed by the judge about the doings of a loan manager that had been tried before him. Yet, notwithstanding all this, that very newspaper had the advertisement day by day as usual, and, although the inconsistency of denouncing plundering rascality and taking money for advertising it was pointed out, yet that same loan-office, dirty and foul as it was shown to be in court, is still kept in its place in the advertising columns of the same journal! Newspapers, as a rule, preserve some link of morality between their writing or teaching, and their advertising, whilst some do not.—A Templar.

[47622.]—**Bisulphide Prism.**—A bottle 2½in. diameter, with two sides ground to 60° perfectly flat, is the best. Tin will not do; shellac will last some time to hold the plates on, or marine glue is better. Ordinary plate glass is perfectly useless to use with a telescope; by accident two plates good enough may be got, but optically worked parallel plates are the only sure things. Far better to get two prisms of flint-glass sp. gr. 3·84 1in. high, refracting angle 60°; this will show D clearly double with a power of 12 on the telescope; that is if the prisms are fairly good.—Prismatique.

[47625.]—**Clock Dial.**—If you live in London, take your dial to a Clerkenwell trader, and it will be perfectly restored for you for about 1s. 6d. or 2s. I venture to say you will not succeed in making a pleasing job of it yourself. Dial-painting is very different work to ordinary painting. The paint is of a special kind, and is, I believe, in most instances floated on; not put on with a brush, the plate being made hot before the paint is applied. The flat smooth appearance, so much like enamel, could not be got perfectly with a brush, as you will find if you try it. Of course I am now speaking of well-finished dials. If you intend to do the whole job yourself, scour the old paint off smooth with pumice, wash and wipe dry, and prime with a preliminary coat of paint, which allow to dry thoroughly before the final one is applied. The paint will adhere better if the plate, or dial, as I should have called it, is slightly heated, avoiding any touching of the face with the fingers. Previously trace the position of the figures on thin paper. When the dial is properly prepared and dry, lay the tracing upon it in position, after having rubbed a little charcoal on the back. Trace the figures over with a point. This will give a faint outline upon the newly-painted dial. Then finish up the figures with a fine camel-hair brush, and japan black, or other black paint.—Alfojoe.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[47629.]—**Compensating Lever.**—Will Mr. Stretton, or some of your railway readers, explain the arrangement of "compensating lever" used on the point rods? In Barry's book on Railway Appliances, a diagram is given showing a short lever pivoted at its centre and connected by short links at its ends to the rods. But it is so shown that a pull on one rod would move the other in the reverse direction; whereas the lever should be so arranged as while compensating for expansion or contraction, it so unites the two rods, that they both move in one direction when pulled by the point lever. I can understand if there are to be two of these compensating levers between the points and the lever; but the book does not say so.—A Railway Student.

[47630.]—**Brakes.**—Your interesting notice of Mr. Reynolds's book (on p. 439) has recalled to my mind a question which I raised a year or so ago in another mechanical paper, and that is, "Whether a brake is most effective when it entirely stops the wheel, or when it is so applied as to be just short of stopping it?" I think I was told the former, although I am not quite sure on the point, was the best. However, my opinion is that the latter is the most effective; and this is confirmed by a guard whom I have questioned. Mr. Reynolds would appear also to endorse it; but the muddled sentence in his book unfortunately leaves me in doubt still. Mr. Stretton will doubtless be kind enough to relieve me of it.—H. Stooke.

[47631.]—**Polarity.**—Will any of your correspondents kindly give a consistent definition of polarity in electricity? Something, in fact, more consistent than "a certain kind of two-endedness."—J. H. W.

[47632.]—**Model Loom.**—I am anxious to learn tweed designing, and think that a small model loom would be a great assistance. Could any of your readers give me instructions how to make one?—Diana.

[47633.]—**Bird-Stuffing.**—I have a quantity of foreign bird-skins to stuff. Will any correspondent tell me the best way to relax them? When I relax them in damp sand they either come out not soft enough or rotten, and when set up they always look shrivelled and not of good shape. I can set a skin up with the body new taken out very fair, but its softening the old skins that puzzles me.—Bobolink.

[47634.]—**Organ Stops.**—Thanks to "H. and S. B." for reply to my last query. I should have said that the pipe lips in the stop referred to are inverted. In that case, should there be ears on the pipes, and will "H. and S. B." kindly tell me if the above is the usual form of the stop, as I am uncertain about it?—L. G.

[47635.]—**Home Study—Universal Political Geography and Physical Geography.**—Will any one well acquainted with the subjects kindly sketch out a course by the study of which (with a moderate outlay for books and atlas, &c.) I can obtain a fair knowledge of them?—Anglo-Indian.

[47636.]—**Gas-engine.**—I have a 3 man-power "Sunlight" gas-engine, but cannot get it to work, and am told that the engine is useless Can any of our readers who have bought from "Sunlight," give me any information (I have written him, but letter was returned) about it? Is the engine any use? If it is, I shall be glad to correspond with any one who can assist me, and if not, I should like to know, as I have already spent a considerable sum over it without any result.—Dun Browne.

[47637.]—**Locomotive.**—I would be much obliged if any reader would tell what became of the express locomotive, built by Messrs. Sharp, Stewart and Co., of Manchester, and exhibited by them at the Paris Exhibition of 1878?—Crank Pin.

[47638.]—**Painting.**—I have a large signboard to paint and letter with gold leaf. I can very well do the lettering, but how must the board be prepared? I find that many blacks in time discolour and tarnish the gold. What is the best black, how mixed, and how many coats on new board, and how to proceed with an old board? Would it be better varnished when finished?—Amature Brush.

[47639.]—**Legal.**—To Mr. Wetherfield.—Will you kindly say if it is necessary to have a gun license for the purpose of killing birds destroying fruit, such as currants, &c., in a garden?—B. J.

[47640.]—**Unipolar Induction.**—In the "Minutes of Proceedings of the Institution of Civil Engineers," Vol. LVIII., p. 430, under the head of "Unipolar Induction," by E. Edlund, it is stated that a metallic cylinder with a steel magnet inside is made to rotate by connecting the current from a battery to different parts of the cylinder. Would some of your numerous readers say by what force this cylinder is made to rotate? What metal the cylinder should be made of, what strength of battery is required in Bunsen elements, how the wires from the battery are connected to the cylinder, and what should be the shape of the steel magnet?—X. Y. Z.

[47641.]—**Dandelion and Rhubarb Wines.**—Can any reader inform me how to make dandelion and also rhubarb wine?—Inquirer.

[47642.]—**Silicate of Soda.**—Can any of your readers inform me if silicate of soda will of itself, used as a paint, keep damp out of outside walls, or if mixed with anything, with what?—Inquirer.

[47643.]—**Spiders.**—To Sir John Lubbock.—How do they manage to fly or float? Last Sunday, at noon, in church, I saw a very small blackish spider running up on the shoulder and white straw hat of a lady, and being unable to proceed higher, at last went to the edge of the hat, span a thread about an inch long, hung on it, then worked for a short while, and flew off over my head. It seemed to float like a balloon, its legs half-stretched and bent and motionless. I should have liked to follow it with my eyes, but would not look round amongst so many people.—H. F. L. Meyer.

[47644.]—**Legal.**—Will Mr. Wetherfield kindly give me his advice on the following: I take a business house and sign usual agreement for yearly tenancy, with quarterly rent payments, and six months' previous notice to quit (terminating at Christmas) at £80 per year; two years later the landlord raises rent to £100, without any further agreement. The landlord dies (having only life interest in house), I continue to pay rent to successor of business; presently the trustees (the vendors) put the house up by auction, without giving me any notice whatever of the sale. The chief condition of sale is that "the purchaser shall, on the completion of his purchase, enter into possession or into receipt of the rents and profits of the premises, as from the 25th day of March, 1882, &c." The purchaser soon after sale, serves me with notice to quit, or in default, double rent, &c. Now the question is—(1) Was it not the duty of vendors to give me six months' notice to quit, for the purpose of sale. (2) Has the purchaser any legal right to serve me with notice to quit, seeing that I have received no notice from vendors who *was* the purchaser, or who is entitled to rent? (3) Can I claim compensation for improvement to house and business, having spent £200 upon sinking floors, new doors and windows, chimney pieces, &c., and having given £300 for goodwill, &c.?—Ignoramus.

[47645.]—**Measuring Railway Curves.**—Will some friend be pleased to give me a simple authentic rule to find the radii of curves (after they are laid down) with chord and versed sine.—Ipse Dixit.

[47646.]—**Artificial Milk.**—Twelve months ago I made inquiry through your journal if any one could give me Dr. Frankland's recipe for making imitation human milk from cows' milk. Mr. L. W. Stansell, on the 29th of July, 1881, replied in the "E.M." that the recipe was to be found in Dr. Frankland's "Chemical Researches." I have not been able to get a sight of that work, and shall feel greatly obliged to you or any of your subscribers if you or they would send the recipe to the "E.M." I think it would be appreciated by many besides—W. A. Hunter.

[47647.]—**Boiler.**—Will some reader of the "E.M." give me particulars of a boiler capable of driving a pair of 1in. stroke cylinders, in a boat 4ft. long, beam 6in.?—J. R. G.

[47648.]—**A Cabbage-Broccoli.**—The English Mechanic is, I know, a favourite journal with my brother gardeners. Can any of these tell me anything about a reported achievement of Mr. R. Gilbert, head gardener to the Marquis of Exeter, who, as it is reported, has, with the assistance of Dame Nature, achieved success in the production of a new vegetable? He describes it as a direct cross between a cabbage and a broccoli, and he has named it Chou de Burghley, after the garden in which he works. The new vegetable is said to be a success admirably adapted to the kitchen garden, and a great acquisition to the present limited number of winter vegetables, being very hardy and totally unaffected by the most severe frost.—W. T. B.

[47649.]—**Legal.**—To Mr. Wetherfield.—I should feel obliged if you would answer the following query: About 13 months since I employed a solicitor to collect a debt; a short time after he told me he had issued a county court summons and it would be heard in about a month, but from then till now he has kept finding some excuse for the delay—he says he will push it on, but I am inclined to think he has not taken any proceedings at all; what is the best and cheapest way of compelling him to do something in the matter? Would the Law Institution do anything if I wrote them all particulars? He has some money of mine in hand, enough for five summonses of this amount? If my debtor is not now in a position to pay would solicitor be liable to me?—T. M. B.

[47650.]—**Annual Loss of Life by Fire.**—Will any reader of the "E.M." kindly give an approximate estimate of lives lost and value of property destroyed annually by fire in England.—Fire.

[47651.]—**Examination of Malt.**—To E. S. Beaven.—Thanks for reply and kind offer to give further information. Will you please inform me how, after having prepared a solution as you directed, to find with Fehling's solution the amount of grape-sugar and dextrine present, and then calculating upon the amount present, what heats should be employed in mashing such malt in order to produce mild beers for immediate consumption, when mashing 5qrs. malt with 9 barrels liquor, running under 2½ barrels and sparging the remainder?—Phœnix.

[47652.]—**Faure Accumulator.**—Would Mr. Lancaster or some other subscriber kindly inform me how far the plates of a Faure accumulator should be apart. I have placed them ⅓ to ½in. apart, but I think they are perhaps too near; but I cannot find out whether that is the cause of my failure or not. I made one cell with 8 lead plates, 4in. by 6in., coated with red-lead and wrapped in flannel very closely and placed in acidulated water, and then charged the cell for about half an hour with a dynamo machine used for plating, and then discharged it by letting it drive an electro-motor, charging and discharging it several times in opposite directions until it had been charged altogether 7 or 8 hours. It then gave out a current which heated one inch of No. 36 iron wire red hot. But although freshly charged overnight, not the least indication of a current could be discovered in the morning after it was charged. I have tried various strengths of acid, but with the same result. Possibly you could explain some accumulator simpler in construction than the Faure.—W. Barton.

[47653.]—**Oiling Fish-lines.**—Will some of the readers of "ours" be good enough to say how the better qualities of silk fishing lines are oiled? I notice they have mostly a lemon colour with shining surface and are beautifully got up. I should be glad to know the modus operandi to be pursued by an amateur, as I am desirous of preparing my own.—Pecheur.

[47654.]—**Printing.**—"A Practical Printer" (20326, page 477) gives much valuable information; would be kindly contribute a little more upon colour printing? How are red and blue words, sentences, or whole lines interspersed in printing among ordinary black type? Perhaps he can name some work which fully explains the method of putting these coloured passages in?—J. D.

[47655.]—**Cotton.**—A friend of mine has made a purchase of a considerable amount of calico for dyeing purposes, which at the time of purchase was represented as pure cotton; but we have been told that it contains a considerable amount of jute, which is, I believe, an inferior class of material whose affinity is also less for colouring matter. How may we ascertain for ourselves the presence of this fraud?—W. Binns.

[47656.]—**Woollen and Worsted.**—What are the characters which distinguish the above? Upon what depends their value in the raw and manufactured state?—W. Binns.

[47657.]—**Railway Signal-boxes v. Thunderstorms.**—In case of a severe thunderstorm are the electric instruments in a signal-box considered a source of safety or danger to the signalman there employed?—A. S. H.

[47658.]—**The Becker Brake.**—Is the Becker brake (a German invention, I believe) in use in this country, if so, where, and what are its leading characteristics?—A. S. H.

[47659.]—**Tricycle.**—I have geared my 44in. machine down to a 25, which makes it very powerful in hill climbing, but the spokes often break on straining up hills on the driving side, though they all seem properly tight; spokes No. 10 wire direct, screwed into 4in. hubs, with $4\frac{1}{2}$ gear wheel, 60 spokes in wheels. Will someone of "ours" kindly explain the reason of the breakages? They always break off at the top of the screw, which makes it a difficult job to drill out.—Ex.

[47660.]—**Metallophones.**—I have now several choice pupils receiving instruction on the pianoforte and harmonium. Experience taught that there is great advantage in the lessons given at the same time to several pupils, not only as to economy of time, but, above all, as rapidity of training. I would extend this system to more pupils, but cannot buy half a dozen costly pianofortes. I fancied that two or three octaves metallophones might be made somewhere at a moderate price, and replace the pianoforte for common practice. I vainly inquired here and found nothing but playthings, without any solidity, and having black keys only painted on the white ones, therefore I have nothing better than to apply again to the kindness of the Editor to get, if possible, one information more through this valuable paper.—P. Robin, Cempuis (Oise), France.

[47661.]—**De-alcoholised Wine.**—In a recent pamphlet entitled, "A Great Natural Restorative," the writer states how he cured himself and others, after all other means had entirely failed, of a complication of diseases by the use of de-alcoholised wine. His directions for preparing the purified wine are, in substance, these:—"Select either of the light, inexpensive, natural wines, such as claret, Bordeaux, medoc, or the like (the heavy wines not being so suitable), boil it rapidly with the lid of the saucepan on for 10 or 12 minutes until it becomes perfectly spiritless, which can be ascertained by applying a light to the vapour, which will cease to burn when all the alcohol is driven off." The writer states that he is "not chemist enough to account scientifically for the wine's wonderful transformation." He only knows from experience that it has been converted into a wonderful healing agent. Now, will some competent reader of the "E. M." kindly say if the above is a trustworthy process for the entire extraction of the alcohol, and, if not, what effectual method could be adopted for that purpose? Would not boiling it in an open vessel facilitate the escape of the alcohol? Also, would it not be preferable to use wine which had not undergone the process of fermentation? Does not the fermentation neutralise or destroy some of the properties of the grape which constitute its restorative and healing effect on the human system?—G. T.

[47662.]—**Circulating Decimals.**—What is the rule determining the maximum number of digits in the circulating period of the decimal corresponding to a vulgar fraction whose denominator is p^n, p being a prime number? When the denominator is the product of the different primes p, q, r . . . . is not the maximum number of digits = L. C. M. of $p-1, q-1, r-1$ . . . ? Is not this contradictory to a statement which I find in the "Mathematical" column of an old *Educational Times*, to the effect that if we multiply a circulating decimal having m figures in its period by another having n figures in its period, the product will be a circulate having $9mn$ figures in its period, when m is prime to n. I have to thank "S. J." for his obliging offer in connection with my former query on this subject, but I live so far from town as to make it impossible for me to inspect his copy of Clarke's "Rationale." Does he know anything of Clarke's "Doctrine of Chances"? Is it the same Clarke?—A. J. Smith.

[47663.]—**Joints and Crossings.**—Is there any system or plan in use which is considered an improvement on the present joints and crossings? Of course, it is known that the wheels of a train have to pass over a space of about 2in. wide in every crossing. The result is jarring, wear and tear, and now and then trains off the line. The present crossing is put up with because a better substitute does not come out; but what we want is some means by which joints and crossings should be continuous rails without any space to jump over. Another objection to the present plan is that in consequence of a crossing a junction or a curve cannot possibly be given the proper amount of super-elevation of the outer rail. This absence of elevation has caused many accidents—for instance, had there been no fixed point for the engine wheel for No. 813 to have struck at Werrington Junction the fearful accident could not have happened. Only last week I witnessed a number of waggons leave the line in consequence of a slightly defective crossing, which makes me ask if there is any better system invented.—A. S. H.

[47664.]—**Brake Failures.**—I should be much obliged if a correspondent will clear up a discussion now existing as to what continuous brake it was which recently failed at Bedford Station, M.R., when engine 823 and an express train completely ran past the platform, as there is considerable controversy on the subject.—A. S. H.

[47665.]—**Government Inspector of Mines.**—Will some correspondent kindly say what is the nature of the examination to be passed for obtainining this appointment, and if there is any difference in the examinations for metalliferous or coal-mining inspectors?—Miner.

[47666.]—**Construction of Maps.**—Can anyone favour me with a proof of the law that any map can be painted with not more than four colours, no matter how many the divisions be? I can find no allusion to the law in Hughes' book; see answer to query 46902.—A. J. Smith.

[47667.]—**Partnership.**—To Mr. Wetherfield.—A. and B. wish to carry on business on the same premises. There is no incongruity between their trades, but yet they are quite distinct businesses. They have thought of entering into partnership, each to have the entire control of his own branch of the trade, be responsible only for his own debts, and get all the profits of his own branch. They wish, in fact, neither to gain any profit nor take on any responsibility for the other. The partner who is to live on the premises takes on himself the rent and taxes, and the other common expenses, such as advertising, &c., to be equally divided between both. Could such an agreement be legally drawn up? I expect while the deed of partnership may specify the arrangement about the management and the profits, &c., each must become responsible for the other's debts. In drawing up such an agreement, would it be necessary to get an attorney to do it? If so, what would be his probable charge? What would the stamp cost? Is the law regarding these matters, and also regarding leases, administrations, legacy duty, &c., exactly the same in Ireland as it is in England.—Shan Sholus.

[47668.]—**Lease.**—To Mr. Wetherfield.—What would be the legal cost of getting a 31 years' lease of a house at £26 a year rent, drawn up? Could a covenant be inserted in it, forfeiting it if it left the person's possession to whom it was granted? If so, would such a clause prevent money being borrowed from a building society on it as security, in order to alter the house and put it in thorough repair?—such repairs and alterations being permanent and necessary improvements.—Shan Sholns.

[47669.]—**Grapes.**—I have a small glass-house with several vine trees; one of them is sweet-water grape, and as fruit ripens nearly every one of them bursts open. I should be glad if any one could instruct me if there is any way to prevent their continuing, or is it the wrong sort of fruit tree to be in a house?—Grape Amature.

[47670.]—**Study of Electricity.**—To "Sigma."—What instruments do you recommend as best suited to a student entering on the practical study of electricity, more particularly with reference to the electric light? Any hints as to the best plan of study and the making of the required instruments will much oblige—Phosphorus.

[47671.]—**Institute of Chemistry Exams.**—I am desirous of sitting for the practical examination of the "Institute of Chemistry." Before doing so it is necessary to hold the advanced certificates of the Science and Art Department in Chemistry, Electricity, &c. Can I sit for the advanced examinations in these subjects at once, or is it necessary to pass the elementary examinations in the same subjects previously? If so, can the elementary and advanced certificates be both obtained next May?—Old Subscriber.

[47672.]—**Limelight.**—Will some kind reader give me instructions how to make a cheap and powerful limelight for illuminating in the open air, how to make the burners, the retort, and whether the bags used in a barm press by brewers would answer?—Gasfitter.

[47673.]—**Electric Lighting.**—Can any readers of the "E.M," recommend a good "arc" lamp of small power, say about 200 candle-power, so that 2 or 3 lamps per h.p. of engine may be used? The "Lampe Soleil" or "Sun Lamp" is highly spoken of in prospectus, but I cannot find any reliable information as to its practical working.—D.

[47674.]—**Electrotyping.**—Will Mr. Lancaster or some other of our friends say if they think it possible to deposit copper $\frac{1}{8}$in. thick on the inside of a plaster of Paris cast, with design on the inside (say of a cylinder), and how the cast could be made water-tight so as to make it into the depositing bath, and put anode inside, and have the cast free from air-bubbles? If any of our friends could help it would be a great boon to—E. Bailey.

[47675.]—**Vacuum Gauge.**—To Mr. Lancaster.—Will you kindly give me some information on the following? 1. What is the best form of vacuum gauge for air-pump, and how to make the same? My pump has a small receiver-plate at the end of foot with screw-plug, evidently for the reception of gauge. 2. Can I use a Voss induction maceine to exhibit Gassiot's cascade, aurora borealis, vacuum tubes, &c.?—Air-Pump.

[47676.]—**Magnetic Exploder.**—To Mr. Tolman.—Will you be so kind as to give me full directions how to make a magnetic exploder for firing small fuses? Also directions how to make a machine for depositing about 1oz. of good tough copper on metal surfaces in one hour? Please state the power required to work ditto, and the speed at which it would have to run.—One in a Fix.

[47677.]—**To Unsize Paper.**—I have a number of well-illustrated circulars which are printed on ordinary sized paper, and shall feel very much obliged if anyone can inform me to how unsize them, so that they may be used for blotting-paper.—D'Evlynn.

[47678.]—**Scratched Plate Glass.**—The counter of my shop is fitted with plate-glass cases, the surface of which is so scratched by the constant friction of money on them that it is impossible to see the goods through. Will one of your numerous subscribers kindly inform me if this can be remedied, and by what?—Argyle.

[47679.]—**Induction Coil.**—Will Mr. Tolman kindly send particulars of the coil he mentioned a week or two since, which would go into the waistcoat pocket?—Os.

[47680.]—**Locomotive Boiler.**—To "E. L. P."—Thanks for sketch you sent in the "E. M." of steam dome and starting valve. Should the dome be placed over fire-box or in centre of boiler? Would not seven or eight 1in. tubes be better than the $\frac{5}{8}$in. diameter simply for this reason—When so small in diameter and crowded together should they leak at any time, there is no getting the soldering-iron between them. Would not it be better to have large tubes, and have them placed more apart from each other, so that the soldering-iron could get at edges of tubes? Ought the fire-box and tubes be brazed? How would one large tube through boiler answer, which would be easily got at to repair? Please find my address in this week's Mechanic.—W. H.

[47681.]—**Painting Stove-poles.**—Can anyone recommend a smooth enamel paint which will form a hard smooth coat on the wooden poles which we use for hanging cotton-hanks on to dry in the stoves? Without this, the wood chips and splinters and the yarn is broken thereon.—Mill.

[47682.]—**Electro-Magnetism and Magneto-Electricity.**—Can any reader favour me with a simple explanation of the mode in which, by aid of the principle of conservation of energy, the discovery of Faraday, which forms the basis of magneto-electricity, can be shown to be a necessary consequence of the original discovery of Oersted?—J. H. G.

[47683.]—**To Electricians and Mechanicians.**—I have 30 bichromate cells with windlass, &c., jars $4\frac{1}{8}$ by $2\frac{5}{8}$ by $6\frac{3}{4}$ (inside), carbons and zincs 7 by $3\frac{1}{2}$; also 20 double fluid cells, jars $4\frac{1}{2}$ by $2\frac{1}{2}$ by 7 (inside), porous pots $3\frac{1}{4}$ by $\frac{7}{8}$ by $6\frac{1}{2}$ (inside), carbons and zincs, $2\frac{1}{2}$ by 7. It is my desire to light three or four Swan lamps for about five hours every night, and for this purpose I am willing to purchase additional porous pots, carbons, or zincs, to convert the whole of the above into a suitable battery of 50 cells, for I imagine the outside jars to be practically the same size. The inconstancy of the ordinary bichromate and the expense and trouble of keeping the Bunsen cell working, make them quite out of the question. Yet I notice that when the plates of the former are agitated (as drawn up and let down again) the original strength of the battery seems to return for a short period, so—(1) To counteract polarisation—suppose I were to make the 50 cells into 5 trays of 10 bichromates—could I not use a piece of mechanism, driven by a weight, to raise and lower each set of 10 once in five minutes, so that there would always be 40 cells available for work at one time, and the whole 50 would have been raised and lowered once in every five minutes? Or—(2) Suppose I cut my large plates to the same size as small ones, buy more porous pots, and charge the whole 50 as a double-fluid bichromate battery, or some other, which requires little attention (Daniell's, could I use these to charge some secondary battery, say "Sutton's," during the 19 hours my lamps are not burning? If (1) be feasible, would some kind reader of "ours" design the clockwork for me? I think I could manage the disconnecting part myself. If (2) be practicable, will someone kindly tell me how many accumulators I should require, their cost, &c.? And if both ideas are useless, can anyone suggest anything to help me?—S. H. Salt, 96, Regent's Park-road, N.W.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Aug. 9, and unacknowledged elsewhere:—

R. E. Oakes.—H. King.—South London Machinists' Co.—E. E. Barnard.—W. Blackett.—E. P. Alexander.—A. C. Malley.—Glasgow.—G. Fryer.—Engineer.—Anxious to Know.—E. Martin.—Cremona.—Country Johnny.—A Constant Subscriber.—W. J. Lancaster.—T. H. Delbridge.—A. T.—James Parkinson.—A Constant Reader.—Geo. Revell.—J. H. Huxley.—Cetewayo.

Amateur Astro. (Purely an optical illusion. 70 time 14′ = 16°. Remove a halfpenny 18ft. from your eye, and it will subtend this angle. We do not know what almanac you employ, but the conjunction of Venus and Mars took place at 11 a.m. on August 2nd, at which hour Mars was 5′ South of Venus. Uranus *was* to the North and Westward of Venus at the time you mention, but it is obviously impossible for us to assert definitely that that was what you saw.)—Delta. (You should procure some water from stagnant ditches, and look up the back numbers for many hints on the use of such an instrument.)—Fred. Davis. (Do you really imagine that the device is new?)—A Brakesman. (Should be carried in earthenware or glass. The acid of the fruit attacks the tin.)—One Who would Like to Know. (They can be cut out or removed by the use of caustics, but an ugly scar may be left.)—G. F. (See pp. 535, 607, 621, 622, last volume, and look through the indices.)—W. Walker. (Answered many times—most recently on p. 431.)—H. Graham. (See pp. 97, 120, 141, 167, 240, last volume, and many replies in back volumes.)—Blacksmith. (A pressure of 60lb. actual in a steam boiler is equivalent to a temperature of 307° Fahr. Water boils at a lower temperature on the top of Mont Blanc than it does at the bottom of a coal-mine shaft, because the atmospheric pressure is less.)—J. Mitchell. (We have really no room for weather forecasts clipped from other papers.)—W. F. Denning. (Sorry to have to keep your letter over a week in order to engrave the cut; the Bank Holiday has thrown things a day behind this week, or it could have been done.)—H. Stoke. (We may as well see the finish of "Stonehenge and Sun Worship" before inserting. How much more is it likely to make?)—J. B. (If you do not take proper medical advice and wear a suitable truss, the inconvenience mentioned may cause you serious injury. No amateur doctoring is likely to help you.)—A Tenant. (You have taken your house on a yearly tenancy, and you are bound to give half a year's notice, terminating at the time of year you took the house; consequently, if you give notice at Michaelmas you can leave at Lady Day, 1883.)—Detector. (We are in no way responsible for advertisers' statements, and could not attempt to verify them.)—Candidate. (You would have to trust to the good faith of any one to whom you confided the details of your invention before you had secured protection for it.)—Steamy Windows. (Must either be thoroughly ventilated or else made nearly air-tight inside, with the lamps outside. Ventilation is the best remedy.)—A Young Electrician. (Your question has been frequently answered. See p. 457, for instance.)—B. N. (Leave well alone. If so excessive as to become really weakening, consult a medical man, as personal examination would then be necessary.)—A. B. C. (You have nothing to do but to fry it in oil, taking care that the oil is in sufficient quantity for the fish to "swim" in it. Use nothing but dry flour on the pieces. Almost all kinds, but white fish preferably.)—J. L. (Practically, yes; but at the moment when just escaping from the gun it moves quicker than at any other time.)—Electrical. (Instructions have been given many times. Make the machine described on p. 179, No. 840.)—H. S., Ashford. (Messrs. W. H. and H. Le May, the factors who sold the pocket, inform us that the price mentioned in the *Echo* and the other paper was quite correct, and they add that this is the worst year for blight ever known. £50 per cwt. is certainly a very long price for hops.)—Wm. Cannon. (Any good optician will fit you with glasses to correct your unequal sight. Queries as to prices, &c., should be put privately to Mr. Lancaster and other makers who advertise in these pages. There is no book that we know of on the subject you mention, but any amount of information in our own back vols. The last query we do not understand, but will endeavour to do so if you put it more plainly.)

CHESS.

26. P takes Kt	26. P takes P

White resigns.

Notes by W. Mead.

(*a*) Staunton recommends this move, and gives the combination 9 Kt to Q B 4, 10 Q to Q 5, 10 Kt to K 3, 11 B to R 3, 11 R to K sq, 12 R to K sq, and White has a good game. I think Black might very well play 10 P to Q 3, to be followed by 11 B to K 3 in most cases. According to the last edition of the *Handbuch*, 9 B to Q 5 for White is irresistible.

(*b*) This seems a bad move, but it was played to get out of the ordinary lines.

(*c*) Why not B takes P?

(*d*) 11 Kt to Kt 6 would not be good on account of 12 B takes P (ch.), 12 R takes B (best), 13 Q takes Q, 13 Q R takes Q, 14 P takes Kt, &c.

(*e*) Unsound play, as the sequel shows.

(*f*) Black dare not take the R, *e g*, 18 Q takes R, 19 Q Kt to B 3, 19 Q to Kt 7 (if 19 Q takes R (ch.), 20 K takes Q, 20 K to Kt 2, 21 P takes P, and wins; and if 20 B P moves, 21 P takes B P and wins), 20 Q to R 6, and mates in four moves.

(*g*) If 20 P takes P, 20 B to Q 5 wins the exchange or a piece. In any case, Black must win with three Pawns ahead.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

Holloway's Pills and Ointment.—Precious Remedies.—Cramps, vomiting, and griping quickly yield to their potent properties; the deathlike sickness passes away, and the glow of health returns as the friction of the Ointment causes the irritated nerves to become soothed and calmed. In local inflammation they act like a charm.

OUR EXCHANGE COLUMN.

◆

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

◆

Wanted, all the back numbers of the "**Electro**-Metallurgist and Electric Light Journal." Exchange.—G. C. T. Carter, 3, Castle-street, Reading.

Organ Bellows and Windchests (new and second-hand), in good condition, ready for wind and pipes.—Address, William Johnson, No. 12, Moxley, near Wednesbury.

Street **Electrical Machine**, with bells, mirrors, clock face, indicator, and battery complete, with travelling case, cost £10. Exchange for Lathe or Bicycle.—J. Skinner, Sutton Bridge.

Splendid pair of **Horns**, 6ft. from tip to tip, and 11in. at base. Exchange for good 52in. Bicycle; or what offers?—Address, W. T. P., Poundisford, near Taunton, Somerset.

Wanted, works on "**Phrenology**" and "Electricity." Exchange "Flint's Dairy Farm," "Stow's Survey of London," "Key's Latin Grammar," &c.—Collier, 13, Ormond-road, Hornsey Rise, N.

"**Coddington's Optics**," splendid copy; also Vols. XII. and XIII. "Mackenzie's National Encyclopædia," cost 24s. Exchange Medical Coil, or offers.—Blamires, 276, Southfield-lane, Great Horton.

Quantity of new **Stocks, Dies, and Taps**, Whitworth thread and gauge, also Gas Threads. Exchange for small Slotting or Planing Machine.—Redfern and Son, Bridge-street, Bury.

Wanted, Hand **Punching Machine** to punch 1in. holes through plates half-inch thick, in exchange for half horse-power Engine and Boiler complete.—Address, James Bilsborough, Alderley Edge.

Wanted, Silver **Albert**. Exchange 1lb. of best thin Ivory for inlaying, 1½lb. small block Ivory for turning, 2lb. Ebony.—Collier, 13, Ormond-road, Hornsey Rise.

"**The Lathe, and its Uses**," with appendix; for lady's Silver Watch. Must be a good timekeeper. Approval.—Thos. Cox, Engineer, Hargrave, near Kimbolton.

Coventry Defiance **Tricycle**, ball bearings throughout, a magnificent machine, never been ridden, perfect in every respect, cost £14 10s. Offers requested.—E. A., care Mr. Garrett, Towcester.

Wanted, **Taps and Dies**, Whitworth. Exchange 191 Nos. English Mechanic to date, 70 Nos. "Design and Work" to date.—H. Dominy, Church-street, Shirley, Southampton.

Wanted, Lancaster's **Le Meritoire** or Instantograph, ¼-plate size. Exchange ¼ plate double combination Portrait Lens and Camera, also ¼-plate Lens for Le Merveilleux.—Blamires, 276, Southfield-lane, Great Horton, Bradford.

Le Meritoire **Camera** and Accessories, equal to new. Exchange for anything useful to the value of 35 shillings.—W. Freeman, 31, Clayton-street, Egypt, Hartlepool.

Wanted, Portable **Photo. Apparatus**. Foot Lathe (complete) in exchange.—J., 58, Crossbank-street, Oldham.

Superior 7½in. back-geared **Lathe**, complete. Exchange good bicycle and cash.—F. Underwood, Beverley.

One half horse-power **Horizontal Engine**, 1 part finished, 1 in rough. Exchange for good 6in. Slide-rest, or offers.—Gould, 3, Keen-street, Warrington.

Photographic Apparatus.—Quarter-plate Camera, Lens, Stand, Glass Bath, Measure, Funnel, Scales and Weights, six Printing Frames, two dozen Glass Bottles and some Chemicals, 1½ gross Glass Plates, Filtering Paper, Blotting ditto, Focussing Cloth, Instruction Book. Wanted, small Lathe with flywheel, or £3.—W. Juggins, Toddington, Dunstable, Beds.

Wanted complete **Photo. Apparatus**, suitable for amateur to photograph furniture, &c. (dry plates). Good value exchange offered, drapery, &c.—Address, H. Moore, care of Mrs. Johnson, 102, Bolsover-street, London, W. No post-cards.

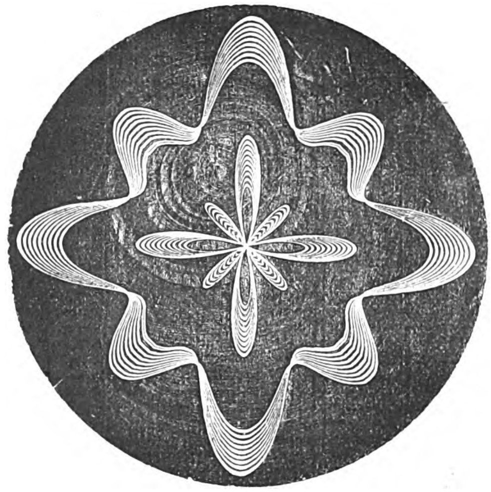
"**Railway Practice and Text**," by Brees, contains upwards of 250 Steel Plate Drawings to Scale, of Railway Plant, Ways, Stations, Bridges, Viaducts, Culverts, Drawbridges, &c., with Specifications of Contracts, in excellent condition. Offers requested in photography. Hot Roller Wanted.—Henry Spinks, 71, Gaisford-street, Kentish Town, London.

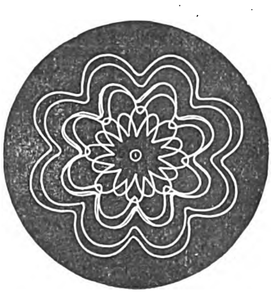
The English Mechanic
AND
WORLD OF SCIENCE AND ART.

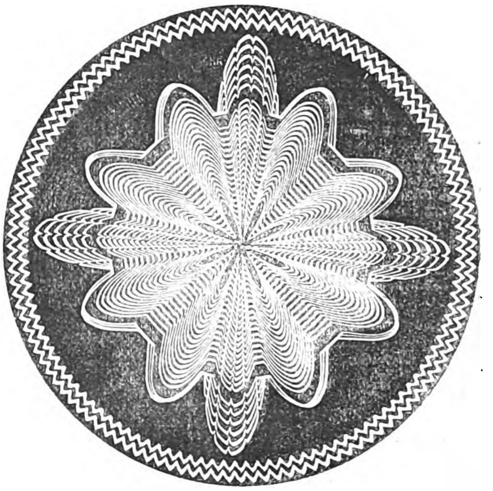
FRIDAY, AUGUST 18, 1882.

THE PRODUCTION OF LOOPED FIGURES BY GEARS.

THIS subject has not apparently received the attention which it deserves, owing, probably, to the fact that it has been chiefly advocated as a means for what an irreverent writer has called scratching patterns. This "scratching," however, when done by able hands produces effects which an artistic eye never fails highly to appreciate; but the work is, nevertheless very tedious, except when done by the aid of that elaborate and ruinously expensive device known as Plant's Geometric Chuck, or by some other apparatus *which does not need the use of a division-plate and index.* These latter appliances call for an amount of patience and resolution which I candidly acknowledge Nature omitted to bestow upon me. To start and stop a lathe some hundreds of times; to tax the eyes and memory by ceaseless peering into a division-plate and remembering the right number of holes to be passed by, is "a caution." Hence, I suspect, originated the geometric and other geared chucks, and also the rose-engine, to say nothing of the geometric slide-rest, rose-cutter, and similar appliances. The self-adjusting index, of which one or two modifications have appeared, only partially meets the difficulty alluded to. The object of the present paper is to call attention to the gear-wheel appliances, by which a repetition of form may be produced; or a repetition of some given motion (as that of a sliding-plate), which, combined with rotary motion, results in the production of waved or looped figures. In the geometric chuck, which is undoubtedly the most perfect of such appliances, the figure is the result of multiplied circular, or cycloidal, or epicycloidal motion, complicated by the eccentricity of certain adjustable slides; while the oval or ellipse chuck and rose-cutter depend for their action upon the motion of a sliding-plate, a given number of times during a single rotation of the mandrel. The rose-engine and geometric-rest carry pattern-plates acting upon the mandrel in the first and on the tool in the second. But in the former, the number of movements to and fro, or oscillations of the mandrel-head, are just so many, and no more, as the undulations on the edge of the rosette; while in the geometric-rest, these oscillations are multiplied by gearing any required number of times. The principle of this rest, therefore, is the same as that of a *geared* rose-engine lathe; and the rest itself is, in all respects, well suited to the intended purpose of cutting many-looped figures. Its cost is, as usual, its one drawback, prohibiting the majority of turners from using it. It does not appear that due attention has been given to the multiplication by gearing of a single simple movement—only one or two amateurs having carried it out in practice. Probably the rocking lathe-head is the best and simplest arrangement to work with, and it is easily fitted up. The lathe-head is mounted on centres, and there is, very generally, a web cast in the bed, just in front of the mandrel-head, which serves to take the centre screw at that part, and if such is not the case, it is easy to insert a plate and secure it by a couple of small bolts. I need not, however, at present enter into details, as any mechanic will readily find means to make so simple an alteration to his lathe. The head and mandrel being thus capable of a to-and-fro or rocking motion, the next consideration is how to produce it. We can put an eccentric disc upon the mandrel with a hoop on it, and carry an eccentric rod to some fixed point behind the lathe, to the wall for instance, which was the fundamental arrangement of the ornamental lathe of the late Mr. Taylor. Or we may put on the mandrel an eccentric disc without any hoop, and let it act against a fixed rubber as the mandrel revolves. Or we may go a step further, and instead of a simple eccentric disc, we may put on the mandrel what is known as a rosette, *i.e.*, a pattern plate of waved outline, or a square plate, or any other. Placing a fixed tool in the slide-rest, faced round to the work, or placing a paper-holding chuck on the mandrel, and a pencil in the slide-rest, we shall find ourselves in possession of an apparatus by which to copy the rosette; but thus far we can do little more. We can make the design large or small, and by certain adjustments of the parts we can somewhat modify the pattern; but we cannot make a rosette of four waves, produce a design of five or six or more, nor can we thereby produce complex-looped figures. But if, as in the geometric rest, we contrive to introduce change-wheels between the rosette and mandrel, we are at once in possession of means for the multiplication to any extent of the oscillations of the lathe-head; and, by giving a suitable ratio to the gears, we can cause a line to travel on and loop itself again and again during a large number of revolutions of the mandrel before returning into itself. Thus the most exquisite looped figures are producible by the simplest means. Then, again, an ordinary rose-engine template, or rosette cannot readily be cut with very deep waves, therefore the undulations are generally rather shallow; but a geared disc, arranged for slow motion, readily produces such a design as that given below. To cut a rosette of such form to work without gears would be a costly matter. The same rosette served for the inside part of the pattern. The second design is also cut in an equally simple way—the pattern plate being, I think, a plain eccentric disc, or a square one—I forget which — but the many undulations are merely the result of the gearing. I have no good block now in my possession of looped figures, although I have some prints of such, showing work that would be taken for that produced by the geometric chuck.*







Now, this kind of lathe merely needs a second mandrel to carry the discs or rosettes. It may be behind where the back-gear is usually fitted, or in front, or above, but so placed as to admit of change-wheels on a radial arm, as in a self-acting lathe. The second mandrel may be carried on centres or in collars. Some kind of fixed bracket fitted to the bed will carry a rubber or rubbers to act on the rosette. An amateur can turn a disc at all events, and set it eccentrically on its mandrel, or fit a cog-wheel; but he will not cut a good rosette, such as those ordinarily used. And there is really no part of this contrivance that ought to be beyond his powers, if he can use fairly the turning tool and file. I do not, however, propose to go into these details of construction in this first paper, but merely to call renewed attention to the capabilities of a lathe of this kind. Nor do I wish to suggest specially this simple and effective mode of working surface patterns. I merely point to it as devoid of the labour and tediousness of eccentric work, and I certainly think it vastly superior in its results. Indeed, nothing but the geometric chuck can excel it in this respect. But I would also suggest the arrangement as a means for producing solid forms. The motion is very slow; it is of necessity of this character, owing to the jar that would otherwise take place at the close of each oscillation, these oscillations being far greater in range than those of a rose-engine. This would allow a revolving cutter—a horizontal one, for instance, driven at speed—to cut out a solid block of the same form as that of the outline of the pattern, much in the way that the Blanchard or copying-

---

* I will lend these for inspection.

VOL. XXXV.—No. 908.

lathe does its work. Or, again, an outline of great beauty may be traced on the surface of a block, and the fret-saw and other tools may then be used to cut the material. But I know of no other plan by which such outline could be well and quickly drawn. I can say, however, that these, when pencilled (which is easier, even, than cutting them), make excellent designs in outline for instruction in freehand-drawing, because all the loops and curves are accurate.

It may, probably strike the rose engine-turner that his own machine will allow the rosettes to be shifted on their axis, or used in combination, so as to enable more complex figures to be cut. But so can those of the present lathe—and they can be used in combination by adding other rubbers, and likewise in conjunction with the eccentric chuck on the mandrel. But the cost is that of plain discs, as compared with rosettes. One can be turned, the other must be designed, drawn, and sawn (or cast), and filed up with the utmost accuracy—one of the most difficult operations, and, consequently, most costly. As to the results, they are not to be compared, the complexity and beauty of those produced by gearing being immeasurably superior.

I have never yet been able personally to understand why the plan advocated of producing many looped patterns by starting with what may be called a single-looped disc, has not been practically carried out by lathe-makers. It is most interesting to watch the gradual development of a design thus produced, whether by Plant's chuck, or such an appliance as the geared rose-engine. Putting gears in the ratio of 12 and 7, we first get, I think, 168, after 24 revolutions of the 7, and 14 revolutions of the 12 wheel. Round and round the mandrel goes, but the line looks hopeless—a very entanglement of bewildering loops—till at last it meets, when least expected, and you have a complex and beautiful pattern. You can deepen it, if you like, for the tool will now start again, and retrace its old path without possibility of error. Keeping the same disc, but altering its eccentricity, you get similar results; but the windings are not so deep. Put the pencil or tool the opposite side of the centre, and all the hills become dales, and *vice versa*. There is not one plan so inexpensive, so simple, or so easy to manipulate; but for really best work the gears should be cut, and all well fitted, and the pattern cut by a fine drill driven by the overhead. The revolution of the mandrel should be by a tangent-screw driven by winch handle, or by a slow-motion pulley on the crank-axle. The small block which I must fain leave to the engraver to copy is the result of a simple square rosette geared as before, and I send it merely to show what unexpected results occur in this mode of tracing patterns. I am well aware of the fact that patterns, even at best, are not equal to solid carving, being chiefly used on draughtsmen, and boxes and stands of various articles. Still, they are extensively worked by the eccentric and other chucks and cutters, and form a not unimportant part of legitimate lathe work. They should be clearly cut, and rather deeply, in order to give the best results, and not merely scratched. Their beauty depends, in fact, on a great measure on the lights and shadows of the delicate tracery. Hence, a printed block gives but a poor idea of the appearance of well-cut designs. I think there is no comparison between rose-work and that produced by an eccentric chuck, even by that of Ibbetson; but if gearing is arranged as well, a very simple rosette of the usual kind will produce work of exquisite delicacy and beauty, and instead of several rosettes being required, two or three and one eccentric disc, quite plain on the edge, will afford means for producing endless combinations of waved and looped figures; and whereas a rose-engine will cost, perhaps, at least, £50—and generally is priced at four times that figure—a good lathe for geared apparatus might be made for £20, capable of far finer work.

J. L.

A CROWN-GLASS ACHROMATIC TELESCOPE.—III.

Aperture.

It now remains to inquire what amount of aperture an instrument of given length will bear. Of course, this will depend upon the exactness of the correction of the various aberrations. Now, if, as in the first number, we suppose red and blue rays to emerge, not parallel, but to be brought to the same point, on the principal axis for direct refractive, or on the secondary for oblique, since there is no secondary spectrum the proposed method would seem to be preferable and more exact as far as chromatic aberration is concerned. Moreover, I have calculated a combination in which the spherical abberration is reduced to something less than the two thousandth part of that of the convex lens alone, which I believe is a more exact correction than has been obtained by the other method; so that we may fairly assume that the ratio of the aperture to the focal length of the convex glass may be made at least as great, if not greater, than when flint glass is used.

Most likely the proportion used by Mr. Wray is, upon the whole, the best for glasses in contact, that is an inch of aperture to about 15in. length of telescope, or, as it may be shown, to 6½in. focal length of convex lens. Thus, for instance, suppose that the focal length of the convex lens is 26in., it will bear an aperture of 4in., and the length of the telescope will be 60. But in the example which I have spoken of above, the length of the telescope, that is, the distance from the convex lens at which the image will be formed, I find to be only 44in., so that an instrument of this length will bear at least as large an aperture as an ordinary one of 60. Moreover, 44 or 45in. is the length of an ordinary 3in. instrument, so that the aperture which the proposed instrument will bear, for a given length, is greater than that of the other in the proportion of 4 to 3, or more.

Focal Length of Instrument.

In ordinary cases, where the convex and concave glasses are in contact, the focal length is identical with the actual length; but when they are separated, it is far otherwise, the actual length is the distance between the image and the convex lens, which is quite a distinct thing from the focal length of the equivalent lens. The focal length of the telescope, I find to be, in the case of the combination above mentioned, 50in., whereas the length of the instrument is only 44.

Recapitulation.

We may now recapitulate the advantages which may be supposed to be attached to this method of construction. The following three appear to be the principal ones:—1. There is no secondary spectrum. 2. The instrument will admit of a larger aperture than one of the usual construction of the same length, in the proportion of 4 to 3. 3. It has greater power, in proportion, 10 to 9. Now, one would really like to know what there is to counterbalance these advantages to such an extent as to make it advisable to use the old method. Perhaps, it will be said, that the practical difficulties of construction will be great. But this only comes to saying that, to produce a first-class instrument a first-rate artist will be needed. Of course, he will, just as with any other method. Each will, doubtless, have its own difficulties, which will require an amount of care and skill which only the best makers are able or willing to bestow. That great exactness is necessary in making the curves of the lenses, I have quite satisfied myself; for, having examined carefully a multitude of combinations, I find that a very small variation in the curves affects the spherical aberration to an extent that was wholly unexpected, rendering thereby great attention to the work necessary. For this reason, I have not added to the list of advantages "a considerable reduction in price;" for though I still suppose that by the method proposed, more optical assistance may be obtained for the money, it will not be to the extent that might at first sight have been expected. One first-class telescope may, on account of the mode of construction, be cheaper than another which is made differently—just as an American clock made by machinery may be cheaper, and perhaps also better, than an English hand-made one. But, as a general rule, whatever requires a first-rate artificer, will always command, more or less, a high price. *Nothing of real excellence can be produced cheaply.* Excellence is what I hope for, rather than cheapness.

As to the mechanical difficulties of construction, the two methods have this in common: that the curves ought to be extremely exact; and, perhaps, this is the only necessary difficulty attaching to the usual method. But in the proposed, there will be an additional thing which requires care—namely, that the *optical centres* of the lenses should be at precisely the proper distance apart, which, however, I suppose will be no difficulty to a good optician. And to this may be added a suggestion made by "F.R.A.S.," that in an ordinary dialyte a source of imperfection is very likely to be incorrect centring; but in this case this difficulty is easily avoided by making the two glasses of the *same size*, and fixing them each at one end of a cell or tube of sufficient length to give them the requisite separation. The cost of making the concave glass as large as the other will not be materially increased, for, by so doing, all trouble and difficulty as to the setting of the concave correctly are avoided. In the example above given, the distance of the lenses is 6½in., the aperture of the convex is 4, and that of the concave 3; that is, the rays transmitted by the former would cover an area of 3in. diameter in the second. If, instead of the latter, we were to substitute one of 4in., we should add but very little to the expense, and, as it will be easily seen, be even less liable to error of centring than when the two are in contact.

But, perhaps, as good a way would be to take a concave no larger than it is wanted, *i.e.*, 3in., and fix them both in a *conical* cell 6½in. long, and 4in. at one end and 3in. at the other. This would render less brass necessary in the main tube, and would, perhaps, be the cheapest. This is Mr. Lancaster's idea.

W. G. Penny.

Lead-Burning.

In directing the attention of my readers to this subject, I am at once introducing them to one of the most interesting and useful branches of the plumbing trade, without a practical knowledge of which, no plumber should consider himself entitled to be ranked as a first-class workman, inasmuch as I consider it to be the most difficult branch of the trade to execute. I also consider that it is the best class work when properly done, because the joints, so to speak, are coalescent. It is a common impression amongst many in the trade, that lead-burning is quite a new art; this, however, is an error, as it is considerably older than is generally supposed. This invention, indeed, like many others, has been doomed to share the usual fate, and has many claimants for its originality, the common idea being that it was invented by Count de Richmont, of France, who, it is reported, instructed one Luke Herbert (a patent agent of the time), to patent the system in England, the patent bearing the date of 1838, though statistics prove that the method was much practised in England far anterior to that date. This only goes to prove that we cannot depend upon dates in the case of many most useful inventions connected with the plumbing trade—for example, ventilation, traps, &c. It is often extremely difficult to arrive at the real origin of many inventions. We read, for instance, of such things as reaping-machines being used on the plains of Rhortia, A.D. 70, or 1812 years ago, and at least 1600 years anterior to the date of our first patents.

Now, since this art of lead-burning was known, as we are aware, at least forty years ago, and much talked about, why is it, we may reasonably ask, that this valuable invention is so little known, and only practised by the leading members of the trade? The answer is, that the machine, as also the bellows necessary for the work, has not been perfected till within this last year or so, and further, sound instruction, in connection with experiments, theoretical and practical, is much wanted from the hands of the practical workman; for it is folly to expect sound and practical instruction from the hands of an unskilled teacher. Such there are to be found scribbling away, professing to teach the whole of the science and art of lead-burning. The teachings of these men only tend to impede progress. They follow in the old rut, which requires new metal to pave the way. They tell a tale about the old square-box machine, and recommend zinc cuttings. I may here remark that there is more difference between this and the modern machine than there is between an old-fashioned brick barrel and a good glazed pipe-drain. The old square machine is clumsy, and totally unfit for general work about a building; whilst the modern one is handy, good working, and not unsightly. Then, again, there is another reason. We have not many good plumbers proficient in the art of lead-burning, who are willing to work in the building trade, no matter how large the firm may be. The few that can burn (I speak of my own burners) are chemical works men, and they are of so selfish a turn of mind that if a lad or stranger asks their advice respecting the art, they are unwilling to give any information—I suppose for the simple reason that they think if a direct and intelligent answer be given that the knowledge will henceforth and for ever be imported from them, and that this is all they will ever be able to learn. Such men should disappear from the company of their co-workers, for they can do better without them. This greediness or unwillingness to impart knowledge is one of the greatest mistakes in the world, and altogether a wrong feeling, based upon a wrong principle, which I will endeavour to overthrow, for experience teaches me that the more a man knows, the more he can learn, and the more willing he is to impart that knowledge, by the very imparting of which he improves himself, thereby becoming more valuable to himself, to society, and to the world at large. It should be known that I am thankful to be able to say that I have not asked any man one solitary question respecting the trade during these last six years of my writings, and that that which I reveal is my own work, not that of my workmen or others. I should, before closing this preamble, state that I have, during the thirty years of my experience and practice, only met with two thoroughly competent lead-burners who were willing to reveal its secrets to the uninitiated in the art—viz., the Messrs. James Pullen and Son, the well-known U-trap makers.

THE ACHROMATIC OBJECT-GLASS.—VIII.

By W. Bradbury.

(*Continued from page* 490.)

I SHALL next give tables of curves computed by Barlow's rules. The compound focus is assumed to be 1,000, and the flint curves invariable for all values of the crown index.

		Flint Curves Invariable for all Values of the Crown Index.											
	·58 ·60 ·62 ·64	474·4 490·8 507·1 523·5	Back surface plane.	386·6 400· 413·3 426·6	Back surface plane.	425·4 440· 454·6 469·2	4254· 4400· 4546· 4692·	343·6 355·4 367·2 379·	3436· 3554· 3672· 3790·	351·3 363·4 375·5 387·6	2810·8 2907·7 3004·6 3101·5	279·6 289·3 299·0 308·6	2237·2 2314·3 2391·4 2468·5

To illustrate the use of these tables, we will take the example previously computed, viz., indices: 1·51 and 1·62, and dispersive ratio = 0·6. By reference to the table, we find for δ = 0·6, that the flint may be either plano or double-concave. Taking it as of the latter form, we find 10 a suitable ratio for the curves. Then at the bottom part of the column headed q = 10· δ = ·6, and in a line with the flint index value ·62, we have 454·6 and 4546· the radii required. Next, in the same column, for the part corresponding to the crown value ·51, and in a line with the flint value ·62, we find 364·5 and 463·1 as the requisite crown radii. These numbers agree with the results we have previously found by calculation.

The next short table is given for the purpose of comparing Barlow's rules with Herschel's. I have taken a fixed value for the ratio of the flint curves, and the inner surfaces are generally adapted for marginal contact. These numbers serve for *one* value 1·5 of the crown index only.

Barlow's rules are useful for finding what kind of crown lens is suitable to combine with a given flint; the reverse process requires a different method. Of course with the aid of the tables, one result can be obtained just as easily as the other; but using only the formula given in the synoptical table, the ratio of flint radii, or value of q', cannot be obtained directly from the value of p. The tables, however, show within what limits the value of q must lie, in order that the inner curves may preserve a definite relation; and we can assume a ratio which we may be certain will give a greater depth to the inner negative curve.

Commencing with the lowest value of the dispersive ratio, it will be seen that this condition of things requires a back *convex* surface: for one not so low, this surface may be *plane*; still, increasing, it becomes *concave*, and beginning with a ratio of 10 to 1 for a value of δ = 0·6, this number may be diminished as δ is increased, until a ratio of 3 or 4 to 1 may be taken as suitable for the highest value of δ.

These approximate guides to the requisite form of the flint lens can only be applicable when the crown is nearly equi-convex, or has its back surface slightly flatter than the front one. The general problem of matching two lenses requires the aid of a simpler formula than that of Barlow: this is supplied by Coddington, whose method we now proceed to investigate.

There is an essential difference in the methods of computing aberration adopted by these theorists which at the outset it may be well to explain. The spherical error of a lens may be considered in two ways—first, as *longitudinal*, and, secondly, as *lateral*—aberrations.

The focus of a ray, nearly coincident with the axial ray, is taken as the standard point from which we estimate aberration. As the ray falls nearer to the margin of the lens, its intersection with the axis is in front of the axial focal point; the difference between these foci is the longitudinal aberration, due to the aperture embraced between the central and marginal rays. If we hold a card square to the axis at the standard focal point, the aberration causes a luminous disc to appear on it, this is termed the circle of *lateral* aberration. Hence longitudinal error is measured *on* the axis; lateral error on a line *square* to it. The former may be said to form the *axis*, and the latter the *radius*, of the base of the aberration cone. Barlow computes the longitudinal error, and treats it as an increment of the focal length, thereby obtaining an intricate expression, which does not admit of reduction or simplification to a convenient form for easy calculation. Coddington computes the lateral error, treating it as an increment of the focal reciprocal; and the expression thus obtained consists of an easy quadratic equation, containing essentially all that is necessary for combining two or more lenses.

Reciprocal quantities enter very largely into optical theorems; and expressions arising therefrom, representing the value of very small quantities, should be kept in reciprocal form wherever possible. Calculations are thereby much facilitated, as we can treat these reciprocals as definite quantities, and take their sum, difference, or product much simpler and easier than by using the actual values.

When a convex and a concave lens are placed in contact, their compound focal length is obtained from the equation:

$$\frac{1}{v} = \frac{1}{F} - \frac{1}{f} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

If now we take into account the error due to a certain aperture, y, we shall have:—

$$\frac{1}{v} + d\left(\frac{1}{v}\right) = \frac{1}{F} - \frac{1}{f} + \omega_1 y^2 - \omega_2 y^2 \ldots. \quad (2)$$

in which ω and ω_2 are the co-efficients of error due to the first and second lenses respectively, and $d\,(1 / v)$ the effect on the compound focus. The lenticular errors are opposite in character; if they are equal in effect a balance of error will result, and the variation of v will be o; or, the focus will be sensibly the same for rays from all parts of the aperture, assuming that it is very small compared with the focal length. As the lenses in contact have equal diameters, we neglect y, and the general approximate condition of aplanatism in a doublet is that $\omega_1 = \omega_2$, or, the coefficient of error must be equal in each lens. Similarly for three lenses, we must have $\omega_1 + \omega_2 + \omega_3 = o$, a condition which implies that one, at least, of the lenses must be concave.

The coefficient of error involves four quantities, besides the constant refractive index; these are the two conjugate focal distances and the two radii. But the sum of the reciprocals of the conjugate foci is constant; so is also that of the radii: therefore each of these pairs may be made a function of one quantity. By this means two values take the place of four, and the aberrational expression becomes simplified to a regular unencumbered quadratic form. A great advantage arises from this result, as one form of equation serves for all kinds of incident rays, for alteration in the positions of the conjugate foci affects the value of one quantity only.

Coddington's expression for the spherical error, when simplified by the rise of the above artifices, takes the following form:—

$$\frac{1}{\mu(\mu-1)}\left\{\frac{\mu+2}{\mu-1}\,x^2 + 4\,(\mu+1)\,ax + (3\,\mu \times 2)\,(\mu-1)\,a^2 + \frac{\mu^3}{\mu-1}\right\}\frac{y^2}{8f^3} \quad \ldots\ldots\ldots\ldots \quad (3.)$$

This is the co-efficient of y or value of ω in eqn. (2); it is the variation, not of the focus, but of the focal reciprocal. Hence, to combine two lenses, we must take the equation of each, and find what valves of a and x make them equal.

The conjugate foci are expressed in terms of a, thus:—

$$\frac{1}{u} = \frac{1+a}{2f} : \frac{1}{v} = \frac{1-a}{2f},$$

or $$a = \frac{2f}{u} - 1 = 1 - \frac{2f}{v}.$$

(a being the radiant and v the refracted focal distance.)

The radii are expressed in terms of x thus:—

$$\frac{1}{r_1} = \frac{1+x}{2f(\mu-1)} : \frac{1}{r_2} = \frac{1-x}{2f(\mu-1)},$$

or $$x = \frac{2f(\mu-1)}{r_1} - 1 = 1 - \frac{2f(\mu-1)}{r}.$$

Or, without using f, we have:—

$$a = \frac{v-u}{v+u} : x = \frac{r_2 - r_1}{r_2 + r_1}$$

That is, x and a are quotients of the difference and sum of the radial and focal distances. The points v and r_2 are measured to the right of the lens; u and r_1 to the left. Ween parallel rays fall on a lens, the value of a is always unity; so that for the front lens $a_1 = -1$. For the second lens, we may express it in terms of the dispersive ratio: f, taken negatively, is the focus of the second lens; u, taken negatively, is the focus of the first, and the ratio of these is δ. So that, instead of $2f / u$ we get $a_2 = (2 / \delta - 1)$, when the crown lens is in front; but if the flint lens be first, $a_2 = (2\,\delta - 1)$.

Hence, for the front lens of an achromatic combination, a_1 is always negative and equal to unity; for the second lens, a_2 is always positive, and may be greater or less than unity; or, if $\delta = 0{\cdot}5$ in the second formula $a_2 = 0$.

From this it will be seen that the second of the involved quantities in the equation may be readily found; one value of x must then be assumed, and it matters not to which of the lenses it relates; as in either case, a similar quadratic equation results, whose roots are easily determined.

Let us examine what values of the root x_1 and x_2 are suitable. If $x_1 = -1$, the lens is plano-convex; $x_1 = o$ equi-convex; $x = +1$ convexo-plane. These are the extreme values; but evidently the most suitable numbers will be small positive or negative fractions not far from zero.

For the second lens, the roots must generally lie between o and $+1$, unless x_1 be a large negative fraction, in which case x_2 may exceed positive unity, showing that the last surface is convex.

When the usual combination is reversed by putting the flint lens in front, x_1 will always be greater than negative unity, and x_2 a positive quantity greater or less than unity.

We will next ascertain the relation between x_1 and x_2 that shall bring the inner curves into contact. For the back surface of the first lens we have:—

$$\frac{1}{r_2} = \frac{1 - x_1}{2F(\mu - 1}$$

For the first surface of the second lens we have:—

$$\frac{1}{r_3} = \frac{1 + x_2}{2f(\mu_1 - 1)}$$

Now, if these equations are alike, evidently:—

$$\frac{1 - x_1}{1 + x_2} = \frac{\delta(\mu - 1)}{(\mu_1 - 1)} \ldots\ldots\ldots\ldots (4).$$

Or, since $(\mu - 1)\,(\mu_1 - 1)$ is the ratio of refractive powers (which we will denote by ρ):—

$$\frac{1 - x_1}{1 + x_2} = \delta \cdot \rho.$$

Either ratio may thus be found in terms of the other.

When the flint lens is first, these expressions become:—

$$\frac{1 - x_1}{1 + x_2} = \frac{\mu_1 - 1}{\delta(\mu - 1)} = \frac{1}{\delta \cdot \rho} \ldots\ldots\ldots\ldots (5).$$

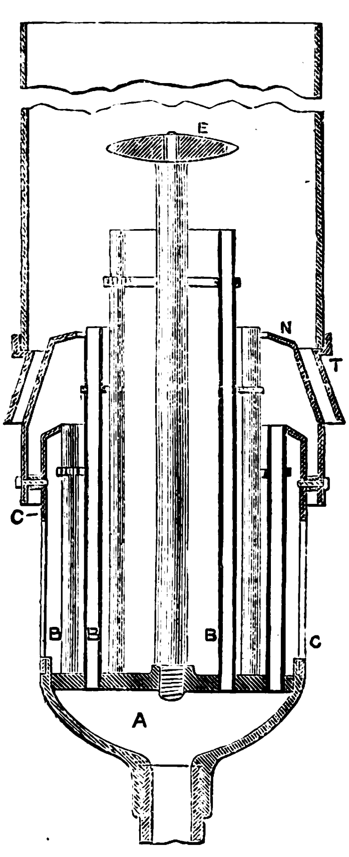
Thus, by slightly extending the calculations, we can introduce the condition of contact between the interior curves; or, by similar reasoning, we can apply any required condition to them.

These are all the preliminary operations that are requisite for using Coddington's formula. Of course, tables of aberrational equations for each refractive index must be formed; this can readily be accomplished by substitution in the literal equation (3) previously given.

(*To be continued.*)

SIEMENS' IMPROVED GAS BURNER.

On page 532, Vol. XXXII., we gave a description of Mr. Frederick Siemens's regenerative gas burner, which has now for some months been fitted to a number of lamps in Holborn and elsewhere. That gentleman and his brother Mr. C. W. Siemens have been devoting much attention of late to the improvement of gas-burners (see the paper on p. 372, Vol. XXXIII.), but to Mr. Fred. Siemens of Dresden seems to have been most successful in the matter of burners, and judging by his most recent device has abandoned the use of the pipe connecting the top and bottom of the "regenerative" burner. The improved burner is of the following construction. From a circular cavity or chamber supplied with gas rise two, three, or more sets of small metal tubes which may be vertical or slightly inclined. Each set of these tubes is arranged in a circle, and the circles are concentric with one another. The tubes of the innermost circle are highest and smallest in diameter, those of the next circle outwards are somewhat lower and larger in diameter, and so on, the outermost tubes being lowest in height and largest in diameter. Outside the outer tubes, is fixed a metal casing perforated at its lower end and having its upper end terminating in a lip or flange projecting inwards level with the mouths of the outer tubes, and this lip is by preference notched or indented so as to present a starlike appearance. Secured to the upper part of this casing above its perforations is another casing of larger diameter, so as to leave an annular air passage between it and the inner casing. This second casing is coned inwards and star lipped reaching nearly to the mouths of the second set of tubes. And in like manner other successive casings are arranged according to the number of circles of tubes. Generally, however, three circles of tubes with two casings as described are sufficient, there being a central star notched button or deflector above the middle circle. Outside of all is a gallery or ring presenting a socket to hold the glass, an annular air passage being formed between this gallery and the outer casing. The gas issuing from the several sets of tubes has air supplied for its combustion partly through the perforations of the lower casing and partly through the annular spaces between the successive concentric casings, and as these as well as the tubes are of metal in intimate connection the heat is very perfectly diffused throughout the burner, and the air is considerably heated during its passage to the flames, increasing their brilliancy, while the cooling effect of the air on the tubes saves them from injury. Although the above mentioned air deflectors are by preference notched, or of star shape, yet they may also be used without notches. In order to regulate the gas supply to the burner notwithstanding variations of pressure a regulator of the following kind is employed. Within a cylindrical casing is fixed a collapsible vessel somewhat like a concertina bellows, consisting of a number of thin rings of elastic sheet metal attached to one another at their inner and outer edges alternately. The lowest ring is attached to the bottom of the casing, and the highest ring is attached to a disc through which there is a small hole or several small holes. The



disc also carries at its centre a cone projecting upwards and entering the mouth of the pipe leading to the burner. The gas enters the bottom of the collapsible vessel from which it can issue into the casing through the hole or holes in the disc, and from the casing it passes to the burners. According as the pressure of the gas is greater or less the collapsible vessel becomes more or less distended so that the cone on its disc throttles more or less the passage leading to the burners.

The sectional figure annexed shows the general construction of the burner. A is the gas chamber connected direct to the supply, and rising from it are the three concentric rings of tubes B. Surrounding the outermost ring is a casing C fixed to the chamber A, but having around its lower part a number of slots through which the air enters freely. The second ring of tubes is surrounded at their upper parts only by another casing N which terminates at the top of the tubes in a notched air deflector. A third casing T serves as a gallery to support the chimney and to admit a further supply of air for cooling the glass. A notched air deflector E is carried on a central stem and is fixed a short distance above the tops of the inner ring of tubes. The tubes are so graduated in size that the inner give the shortest flames, the object being to insure the termination of all the flames at about the same level. The air entering through the openings in the lower part of casing C passes between the tubes of the several rings and rises up in a more or less uniformly distributed manner, as does also that entering the lower ends of the casing N and being caused by the several notched deflectors to impinge in divided streams upon the ignited gas jets issuing from the tubes, produces an intensely luminous flame. All the metal parts of the burner are in solid connection with each other, so as to prevent the injurious overheating of certain parts, by causing the heat to be more or less uniformly distributed by perfect conduction, which heat is then in great measure taken up by the entering air, thereby also increasing the luminosity of the flame. In consequence of the good conduction of the heat from all parts of the burner, the use of porcelain or steatite for the mouths of the burners can be dispensed with, but the central deflector E is by preference made of porcelain in order to act as a reflecting surface for the light. The heat conducting powers of the metal gas tubes B and the comparatively large issue orifices effectually prevent the deposit of solid carbon within the tubes, and as the air becomes heated by contact with the external surfaces of these, an upward draught is produced whereby a comparatively short glass chimney is rendered applicable.

PERRY'S METHOD OF DISTRIBUTING ELECTRICAL ENERGY.

A METHOD of distributing electrical energy has, together with the apparatus necessary for carrying it out, been recently patented by Mr. John Perry, the professor of mechanical engineering at the Finsbury College of the City and Guilds Institute. In any scheme for distributing electrical energy, it is of the first importance to so arrange the wires, &c., that any consumer may use the current for the purpose of illumination, or for motive power, just as he pleases, without being interfered with in any way by the fact that other consumers have turned off their lights or turned on their machines. Various methods have been suggested for effecting the constant and unvarying distribution of electricity; but the method preferred by Prof. Perry consists in combining with the dynamo-machine, one or more magneto-electric machines or other form of electrical machine or battery which will produce in a circuit an electromotive force which is constant and independent of any other electromotive forces in the same circuit. First: When the consumers' wires are arranged in parallel arc, it is usual to employ a "series" dynamo, and in that case is introduced into the main circuit a magneto-electric machine or battery producing a constant electromotive force equal to the electromotive force which ought to exist between the supply cable of any consumer and the return cable or earth. The dynamo-machines ought to get constant speeds, being driven by engines with good governors, and these speeds ought to be what have been termed the critical speeds. That is, the speed of each dynamo-machine ought to be such that the electromotive force created in it by its motion ought to be proportional to the current circulating in the coils of its field-magnets. In scientific language the intensity of the magnetic field in which the armature rotates ought to be proportional to the magnetising current. It is evident that one large dynamo-machine is preferable to two or more smaller ones in such a case, and it will be better to employ larger field-magnets than are usual in dynamo-machines; but to use the dynamo-machines at present in use will not introduce much discrepancy from the conditions required. As an example, if there is only one dynamo-machine, and if the resistance of the main cable, return cable, and machines, in fact of that part of the total circuit which is supposed to be constant be, let us suppose, 3 ohms, then we find that the dynamo-machine ought to be run at such a speed that the electromotive force in volts produced in its moving parts is three times the current in ampères which flows through the field-magnets; consequently, this speed can readily be found by experiment. Suppose the constant electromotive force of the magneto-machine to be 50 volts; its resistance 0·3 ohm, and the resistance of the dynamo-machine and of the other unchanging parts of the circuit 2·7 ohms, and suppose that the speed is that at which the electromotive force produced by the rotating armature of the dynamo is 3 times the current. Now let there be a consumer's resistance of 2 ohms, the total resistance is 5 ohms. Evidently the electromotive force produced in the dynamo is 75 volts, and the total electromotive force in the circuit is, therefore, 125 volts, and, as the total resistance is 5 ohms, the current is 25 ampères, giving an electromotive force of 50 volts between the ends of the consumers' part of the circuit. Now if the consumers' resistance increases to, say, 12 ohms by some of the consumers ceasing to use their circuits, there is an instantaneous alteration of the electromotive force produced in the dynamo to 12½ volts or 62½ volts in the whole circuit, and 62½ divided by 15 gives 4 1-6th ampères; and this means 4 1-6th multiplied by 12 or 50 volts as before between the end of the consumers' part of the circuit. Instead of using the dynamo-machine of the ordinary type, that is with its field-magnets forming part of the main circuit, it is sometimes used in the form where the field-magnets act as a shunt. When using a dynamo-machine of the shunted field-magnet type, it is preferred to place the magneto-machine or other source of constant electromotive force in a part of the circuit which is quite outside the machine; that is in the main circuit, so that the current passing through it is that which goes to the supply cable. The speed may be determined, which will produce the desired result. Second: So far, we have considered the lamps or machines which are supplied with electricity to be "in parallel arc"; when, however, the lamps or machines to which electricity is given are "in series,"—that is when the same current is to go through them all, what we effect is that they shall all receive the same current of electricity, however the resistance of one or more of them may vary. This is attained by using, instead of an ordinary "series" dynamo-electric machine—one or more dynamo-machines constructed so that their field-magnets are a shunt between their brushes, or the binding screws connected with their brushes, combined with one or more magneto electric machines or some other form of electrical machine or battery which will produce an independent electromotive force. For simplicity, take the case of one dynamo-machine and one magneto-machine. Let the shunt part of the dynamo be called M, whether it contains merely the wire of its own magnets, or has the magneto-machine inserted in it. Let the part of the dynamo which contains the wire of the revolving armature be called A, and let us be able to insert a magneto-machine in this portion of the circuit if we please. Now the two ends of A and the two ends of M are the same, and these may be called the binding screws of the machine. If these binding screws are joined to the two ends of any external wire or cable or system of lamps in series, which we may call the external circuit being really the part of the whole circuit which is external to the machine, then if we introduce a magneto-electric machine in the part A or in the part M, or if we have a magneto-machine in A and another in M we can, by giving a certain constant speed to the machine, deliver a constant current of electricity through the external circuit, however the resistance of that circuit may vary. The constant current we find to be that which the magneto-machine or machines would produce in a circuit whose total resistance is equal to the resistance of A. Thus if a magneto-machine or other constant source of electromotive force producing a constant electromotive force of 100 volts is inserted in A, and if its internal resistance is 0·3 ohm, and if another magneto-machine whose constant electromotive force is 160 volts and internal resistance is 2 ohms be inserted in M, and if the resistance of the revolving part of the dynamo (from brush to brush if it were working in the ordinary way) be 0·5 ohm, then when joined up to an external circuit in the manner described, and run at constant speed, the current in the external circuit will be the sum of 100 and 160 divided by the sum of 0·5 and 0·3, or 325 ampères, or else it will be the difference of 100 and 160 divided by the sum of 0·5 and 0·3, or 75 ampères; the latter case being one in which the magneto-machines oppose each others' actions. But in either case the current in the external circuit will not alter although its resistance be altered. The constant speed at which the Dynamo-machine should be run may be determined by experiment and calculation. The speed should be such that the electromotive force produced in the armature by rotation is equal to the current in M which includes the field-magnets multiplied into the sum of the resistances of A and of M. It is possible by running even an ordinary Gramme machine at lower speeds than usual to get the electromotive force produced in the armature to be proportional to the current in the field-magnets. As to the distribution of electrical power to persons who consume it in parallel arc, and distribution of electrical power to lamps or machines which are joined up in series in one circuit, the dynamo-machine must be run at a constant speed. Suppose it is found by calculation that it is necessary to run a dynamo-machine at such a speed that the electromotive force in volts produced in the revolving armature is equal to the ampères of current passing in the field-magnets multiplied into 2 ohms. Make an experiment letting a current of 20 ampères pass through your field-magnets, and let them be disconnected from the armature circuit. Revolve your armature at a speed of, say, 200 revolutions per minute, and let us suppose that you find that an electromotive force of 160 volts is produced by the rotation. If the machine is a suitable one for your purpose, so that the proportionality of electromotive force to the product of field-magnet current and number of revolutions holds, then the constant speed required is 2 multiplied by 200 and by 20, and divided by 100, or 80 revolutions per minute. In the process of electroplating, we have exactly the same conditions as there are in the distribution of electrical power when the consumers' connections are in parallel arc; that is, in an electroplating bath there ought to be maintained a constant difference of electrical potentials between the two sides of the bath however few or many objects may be undergoing the electroplating process. Instead, therefore, of employing a single dynamo-machine, which is the common plan at present, Prof. Perry employs in the circuit one or more magneto electric or other electrical machines or batteries, which will produce a constant independent electromotive force, as well as one or more dynamo-machines. In the process of charging accumulators the current that should pass through each cell depends on the size and weight of the accumulator, but not at all on the number of accumulators to be charged. When it is desired to vary at will the number of accumulators to be charged, we arrange them partly in series and partly in parallel circuit, and use either the first or second system of supplying constant electric energy to each accumulator. With the first arrangement, when it is desired to increase or diminish the number of accumulators charging, we increase or diminish the number in parallel circuit, leaving the total number in series unaltered. On the other hand, when the second arrangement for supplying constant electric energy to each accumulator is employed, and it is desired to increase or diminish the number of charging, we increase or diminish the number in series, leaving the number in parallel circuit unaltered.

Prof. Perry gives the following explanation with algebraic formulæ:—"In the first case where we want a constant difference of electric potential a established at the two ends of a resistance r, if R is the resistance of a magneto-machine or battery and dynamo-machine and any other unchanging part of the whole circuit; then let the constant electromotive force produced by the magneto-machine be a, and we know that we can have the electromotive force produced by rotation of the armature of the dynamo-machine proportional to c the current, say that it is equal to $n\ b\ C$ where n is the number of revolutions per minute, and b is a constant number which can be determined by experiment. Then the whole electromotive force of the arrangement is $a + n\ b\ C$; but by Ohm's law this must be equal to $R\ C + r\ C$. If, now, we make $n b$ equal to R it is obvious that $r\ C$ must always be equal to a, however r and C may vary. Again, in the second case, where we want a constant current C to flow through the external circuit of a shunted dynamo-machine. Let there be a magneto-machine, or battery of constant electromotive force inserted in the armature circuit of the dynamo-machine, and let the current in the armature be c, in the magnets c^1, and let the electromotive force e produced by rotation of the armature be $e = n\ b\ c^1$. Then we know that the following statements are true, R being resistance of dynamo armature from brush to brush, R^1 being resistance of magneto machine, r^1 being the resistance of the shunt circuit of dynamo, r being variable resistance of outside circuit. $c + a - (R + R^1)\ c = r^1\ c^1 = r\ C$ and $c = c^1 + C$. It follows from this that $C \left\{ (R + R^1)(r + r^1) + r\, r^1 - n\ b\ r \right\} = a\, r^1$. Hence, if $R + R_1 + r^1 - n\ b = o$, then $C = \frac{a}{R + R^1}$ and is, therefore, constant. Again, in the second case, if the constant source of electromotive force a is inserted in the magnet circuit, we have $c = n\ b\ c$, $e - R\,C = (r^1 + R^1)\ c^1 - a = r\ C$, $c = c^1 + C$. It follows from this that $C \left\{ R\ r + R\,(R^1 + r^1) + r\,(R^1 + r^1) - n\ b\ r \right\} = a\,(n\ b - R)$ so that if $n\ b = R + R^1 \times r_1$ we must have $C = \frac{a}{R}$ that is the constant current produced in the outside circuit of the shunt dynamo is the current which the constant electromotive force of the magneto machine or battery is capable of producing through a total resistance equal to that of the armature circuit of the dynamo-machine. In the above mathematical demonstration I have only spoken of resistance in the outside circuits as varying; it is obvious that when we work motors or charge secondary batteries, these exert back electromotive forces which may vary, and such varying electromotive forces will enter into the calculations as if it were the resistances that varied."

CHANGES IN MEDICAL OPINION AND PRACTICE.

IN an address at Worcester last week before the British Medical Association, Dr. Wade, physician to the Birmingham General Hospital, dwelt at some length on the change of opinion which had occurred with relation to blood-letting, and the causes which led to it. In 1832 this was an all-pervading method of treatment. Indeed, at first sight, it almost obscured the perception of any other therapeutical means or agents. The difficulty was to name diseases in which it was not used, not those in which it was. Its prevalence might be brought very vividly before them by a quotation from a contemporary author, who said "Blood-letting is not only the most powerful and important, but the most generally used, of all our remedies. Scarcely a case of acute, or indeed of chronic disease, occurs, in which it does not become necessary to consider the propriety of having recourse to the lancet, or to estimate the effects of blood-letting already instituted." But, to get a full impression of this frequency, they must read, one after another, the records of cases in which medical, surgical, traumatical, and obstetrical bleeding from the arm was practised. Indeed, that did not exhaust the category. The chief resource of preventive medicine was to let blood from the arm every spring and fall. Since 1832 a revolution of opinion had taken place, the like of which the history of medicine wots not of. For, be it remembered, this was not the case of a transient phantasy, but the well-established practice of centuries, which had withstood, not only the ravages of time, but repeated volleys from the batteries of wit and satire. In tracing the causes of the revolution which had taken place, he pointed out that the intellect of the period to which he referred was coming to distrust, and ultimately to banish, "violence, harshness—the darker shades of repression—from the education of the young, from the treatment of the insane, from the punishment of criminals, and to substitute for those time-honoured but most ineffectual processes a rational moderation." Well-known political reforms were the work of that period, and the outcome of the spirit just mentioned. Reconsideration of ancient dogmas was the order of the day; and that reconsideration in many instances led to their effacement. Another influence was coming into play. The *vis medicatrix naturæ* had been recognised in medicine from time immemorial; but its efficiency as an antagonist to disease had been at different times very differently estimated. The formula might be the same; but the conceptions it embodied might differ to an extent which was equivalent to a difference in kind. It would seem that formerly nature was esteemed but a very feeble and humble assistant, whose influence was nothing unless rigidly controlled and directed by a more intelligent, or reinforced by a more potent, agent. This idea was all in favour of robust and strenuous therapeutics, and they were accordingly dominant. It was assumed then that nature could do nothing without assistance. We do not assume, but know as a matter of fact, that in many instances nature unassisted can do everything. "Expectant medicine" is the term used to designate the line of conduct, or perhaps rather the mental attitude, which this knowledge imposed upon them. It was sometimes derisively described as the art of laboriously doing nothing—of trusting to Providence; and it was supposed to be a lazy, shiftless mode of shirking responsibility. All sound principles were liable to corruption; and this particular principle might—indeed, in the hands of those who did not appreciate its essence, did—lead to a neglect of therapeutical means. But, rightly understood, it was anything but a lazy and shiftless method; it necessitated a constant, anxious, and laborious study and observance of the tricks and turnings and vagaries of disorder and disease. So far from this system, when intelligently followed, leading to a disbelief in the potentiality of drugs, it seemed to him to do exactly the opposite. Having learnt with more accuracy and greater fulness the natural progress of disease, they were the better able to estimate the extent to which the direction of that progress was capable of deflection by the administration of remedies; and it passed his comprehension how any person who had intelligently and dispassionately watched the progress of disease, when subjected and when not subjected to drugs, could refuse to believe that they held in their hands gigantic forces to oppose to those of an aberrant nature. Various causes, no doubt, co-operated in generating and maturing expectant medicine. One, which we know did at a later period markedly contribute to its development, was even at this period beginning to attract attention. Laymen for the most part do not pretend, and do not seek, to understand the merits of opposing medical theories or schools of thought. It is on this broad ground, and as an historical fact and not a critical opinion, that I say that Hahnemann was commencing to subject, not so much the public mind to his doctrines, as the bodies of the public in this country to his treatment. The bulk of the medical profession rejecting his doctrine of infinitesimal doses, the cures apparently wrought by such medicaments were and are judged to be instances of spontaneous recovery. That interpretation necessarily facilitated the reception of that higher ideal of the powers of nature which was then arising; indeed, from that it was possible that the suggestion proceeded. Such a conception would undoubtedly make more easy the relinquishment of severe and violent modes of treatment, and amongst these blood-letting was conspicuous. But systems were not swept away without some faults inherent either in themselves or in the individuals who administer them, and the misuse of blood-letting, Dr. Wade contended, was the real origin of its abandonment, as the misuse of certain drugs had led to their being altogether discontinued. In 1820 a provincial practitioner, a physician at Nottingham—Marshall Hall—opened the first parallel of the siege, which, in his opinion, eventuated in the razing of this stronghold. Hall's last words on the subject were published in 1836, and but a very few years elapsed before it had ceased to be practised. It was most curious that the intention and object of his publication was to regulate, not to abolish, bleeding. It was true that he clearly demonstrated that it might be, and had been, so employed as to produce not only injurious, but distinctly fatal, effects; but he also taught its utility, authorised and, indeed, recommended its employment, though with limitations not previously laid down. How, then, it may be fairly asked, could such teaching result in its abandonment? The printed records showed distinctly that this remedy had come to be used in all sorts of cases, at all sorts of times, as a matter of course; as one that could do no harm at the beginning of an illness to cut it short, in the middle as routine treatment, and when things became desperate as a forlorn hope—as the last, the only, chance. The plain blunt statement that persons had been bled to death *secundem artem*, the simple detail of the facts of individual cases, proving to the most unwilling reader that this statement was true, must have pricked the conscience of many an honest practitioner. Men came to look at bleeding from an exactly opposite point of view to that which they had previously occupied, and began to see that it was not absolutely necessary at the onset of disease, was of doubtful safety as a routine treatment during its height, and at a grand crisis might even be fatal. Could they wonder that in a few short years the practice had ceased to exist. It would be improper, and indeed be misleading, to leave this subject, without adverting to another explanation of this astonishing change in practice. It had been attributed to a change of type in disease. A chief supporter of this view was one of the ablest and worthiest representatives of medicine in our time—worthy, indeed, of any age—Sir Thomas Watson. "What has not been shown," he says, writing in 1857, "is that the human constitution is incapable from influences to us unknown, of undergoing alterations, in respect to the manner in which it is affected by inflammation, and by the reputed remedies of inflammation. For my own part, I am firmly persuaded, by my own observation, and by the records of medicine, that there are waves of time through which the sthenic and asthenic character of disease prevail in succession: and that we are at present living amid one of its adynamic phases." It was not necessary to discuss the soundness of the view so succinctly stated. For the purpose of his argument, he could have wished to be able to give it an unequivocal assent. It enforced, with the most eloquent brevity, the supreme and paramount necessity of a constant, even suspicious, watchfulness, of their own operations and of the workings of nature. Let them turn to some further considerations, which especially enforced this obligation. Whilst unreservedly admitting that medicine was imperfect, they all believed that it was not stationary, but progressive. Each year furnished more exact knowledge as to the structure of the body; the uses of various organs; their *modus operandi* in health; the manner in which their operations are disturbed by disease; the effect of such disturbance upon other organs; the causes of these disturbances; and the extent to which they may be controlled or interrupted by diet, drugs, or other agents. They were from time to time presented with new instruments, or new means of exact research, with new drugs, and with new facts or theories respecting old ones. But that was by no means all. They were furthermore being, not infrequently, urged to apply that new knowledge, or those new views, to the treatment of disease; to employ a new drug, to discard an old one, or to use it in conditions to which it had heretofore been considered inapplicable, or to use it in doses of much less or of much greater magnitude than they had been wont to administer. Examples would at once occur of beneficial changes, which had of late years been in this way introduced. It was possible that they might have to go much further in some of these directions. As regarded the dosage of drugs, he was strongly inclined to think that both as regards *maxima* and *minima*, we were too closely bound by the fetters of posological tables, or of our habitual prescriptions. It should, however, be remembered that there were frequent pitfalls being daily dug in their path by the constant search after improved methods, and there was especially the danger of too hasty generalisation. It was not so many years ago that there flourished a great clinical teacher, famous alike in the wards of an important metropolitan hospital and by the bedside of the wealthy. Was it a truism that to be sound, medicine must be based on physiology? He was an assiduous cultivator and eminent teacher of this science. In the zenith of his fame he sought, as they knew, to establish the plan of treating acute disease by alcohol in almost unlimited quantity. Was it surprising that his views—earnestly enforced by word of mouth and in fascinating essays, propagated by an enthusiastic and numerous band of disciples, and not without an important substratum of truth—became popular, and that his example was for a time largely followed? What was their position now with regard to alcohol and its administration as a drug in acute diseases? Exactly what it was before this mischievous delusion arose. There was no acute disease in which alcohol was necessarily required. On the other hand there was no acute disease in which special circumstances might not arise which necessitated its use in small, or in large, and even in very large doses. The medical mind never had ceased, and probably never would, to hanker after specifics. From time to time some drug was elevated by its undeniably remedial effects into this position, and their hopes were flattered that they possessed one. The idea was most grateful. In the first place, what a saving of labour, thought, and trouble; nor was there anything in that feeling of which they need to be ashamed; for with many specifics to lean on, their lives would be sufficiently arduous. Then, again, they all felt, though perhaps they might try to hide it from themselves, the uncertainty of medicine. How delightful to know that, to the credit of their own reputation, and to the advantage of their patients, they had for at least one disease a remedy that could not fail. They might, however, depend upon it, that to those who harboured such a wish, and indulged in contemplating the possibility of its fulfilment, the danger was great of erroneously believing that they had achieved the result. The danger was still greater that they would come to look at many drugs in the light of quasi-specifics, and so relax watchfulness over their effects. Dr. Wade went on to adduce further illustrations of past errors and to condemn the widespread prevalence of the practice of unduly subordinating the physiological basis of treatment to the restorative basis, and concluded by urging the duty of untiring observation. They were told that to the few only was it given to extend the landmarks of science, or to reclaim the waste lands of ignorance; but to each one was given the power to cultivate and utilise those which had been reclaimed. To each one it was given to make the practice of medicine more rational, more common sense, and therefore more truly scientific, to render more rare in the future such dark blots as they had regretfully recognised in the past.

RECENT ADVANCES IN PHOTOGRAPHY.—V.*

By Capt. Abney, R.E., F.R.S.

DR. VOGEL has recently introduced a new kind of emulsion, which is a sort of mongrel between collodion and gelatine emulsion. It is made with acetic acid, gelatine, pyroxylin, and bromide of silver; but I will not coat a plate to-night with it, as the smell of acetic acid is very strong. It is a very good emulsion, very clean, and very fairly rapid. I pass on from this, merely saying that plates are more readily coated than by gelatine emulsion, but less so than with collodion emulsion.

But we come now to a decided advance in photography, and that is the doing away with glass as a support for the emulsion. Anybody who has travelled, and had to make mountain ascents, will know perfectly well that glass is a serious drawback to the mountaineer; he would do anything to save himself the infliction of taking twelve whole plates up to the top of Mount Blanc. My friend, Mr. Warnerke, who is generally to the fore in all matters of photography, was to the fore in doing away with glass for carrying collodion films, and is now to the fore in doing away with glass for gelatine films. He has perfected a process by which the photograph is taken on paper instead of on glass, and he has kindly brought me here some illustrations to show the method pursued.

First of all, he has a sensitive tissue, which can be made of any length. I do not know whether he has made it a mile long, but certainly a great many yards, and it can be rolled on a roller, and exposed in the dark slide. By simply turning another roller, a fresh surface is brought into the plane of the focussing-screen. The sensitive tissue is developed in the ordinary way with alkaline development. Here we have it in the developed state. The film can be either stripped off, or else transferred to glass. In the latter case, we come to another point, which is a distinct advance in photography. Mr. Warnerke has found that when you develop a gelatine plate with alkaline development, that is to say, with pyrogallic acid and ammonia, the parts which have been acted upon by light, and which have been developed, become insoluble in hot water. He thus is able, after development instead of using the hyposulphite bath to fix the print, to transfer it to glass, and wash away with hot water the parts of the film which have not been acted upon by light, and he gets a transparency. It should be noticed that, to do this, it is necessary that the back surface of the gelatine film should be exposed to the water, as in carbon printing, and this is secured by transfer to glass. Mr. Warnerke is not satisfied with doing away with glass for the camera, but he does away with glass for printing; and in order to accomplish this, he re-transfers the negative from the glass to a sheet of gelatine. I may say that the glass is freshly collodionised, which enables the film to strip off readily. An advantage of these film negatives is, that you can print from either side, each one yielding sharp prints, which is a desideratum when using the single transfer carbon process, and other such processes where reversed negatives are required. I think that Mr. Warnerke has really made a very great advance by enabling us to do away with glass.

In the matter of gelatine films, we have Professor Stebbing's, which are really workable. The gelatine emulsion is apparently flowed on an insoluble gelatine film on glass, which is then stripped. They are developed by placing them on glass. The next point I am going to touch upon is the enlargement of negatives. Now, the question arises, how are you going to get an enlarged negative? Of course you will at once say "get a transparency by contact, and then enlarge it in the best way you can." The best way you can is, of course, to do it very perfectly indeed; but, unfortunately, by the wet process, an enlargement is very often sadly defective. The best way which I know of getting an enlargement of a negative, is one which was brought forward a few years ago by Mr. Valentine Blanchard, and it is this. He takes the original negative which he wishes to enlarge, and places it in an enlarging camera. He then takes a transparency of the exact size which he wants his negative to be. He next takes a piece of common albumenised paper, and prints that transparency upon it, and by this means get a very soft and beautiful negative. If you have a hard negative it is almost impossible to get a soft transparency by the wet plate process, but by this artifice of "printing out" your transparency, and using that as a negative, you get a decidedly soft paper negative. If you trace the reason of this, it is as follows:—When the albumenised paper is acted upon by light, we know it blackens immediately, and, of course, light acts less violently on the underneath portions where it has been blackened. Thus, in printing from a transparency, the most transparent portions first blacken, then the next most transparent part blackens, before the first blackened part becomes too intense, and so on. So you see, by the shielding of the film by the blackening action, you are able to get a softness which you otherwise would not get. I have here such a negative, which I prepared several years ago, by which you see we get some of this softness. Mr. Blanchard, I am sorry to say, has gone back from his old love, and recommends now that you should use a gelatine plate instead of the albumenised paper. A gelatine plate is a very good thing, but I think the albumenised paper negative beats it when you have to enlarge from a very small negative to a very large one. I think the grain of the paper, too, is an improvement in large photographs, and you get no grain in a gelatine negative. I will next show you how to obtain a paper negative by the ordinary lantern. I will make an enlarged negative from a transparency taken from one of my Egyptian negatives, developing it before you. This is ordinary paper, to which a couple of washes of bromide of potassium were given, and which, when dried, was floated on silver nitrate. Half a minute's exposure to the light coming through the transparency will be sufficient. I shall use the developer, which I recommended to your notice some time ago, the ferrous-citro-oxalate. [The negative was developed and shown to the audience.] We now come to another great advantage of the gelatine process, which is that by it you can get soft transparencies. I am aware that it is said there is a certain amount of blurring in gelantine transparencies, but I am not prepared to say that is necessary; in fact, I should say it ought not to be the case, as I think I shall be able to show you in the next lecture. Therefore, if you have a hard negative by the common process, it is always possible, by the gelatine process, to get a soft negative from a gelatino transparency, in which case you can substitute for the paper, such as I used just now, a gelatine plate, or a collodion plate, or a wet plate, whichever you prefer. The main point to aim at in getting enlarged negatives is to get thin delicate transparencies, with every atom of detail present in them. If you get that you can always get a decent enlarged negative from them. If the detail is blocked up, you will not do so, unless you use a paper printing process, such as I showed you, with the albumenised paper negative.

After these preliminary remarks, I propose to show you one of the new applications of the gelatine emulsion process, and that is the development of a print on paper coated with gelatino-bromide. The paper is prepared by coating ordinary paper with gelatino-bromide (of the most sensitive kind if you like). Such paper can then be exposed to the image formed by an ordinary magic-lantern; by that means you can get an enlarged print. The lantern before you is a triple-wick oil lamp. and I think you will be able to see that I shall get a very good print indeed from the negative, which is at present placed in front of the condenser.

For my own part, I prefer gelatino-chloride paper, as it gives a very black image which beats the bromide out of the field altogether. The reason why the tone is black is that chloride of silver, when developed, is developed in two states, in a red or ruddy state, and also in a green state, and when you put red and green together the result is not far from black. I think you will see, when this is developed, that we shall have the ruddy state first. I use the ferrous-citro-oxalate. It will not bear the ferrous oxalate at first, although it may be brought out more quickly with it. Now, if I turned up the light, you would see it in the pinky state; as it goes on the pinky state gives place to the green, and the two together make up the black, and you will see afterwards that this black is of a most beautiful hue. I want particularly to call attention to the beautiful black tone it has. On the table there are some plates prepared with gelatino-chloride to show the same black tone.

We may thus say that an advance has been made when, by an ordinary magic-lantern, with a good negative, you can get a perfect enlarged paper print by development. Perhaps they will not have that lustre which albumenised prints have, but it is a matter of taste whether you like that gloss or not.

I have now to allude to Mr. Warnerke's invention again. He has found that he is able to mix with his gelatine emulsion colouring matter, and you will at once perceive the value of this. When you wash away the unaltered bromide of silver that is not acted upon by development, you get silver left behind, plus the colouring matter embodied in it. I have a developed print containing colouring matter, and to save time I have placed it on a transfer paper. The image was developed with alkaline pyrogallic acid, and was placed in contact with gelatinised paper, rendered insoluble by chrome alum. I propose to wash away the soluble gelatine containing the bromide of silver and the pigment, to show what a power this discovery places in our hands. I first place it in hot water, and as soon as it has soaked a little the outside paper on which it has developed will peel off, leaving the gelatine film on what we may call the transfer paper. The subject is one of Mr. England's statue subjects, of which he was kind enough to give me the negative. Stripping away the paper on which the print was developed, the picture remains on the transfer paper, and we have the image waiting to be freed from the soluble matter. The print before you was taken in my laboratory with the electric light; and had a very short exposure. The soluble matter is now gradually washing away, and the whites are gradually coming out, and we get a picture in the colour of alizarine. You can get almost any variety of colour; but it is not every colour the operator can use, because some would destroy the sensitiveness of the gelatino-bromide, but most colours he can use. I can hardly thank Mr. Warnerke enough for the trouble he has taken in illustrating this part of my lecture for me. He has furnished me with pictures showing a variety of tints, from sepia and photographic purple to almost any colour, This I may claim as a great advance in photographic printing, and I hope, before long, the public will have the advantage of this invention, which at present they have not.

A TRAIN TELEGRAPH.

A TRIAL was made recently on the Atlanta and Charlotte Railway, in America, of a new plan for enabling a railway car in motion to communicate by telegraph with the stations on the line. It is the invention of Captain C. W. Williams, U.S.A., and consists of a telegraph line laid along the track but interrupted at frequent intervals, and the ends of the break brought to key blocks mounted upon the sleepers or "cross ties." The key blocks carry two metal rollers, to which the ends of the line are connected, and when these rollers are depressed they interrupt the circuit of the line. When in their normal position the circuit of the line is complete. The bottom of the special car, which is selected as a telegraph office, has a projecting shoe covered with two metal strips or bars which, as the car passes along the line, make contact with the rollers and depress them, thus interrupting the circuit at that point, and thereby throwing the telegraphic apparatus of the car into the circuit at that point. This is effected by having the apparatus connected up between the two strips. These are made of sufficient length to keep the car always in circuit with the line by the rapidly suceeding key blocks and rollers. The current enters the car through one roller and strip, and after passing through the telegraph instrument on board returns to the line through the other strip and roller. The advantages of this system may be considerable in certain American districts, or in case of accident. It enables a station-master to clear the position of a train on the way; or two trains to inform each other of their whereabouts. The establishment of such a system would, however, entail considerable expense in this country, owing to difficulties of insulation.

---

* Condensed from a series of Cantor Lectures delivered before the Society of Arts.

In the trial at Atlanta some 200 yards of track were adapted to the apparatus; the key blocks being placed every 40ft. Messages were received in the car when at rest and in motion, the highest speed tested being 25 miles an hour.

ELECTRICITY AND EVAPORATION.

It has been very commonly believed that evaporation is an important source of atmospheric electricity. Thinking further inquiry desirable, Mr. Freeman, of the John Hopkins University, Baltimore, lately experimented thus:—

A copper or tin evaporating dish was supported on a wire frame hung by silk threads, and connected with one pair of quadrants of a sensitive Thomson electrometer, the other pair being connected with earth. To prevent electrical disturbance, the whole apparatus was inclosed in a metallic case, in which were openings to facilitate evaporation and observation. Water, alcohol, a solution of chloride of sodium, and other liquids were tried. After eliminating some discovered sources of leakage as much as possible, and correction on account of deflections obtained with the evaporating dish dry, the deflections of the electrometer were found very small—*e.g.*, for water, less than 0 01, and generally less than 0 005 of a Daniell's cell. The sign of the charge, too, for the same liquid was sometimes positive, sometimes negative. Supposing the deflections really due to evaporation, Mr. Freeman, applying them to the case of atmospheric electricity, shows that the quantity of water required to produce a single flash of lightning is very much greater than the actual quantity ever found in a thundercloud; while such a cloud usually gives not one but many flashes. If it be held that the cloud collects electricity produced by evaporation of more water than that in itself, this is met by a calculation (by the author) of the total evaporation from the earth's surface and the resultant lightning, he estimates that observers regularly distributed over the earth's surface, and seeing every flash within 18 kilomètres, would each see, on an average, only 28 in the year (assuming all electricity to be discharged in flashes). Evaporation is at most, Mr. Freeman thinks, a very insignificant source of atmospheric electricity, and the experiments do not certainly trace any electricity whatever to this source.

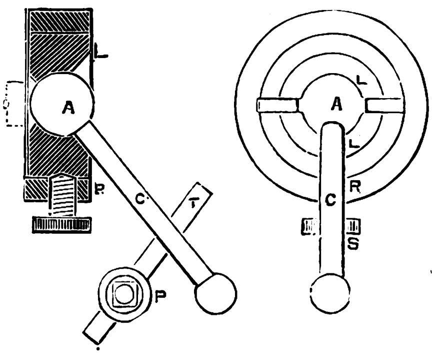
Recently Mr. Blake has followed a line of experiment bearing on the same subject, in Prof. Helmholtz's laboratory. In this case a layer of water (or solution) on one plate of an electric condenser was evaporated by heat and the rising vapour was condensed on the other (cold) plate. The heated plate was also connected with one pole of a galvanic battery, the other pole being led to earth. Both the temperature and the strength of the battery were varied, and a very sensitive quadrant electrometer was used to indicate whether, and how much, electricity was carried away. The conclusion come to was that with quiet vaporisation from electrified water or its solutions, when no drops spring off, there is no convection of electricity.

GRINDING SPHERICAL ENDED CONNECTING RODS.*

In the shop of the Chandler and Silver Water Motor Co., at Lewiston, Me., is used a device for finishing the spherical ends of the connecting rods used in their water motors, which the writer believes to be new and which is superior to anything with which he is acquainted. It is the suggestion of Mr. J. F. Perkins, foreman of a shop in the vicinity, and is based upon the principle that lines of revolution drawn about the surface of a sphere in any direction are circles, and *vice versâ*; if these circles are taken to represent cuts and are made to cross each other in constantly changing directions, the surface developed will be a sphere. In practice, this condition is complied with by a revolving ring, whose axis of revolution perpendicular to the plane of the ring, lies at an angle to the axis of revolution of the sphere operated upon, which axis is determined by the stem of the connecting rod. The process is one of "lead lapping," the ring being of lead and supplied with a mixture of oil and flour emery. The accompanying sketch will give an idea of the device, and although the apparatus was a rough and temporary one, the results obtained were very satisfactory. R is a collar, with a set-screw S, held in the jaws of a chuck on the lathe spindle. L is the lead ring, which is in halves, so that it may be closed up as it and the ball are ground away. A is the ball operated upon, and C the stem or body of the connecting rod. P is the tool post of the lathe, and T a piece of wood provided with a notch in which rests the stem C of the connecting rod. The ring L should be cut away on the front side so that the stem of the rod may swing round as shown to an angle of 50° to 60° with the axis of the lathe, and the angle of the opening O should be something less than the angle of the rod C, as it is necessary that the surface of the lap extend so far around as to pass the axis of the rod C extended. The dimensions are approximate only, and may be varied considerably without affecting the results. If, however, the angle between the axes of the lathe and rod be small, it will be necessary, in some cases, to apply a light end pressure to the rod C to prevent a tendency to wear forward in the ring.

The process is as follows:

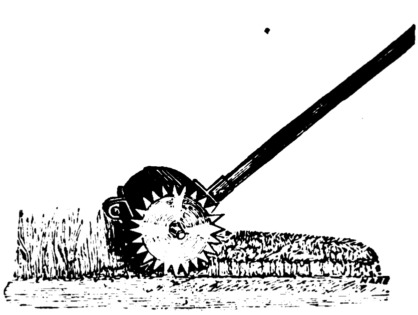
The ball is first turned by a ball-turning device, and then inserted into the ring with the stem C resting in the notch of the stock T. The ring L runs, at a moderate speed toward the front of the lathe, and its friction on the sphere A causes it also to revolve, but as the axis of the rod C lies at an angle with the axis of revolution of the ring L, each particle of emery makes a cut in a diagonal direction, on the surface of the sphere A, and as the revolution of the parts constantly changes the relative position of the surfaces of ring and sphere, the cuts cross each other in all directions, and as the cutting particles all move in circles, the surface produced mnst be that of a sphere. A constant supply of emery and oil is fed to the ball A, and by its revolution is carried into the cutting surfaces of the lap L. The head of the set screw S may be a ratchet on the principle of the star feed, and may strike against a spring stud, thrown up at the will of the operator. It is not necessary that the centre of the sphere and the axis of the lathe should coincide, as the results will be the same in either case. The time occupied in grinding down each ball 1¾in. in diameter, with No. 00 flour emery, the balls being turned up from steel castings with a feed of about 100 to 1in., is about eight to ten minutes, and this includes changing and all necessary operations.



A NEW LAWN-EDGE CUTTER.

Some time ago we introduced to the notice of our readers two useful implements, one for hedge-clipping, and the other for grass-cutting, invented and patented by Mr. Alfred Ridgway, of Macclesfield, which we understand have met with general approval.

The same inventor has just brought out a very efficient, simple, and cheap machine, devised for the purpose of cutting and trimming lawn edges, borders of flower beds, &c., the accompanying illustration of which will give a good idea of its *modus operandi*. The machine, when rolled along the side of the lawn or verge, cuts or clips the same with a continuous series of shearlike cuts, doing its work in a very complete and superior manner. It will also cut equally as well drawn backwards or forwards, which enables the user to cut into any corner or round curves, and, being very portable, it can be easily carried from one place to another.



TRICHINÆ IN SALTED MEATS.

Some time ago M. Colin declared that the salting of meat was a sure and certain method of destroying trichinæ, an opinion opposed to that expressed by German investigators, and also to the fact that several cases of trichinosis, believed to have resulted from the eating of American hams that had long been salted, had been reported. Among other chemists, Schmitt, Chatim Girard and Pabst, and De Benecke and Libon, may be mentioned as observers who had found the trichinæ still living in meats that had been salted for several months. The experiments of M. Colin led to others by M. Fourment, the results of which have just been published as a report to the French Academy. These experiments show conclusively that the salting of meats cannot be regarded as a safeguard against trichinosis. M. Fourment took a piece of meat on the 19th of April, 1881, from some American salted meats examined at the Havre Docks and found infested. This meat was placed in a flask and imbedded in fine salt. It was then hermetically sealed and not opened till the 1st of April, 1882. By this time the meat had undergone a year's salting carried to the highest degree, and if we add the time that must have elapsed since it was first put in salt in America (which could not be put at less than three months), the meat may be said to have been in salt for at least 15 months. The meat was then cut up into small pieces, and these were placed in water, which was frequently changed to remove the salt, and remained for several hours in a temperature of 71·6° F. On the 4th, 5th, and 6th of April this was fed to a mouse, which died on the 7th, after presenting symptoms of diarrhœa. The intestine was evidently inflamed, and contained sexually developed trichinæ. A second and a third mouse were fed with more of the meat, and with exactly similar results in each case Several other experiments were made. M. Fourment says that all show that the trichinæ were then certainly alive and capable of reproduction after 15 months of salting; and it is consequently manifest that salting does not surely and rapidly destroy these parasites. They may die in salted meats as well as in any other situation, and thus explain the negative experiments published by distinguished observers; but they may also live a considerable time without our being able to determine the length of the period after which death necessarily follows latent life. It is also proper to point out that, while salting is too often powerless to kill the trichinæ, one effect is to remove them to a certain extent from the action of heat. This fact is plainly shown by the experiments of Doyere Laborde. It may be useful to point out here that, although several physiologists have found that salting does not destroy the trichinæ, in several sets of experiments they were found to be killed. Zundel, Louis, Rechlinghausen, Kopp, Siegmand, and Dele all made numerous experiments, and in none was it found that, after treating with salt, the trichinæ were capable of development and reproduction. It is very probable that the solution of these disagreements is to be found in the life-history of the trichinæ. It may be pointed out that when the trichinæ penetrate the muscles they are perfectly free, and have no covering whatever to protect them, and a month or more elapses before they accept the situation and coil themselves up, to quietly await their chance of being eaten up by some other animal, which must occur before they can possibly develop into the perfect adult condition. But it is only at the end of three months that a fibrous cyst begins to form around them; and it is, perhaps, a year before the covering is sufficiently dense and impermeable to entirely protect it from the action of salt. Thus, it is seen that at one stage in the life of the trichinæ salt may effectually destroy them, while at another stage it would be almost powerless to act.

DEATH NOT UNIVERSAL.

Whatever lives, we hear it said, whether plant or animal, must, sooner or later, die. It will, therefore, greatly shock many persons to learn that this is not strictly the case. We wish here to give room for no misunderstanding, and, if possible, for no intentional misinterpretation. All animals *may* die, but death is not in all departments of the animal kingdom an inherent absolute necessity. On the contrary, in one of the two primary divisions of the animal world, the Protozoa, it is, though common enough, merely casual, the result of some accident. A Protozoon may be swallowed up by some larger animal; it may be crushed out of existence, burnt, or poisoned by "disinfectants" introduced into the water or other fluid which it inhabits. But it has no natural term of life, and, as we shall presently see, cannot be spoken of as young or old.

That this may be understood we must briefly compare the life history, and especially the reproduction, of the *Metazoa* and the *Protozoa*. In the former group—which includes all the backboned animals from man down to the humblest fish, all the insects, mollusks, as well as lower forms of life which scarcely attract popular notice—there is always a distinct difference between parent and offspring. The latter is certainly a portion separated from the body of the parent—from the female in all those forms in which there exist two sexes—but it is as compared with the parent minute in size, rudimentary in structure, and it has to increase in bulk, and still more to undergo a process of development, a series of transformations, before it reaches the normal stature and make of its species. When this point has been attained it enters upon the task of reproduction, and gives birth to one brood of young ones, or in the higher forms to several. With these it coexists for a longer or shorter time, and then dies, the matter which constituted its body passing into decomposition. If we look at these very familiar facts in the life of a Metazoon, be it a man or an oyster, we find that the ideas of birth, of growth, of maturity, of parenthood, of a natural term of life ending in death, at once suggest themselves. If we examine such a Metazoon we can, in most cases, at once decide whether it is in the immature or the adult phase of its being.

---

* By A. J. Shaw, M.E. in the *American Machinist*.

But in the *Protozoa*—as Herr Bütschli has not long ago pointed out in the *Zoologischer Anzeiger*—this is distinctly different.

Let us suppose we are watching through a microscope one of these minute single-cell creatures. We see it expanding into an ellipsoidal figure, which becomes for a time longer and longer. It then begins to contract about what we may, for the sake of popular intelligibility, calls it equator. It assumes the form of two nearly globular bodies, connected, dumb-bell like, by a narrow neck. This neck becomes narrower, and at last the two globes are set free, and appear as two individuals in place of one! What are the relations of these two new beings to the antecedent form and to each other? We examine them with care; they are equal in size, alike in complexity, or rather simplicity, of structure. We cannot say that either of them is more mature or more rudimentary than the other. We can find in their separation from each other no analogy to the separation of the young animal or the egg from its mother, or to the liberation of a seed from a plant. Neither of them is parent, and neither offspring. Neither of them is older or younger than the other.

Or shall we try to regard them as brothers sprung from the same parent? If so, where is that parent? If living, let it be shown; if dead, where are its remains? No organic—or indeed any other—matter was separated out when the two new beings took their rise. All the substance of the body of the original Protozoon is included, and equally included, in the body of the two individuals before us. Thus we see that the essential ideas of the life of the higher animals—birth, growth, maturity, parentage, brotherhood, term of life, and successive generations—have, if applied to these humble and minute beings, simply no meaning.

The process of reproduction, or rather of multiplication, must, as far as we can see, be repeated in the same manner for ever. Accidents excepted, they are immortal; and frequent as such accidents must be, the individuals whom they strike might, or rather would, like the rest of their community, have gone on living and splitting themselves up for ever. It is strange, when examining certain infusoria under the microscope, to consider that these frail and tiny beings were living, not potentially in their ancestors, but really in their own persons, perhaps in the Laurentian epoch!

This consideration opens up another question. These beings are not wholly unconscious. They experience and retain impressions, however dimly and in however limited a sphere. But when the splitting up of one individual into two distinct personalities takes place, as we have described above, we have then the curious phenomenon of two distinct and equal beings whose past life is one, who will remember the same incidents and the same reactions to which such incidents have given rise. Here again is a phenomenon which we cannot realise—two contemporary and coequal beings possessing, up to a certain point at least, a common psychical life. Let us for a moment suppose that the propagation of the higher animals took place in a similar manner. We should see, *e.g.*, the mature man split up into two equal and similar men, each remembering, knowing, believing, and feeling, up to the day of fission, all that the other remembered, knew, believed, or felt; each, too, it might be contended by moralists, equally sharing the merits or demerits of the antecedent form, and each at a loss to say when his own personality took its rise.—*Journal of Science.*

THE THEORY OF WELDING.*

THE operation of welding is one of so much importance in metallurgy, and one around which so much mystery may be said to have accumulated, that any attempt to investigate and explain it on rational principles deserves to be welcomed. To some such attempt we propose now to direct attention. An opinion has lately been gaining ground on the Continent that difficulty in welding is entirely due to the influence of foreign substances, and not to any differences in the condition of the iron itself. Professor Ledebur is the latest exponent of this idea. He tested a number of specimens of rolled iron, both easy and hard to weld, and found that the total percentage of silicon, sulphur, phosphorus, oxygen, manganese, copper, &c., was on the average 70 per cent. higher in the latter than in the former. He also found that the presence of oxygen in chemical combination up to 0·7 per cent. was less injurious than a larger quantity of manganese, silicon, or phosphorus; but that if the oxygen exceeded 1 per cent. welding became impossible. On these experiments he based the theory that all foreign elements, equally with carbon, have an injurious effect upon the welding capacity of iron; and this in two ways—first by lessening its ductility; and secondly, by lowering the welding point. The first evil prevents the molecules at the surfaces to be welded, from flowing into intimate contact with each other under pressure; the second makes the iron so nearly liquid at the welding heat that it flies to pieces under the hammer.

This interesting theory has been partially adopted—but partially only—by another worker in the same field, Herr Reiser, of the Kapfenberg Ironworks in Styria. While admitting that phosphor and manganese, as well as carbon, have a hardening effect upon iron, and thus lessen its ductility, he points out that Ledebur's specimens were, after all, wrought iron, not steel; that they were therefore far more ductile, for instance, than ingots from open-hearth steel containing 0·08 to 0·1 per cent. of carbon; and yet such steel is easily welded. The want of ductility cannot, therefore, play more than a secondary part. With respect to the melting-point, this is no doubt lowered by the presence of silicon, of sulphur, and—especially with a high percentage of carbon—of phosphorus. Manganese, however, even in small quantities, raises rather than lowers it; for steel which, on account of a high proportion of silicon, is red-short, may be cured by an admixture of manganese. Chromium and tungsten have a similar effect, so that the elements enumerated by Ledebur do not all act in the same direction. It seems, then, that other causes for the unfavourable influence of such elements upon iron must be sought for, and these may be found, according to Reiser, in their capacity for oxidisation, their own capacity for welding, and their tendency to crystallisation.

With regard to the first, or oxidisation, it is well known that steel, if heated too long or too highly in the presence of air, becomes weak, and loses its steely properties. This is, no doubt, due to a partial oxidisation of the material. Some kinds of steel are more easily damaged than others; and it is feared that such steels contain higher proportions of elements, such as chromium and tungsten, which oxidise easily at high temperatures, and thereby lose their hardening properties. Now, it is well known that oxidisation of the surfaces is fatal to good welding, and the only advantage derived from the various welding nostrums, such as borax, lies in their rendering fluid, and, therefore, easy to remove any scale of oxide which may have accidentally formed. But supposing the surface thus to be cleaned, yet, if there be oxidised elements deeper down in the mass, their tendency will be to cause the oxidisation to spread again to the surface, and hence we see why the presence of easily oxidised elements is injurious to welding. With regard to the second point, the presence of a metal, even in small quantities, which cannot itself be welded, must of course have *pro tanto* a bad effect on the welding of the entire mass. This applies to copper—which can only be welded by special methods—and no doubt also to such brittle and oxidisable metals as manganese, chromium, and tungsten, though direct experiments on these are wanting; nickel and cobalt, on the other hand, are easily welded. With regard to the third point, iron, to weld easily, must be in a plastic and coherent condition; and this is characteristic, not of crystalline, but of amorphous structure. Steel is harder to weld the higher its proportion of carbon; but at the same time it becomes so much the more liable to crystallise, and at lower temperatures. This tendency reaches its maximum in the well-known crystals of spiegeleisen. The effect of crystallisation, according to Reiser, is twofold. In the first place, the polar forces, whatever they are, which give the form to the crystals, seem to concentrate, as it were, the attraction of the molecules, and prevent them from exercising that attraction freely on other molecules which may come into their neigbourhood, as they do when in the amorphous condition. In the second place, the effect of crystallisation is to bind up in intimate connection with each minute crystal a portion of some foreign substance which melts at a lower temperature than the iron itself; when a welding heat is reached these foreign substances are apt to liquefy, and in so doing to destroy the cohesion throughout the whole mass.

It will be seen that the general conclusion reached by Reiser, equally with Ledebur, is that all foreign substances—except the special fluid silicates, which are known to assist the removal of scale—are an obstacle to welding; and consequently that we may lay down the general principle that the purest iron is the easiest welded. The reasons, however, why these substances exercise a deleterious influence are of high importance, not so much to the theorist as to the practical ironworker, since it is only by knowing the reasons, and knowing them thoroughly, that he can hope to devise means for removing or diminishing the evil effects. Herr Reiser's conclusions are at once practical and scientific, and deserve the attention of all who are interested in the using or making of iron. They add another argument to the conclusion which most engineers will be prepared to endorse,—namely, that wherever iron has to be worked, hot or cold, or to be used for any but the most ordinary purposes, it is worth while to spend very great pains in manufacture, in order to reach the highest practical standard of purity. We do not mean by this that it should reach the excellence of Swedish or best Yorkshire; but that it should at least be as good as the best Staffordshire of former days—iron that a blacksmith or an engineer can take up and use as it comes to hand, secure that it will answer well to any fair test that is put upon it. To take only the present instance of welding, the cost of a bad weld that is discovered will many times outweigh a saving even of some pounds per ton in the prime cost of the iron, while the cost of a bad weld that is undiscovered may be most incalculable, not only in hard cash, but in human life. From this point of view even the carbon of steel must be considered an impurity, since it undoubtedly diminishes, to some extent, the welding ability of the metal. As a matter of fact, however, there is no real difficulty in welding, at any rate, the "mild steel" or "ingot iron" of which we now hear so much. It is true that Dr. Siemens has been charged with committing himself to the opinion that "steel will not weld"; but if his speech on the subject—which was delivered many years ago—be examined, it will be found that he was merely referring to the question whether white-hot fragments of steel, such as a mass of scrap, will close up into a solid and firm mass under the hammer, as iron scrap is known to do. In a word, he denied that steel would weld itself; he did not say it could not be welded. In any case the welding of mild steel is now a simple and every-day fact of the workshop; and steel may even claim a pre-eminence over iron in this particular, inasmuch as, if richer in carbon, it is far purer as regards the more hurtful ingredients than any but the costliest forms of wrought iron can be. Practically, a smith dealing with steel has nothing but carbon, and possibly manganese, to think of; he need not trouble his head about sulphur, phosphorus, arsenic, and other materials, whose influence on welding Herr Reiser has done his best to set forth in detail. No difficulties as to welding will be likely seriously to hinder the advance of mild steel as the metal of the future.

The facts we have been considering may be looked at from another and not less interesting point of view,—namely, as throwing some light on the meaning and nature of the process of welding itself. What has happened when two masses of iron have been welded together? Simply, we believe, that the forces of cohesion, which were previously in action on either side of the bounding surfaces, have now crossed those surfaces, and formed the two masses into one coherent whole. With a perfect weld any signs of the former division should be completely obliterated, and the cohesion over the original surfaces as strong as anywhere else within the mass. Probably this is never quite the case. Recent German experiments are said to have shown that, even with thoroughly satisfactory metal, there was a diminution of cohesion to the extent of about 17 per cent. This average diminution is doubtless due merely to the fact that at certain points of the welded surfaces the causes which prevent the cohesive forces from asserting their action have not been entirely removed. These causes have been already indicated. They fall under two heads—(1) the presence of any coating, whether consisting of a foreign element or an oxide upon the surface of the pure iron; (2) the presence of any crystalline structure in the iron itself. The exact way in which these causes act we cannot hope to determine, until we come to know much more than we do as to the forces of cohesion; but that they do act to the prejudice of welding cannot be doubted. Conversely, the two great requisites for a successful weld are (1) to ensure that the surfaces shall be perfectly clean, and (2) to bring the iron into an amorphous but not into a fluid condition. It only remains to use a moderate pressure, such as shall force the molecules at the surfaces into close and intimate junction with each other, and thus introduce them within the sphere of each other's cohesive action.

On the other hand, any attempt to cement the pieces together by means of a film of fluid metal interposed between the surfaces, is known to be useless, probably because the molten mass oxidises more rapidly than it sets, and thus takes the form of a scale, instead of uniting itself firmly to the surfaces on either hand. It may be suggested to physicists, in this connection, whether the interesting phenomenon known by the name of regelation—in which two pieces of ice, when pressed together, form themselves into a single mass—is, after all, anything more than a case of welding. It has generally been supposed that the union is due to the freezing of a film of moisture enclosed between the surfaces of junction; and much ingenuity has been expended to explain why this freezing takes place, even when the mass is at a temperature of 32° Fah. It seems at least worthy of inquiry whether this film of moisture really freezes at all—whether it is not, as a fact, driven out by the pressure, either at the edges or into the porosities within the mass; and whether the regelation is not merely the junction, by true welding or cohesion, of the still solid material on either side of the surface of junction.

---

* From the *Engineer.*

PLATING ORGANIC BODIES WITH METAL.*

THE following recipes, says the author, have been used by me for several years past, and in my hands have proved entirely satisfactory:—

For Silvering without a Battery.

The object to be silvered, after being freed from adherent dust, dirt, &c., is immersed for two or three minutes in a saturated solution of gallic acid in distilled water. It is then dipped in a solution of 20 grains of crystallized nitrate of silver in 1,000 grains of distilled water. This operation is to be repeated two or three times, moving the object alternately from one bath to the other until it has acquired a silvery appearance. It is now rinsed in distilled water and laid on clean bibulous paper to dry. In the meantime have prepared two solutions as follows:—

Reducing Solution.—Grape sugar or honey, 5 parts; quicklime (CaO), 2 parts; tartaric acid, 2 parts; distilled water, 650 parts. Mix, dissolve, and filter.

Silvering Solution.—Dissolve 20 parts of crystallized silver nitrate in 650 parts of distilled water. Add strongest water of ammonia, drop by drop, continuously stirring the solution with a glass rod, until the brown precipitate is nearly but not quite redissolved. Filter and put in a glass stoppered bottle.

If more of the reducing solution be made up than is needed for immediate use it should be kept in a closely stoppered vial, filled to the top, so as to prevent atmospheric action. Equal parts of these solutions are mixed together in a gutta percha or japanned dish, and, after thorough stirring, filtered. The object to be silvered is immersed in the mixture, care being taken that the fluid shall come in contact with every part. The deposition of silver commences in from twelve to fifteen minutes, and continues for two or three hours, until the fluid is exhausted or the object sufficiently plated. The rapidity of deposition depends on the temperature, intensity of light, etc. After the object is plated it should be washed in a solution of carbonate of lime, rinsed in distilled water, and dried. All sorts of organic matter may thus be treated and hermetically inclosed in pure metal. I have thus coated leather, bone, wool, hair, horn, silk, flowers, leaves, insects, and anatomical preparations. Glass, porcelain, and earthenware may be coated without first using the preparatory bath. If the latter (earthenware) be porous it will be necessary to first coat it with water glass or varnish, otherwise there is great waste of material. I have before me a sprig of arbor-vitæ, on which a dragon fly is affixed, silvered by this method more than six years ago. The coating is without a visible break, though it has been somewhat roughly handled.

Processes with a Battery.

The success of these processes depends upon making the surfaces of the objects to be plated good conductors of electricity. The principles and *modus operandi* are nearly the same in all of them. The object to be plated is immersed in a solution of some easily reducible metallic salt, and kept there until its surface absorbs more or less of it. It is then so treated chemically that the absorbed salts are reduced to a metallic state, and so intimately attached to and connected with the surface of the material to be plated that they will not peel off or separate under any ordinary circumstances. The subsequent treatment is the ordinary electrotypic or galvanoplastic one of plating with any desired metal. On account of their easy reducibility, the salts of silver are those usually chosen for the preparatory manipulations.

Cazeneuve's Method.

Dissolve 40 parts of crystallised silver nitrate in 1,000 parts of wood spirit. Macerate the object in this solution until sufficient absorption has taken place. The length of time needed for this will vary according to the material, the horny shields of beetles, for instance, requiring much longer time than the softer parts, or than a piece of leather. Removing the object from this bath it is partially dried by draining off any surplus fluid attaching to it, and immersed in the strongest water of ammonia, by which the easily reducible double nitrate of silver and ammonia is formed. The object is now dried and suspended in mercurial vapour. In a few moments the surface is completely metallised, and can be electroplated in the ordinary manner. This method gives excellent results, especially for hard, compact, organic substances.

Oré's Method.

This process is that which has recently been much used in France for plating anatomical preparations, and when properly manipulated gives exquisite results. The preparatory bath, like the foregoing, is silver nitrate dissolved in alcohol or wood spirit, six grammes of the salt to one liter of the fluid. In this the object is immersed for ten minutes, when it is taken out and carefully drained. It is then transferred to a close box, in which sulphuretted hydrogen is liberated, and left for fifteen to twenty minutes. When it is removed the surface will be covered with a dark deposit of silver sulphide. The object should be exposed for a few minutes to the air before transferring to the galvanoplastic cell where the operation is completed. A human brain prepared by this process over a year ago is still a beautiful object, and bids fair to remain so for an indefinite period. In using this method for the preservation of brains and such material, the object should be kept in alcohol at least one month to give it the requisite hardness and consistency. Pledgets of cotton should be introduced into the fissures so that the circumvolutions are separated and the preserving fluid may penetrate every part. The pledgets must be removed before plating.

To keep Silver Plated Articles Bright.

Articles of silver and silver-plated ware rapidly tarnish when kept in rooms where gas is used for illuminating purposes, and everywhere in cities like St. Louis, Pittsburgh, Cincinnati, etc., where the air is constantly filled with sulphurous vapours. My cabinet of silver-plated specimens, instruments, and water pitchers used to give no end of trouble this way. This is all avoided now by dipping the articles occasionally in a solution of hyposulphite of soda. Large articles, like pitchers and salvers, should be wiped off with a rag dipped in the solution, and dried with a soft towel. A rub with a bit of chamois leather makes them as brilliant as new.

---

* By Dr. Frank L. James, Prof. of Chemistry and Toxicology in St. Louis College of Physicians and Surgeons, a communication to the *Scientific American*.

Fauna of Light and Darkness.—It is remarked by Herr Fuchs, in a recent memoir, that while the littoral or shore animals do not extend much beyond 30 fathoms, one finds at about 100 fathoms, over the whole earth, that deep sea fauna whose similarity of composition everywhere is easily recognised, the chief types being deep-sea corals, lampshells, glass sponges, feather-stars, sea-urchins, glasmopodia, and flat fishes. At about 50 fathoms generally, the first of the deep-sea fauna are met with, and that depth may be taken to indicate the critical zone between the two fauna. In the tropics the two are separated by a very sterile region, reaching from about 30 to 89 fathoms; in temperate and cold seas, they mix in abundance in the critical region. It can be shown that neither the temperature nor the chemical composition, nor the movement of the water, will account satisfactorily for this vertical distribution. One factor remains to be considered, viz.,—light—and it is remarkable that the depth to which light penetrates in sea water is stated by Secchi, Pourtalès, and Bougner to be between 43 and 50 fathoms. Herr Fuchs infers that the shore fauna are fauna of light. The deep sea fauna, fauna of darkness. This view gains support from the fact that in some places where the light limit is higher, the deep sea fauna extends higher, and in fresh water lakes, where the light penetrates to greater depths, the shore fauna reaches further down. Again, many deep sea animals have either uncommonly large eyes like nocturnal animals, or are quite blind. They are mostly either pale and colourless, or entirely of one colour; and many have strong luminosity, while none such are found among shore animals. The so-called pelagic animals, which spend their life swimming in the open sea and never need to visit the ground, have much similarity to the deep sea fauna. The great majority are animals of the darkness; remaining in the dark depths by day, and only coming to the surface at night, and they are largely phosphorescent. The conception of the deep sea fauna as fauna of darkness accounts simply for their presence being wholy independent of temperature, and for their being found at nearly the same depth over the whole earth.

SCIENTIFIC NEWS.

WE regret to announce the untimely death of Prof. William Stanley Jevons, M.A., F.R.S., the eminent professor of logic and political economy. Prof. Jevons was born at Liverpool in 1835; he was educated at University College, London, and for some years held an appointment in the Sydney Mint. Returning to London, he took his M.A. degree in 1862, and was made a Fellow of his college in 1864. He was appointed professor of logic and political economy in Owens College, Manchester, in 1866, and professor of political economy in University College in 1876. Prof. Jevons was drowned on Monday whilst bathing between Bexhill and St. Leonards. He had not completed his 47th year. His chief works were the "Principles of Science" and the "Theory of Political Economy," which embody his ripest theories on the fundamental doctrines of logic and economics. A new work from his pen on "Currency and Finance" was almost completed by him at the time of his death, and will be issued shortly by Messrs. Macmillan and Co.

The official programme of the British Association meeting states that the first general meeting will be held in the Victoria Skating Rink on the evening of the 23rd inst., when Dr. Siemens will deliver his address. On Thursday evening the soirée will be held at the Hartley Institution, and on Friday evening Sir W. Thomson will deliver a discourse on the Tides, in the Skating Rink. On Monday evening Mr. Moseley will deliver his discourse on Pelagic Life, in the Skating Rink, and on Tuesday there will be a soirée at the Hartley Institution on the invitation of the mayor and corporation of Southampton. There will be five separate excursions on the Saturday afternoon to various places of interest, including one to Broadlands and Romsey, on the invitation of Lord Mount-Temple, and another to Netley Abbey and Hospital. For Thursday, the 31st, four whole-day excursions are arranged, and advantage will be taken of the opportunity to visit Osborne House. The so-called lecture to the working classes will be delivered by Mr. J. Evans, D.C.L., on "Unwritten History, and How to Read it." That will be given in the Skating Rink on Saturday evening. The Bishop of Truro will preach at St. Mary's on Sunday morning, and the Rev. C. Pritchard, the Savilian Professor of Astronomy at Oxford, in the morning will preach at All Saints. A useful "guide" to Southampton and its neighbourhood has been prepared by Mr. T. W. Shore, of the Hartley Institution.

The French Association also meets at the seaside this year—Rochelle being the selected spot. M. Bouquet de la Grye will deliver a lecture on the deep-water harbour of the port, and M. Hospitalier will discourse on the electric light. Amongst the excursions will be one or several for deep-sea dredging, under the direction of Prof. Giard, of Lille, and others to the oyster and mussel farms in the vicinity of Rochelle.

A minor planet was discovered by M. Paul Henry at the Paris Observatory on August 12. R.A., 22h. 1m.; Dec. south, 13° 35′; small motion south; magnitude, 12½.

Lieut. Darwin, R.E., has been appointed to the Brisbane station for the transit of Venus observations, Lieut. Thomas, R.A., will be at Barbadoes, and Capt. Macinlay, R.A., at Jamaica.

A sum of £18,000 has been voted by the French Chambers for the transit of Venus expeditions, and all the preparations are in a forward state. The French will have three parties in Patagonia, and amongst them will be M. Guénaire, photographer to the Nice Observatory. The results of the photographic experiments during the last eclipse were not remarkably good; but M. Guénaire, by using the Daguerreotype process, hopes to produce some plates from which accurate measures can be made.

The Argentine Republic is fitting up two stations for the observation of the transit, both of which will probably become permanent observatories, in addition to that presided over by Mr. Baring Gould at Cordoba. One of them will be at Buenos Ayres, the other near a place called Tandil, in the south of the province.

In M. Flammarion's *L'Astronomie* for August, the editor has a paper on "La planète Mars et ses conditions d'habitabilité," while M. Schiaparelli describes his new discoveries on the planet, and gives a Carte géographique des canaux nouvellement découverts sur Mars.

A new dynamo-electric machine, patented by Lord Elphinstone, and Mr. C. W. Vincent, of the Royal Institution, is attracting some attention. As the patent is not yet complete, full details cannot be published; but the machine is based on the discovery that the nearer the approach to a closed circuit, the stronger becomes the field, and the longer the iron retains its magnetism. Experiments are, we understand, being made on a large scale.

Sir W. Thomson has also taken out a patent for dynamo machines, in the specification of which several improvements are described. It is No. 5668 of 1881, and contains altogether 59 figures.

Two fires, produced by the use of electric lamps, have occurred in Philadelphia within a few months. In one case, the attendant had neglected to screw on the catch-basin to a Jablochkoff lamp used in a show window of a dry-goods store, and directly the current was switched on, a shower of sparks fired the goods. In the other, an incandescent lamp was joined with bad connections to the leads, the wires becoming white hot, and the insulating material, largely composed of paraffin, blazing away in close proximity to the floor above.

Prof. E. du Bois Reymond has been elected rector of the University of Berlin, and will enter upon his duties in the middle of October.

The fact that lambs have been reared on animal food will probably create some little astonishment; but the idea is not new. All animals reared on milk have been reared on animal food; but M. Regnard has been utilising dried blood from the slaughterhouses, which he dried at 212° Fahr., pressed and powdered in a coffee-mill. This powder of blood was given in doses of ten to eighty grammes daily, mixed with other food. The experiments were made on six lambs deserted by the ewes. Three were fed with the usual diet of beetroot, hay, &c., and to three the powdered blood was given. The first steadily lost flesh, while the latter increased to three times the original weight, and connoisseurs declared that they had never seen such fine lambs of the same age. The animals surpassed their fellows which had been suckled by their dams both in weight and size, and their coat of wool became doubled in thickness. Experiments of the same kind are now in progress with calves, and promise to be as successful as the others. Rickety children are also stated to thrive on the blood diet.

The Institution of Mechanical Engineers commenced its annual meeting on Tuesday at Leeds, under the presidency of Mr. Percy G. B. Westmacott. Amongst the papers promised are, "The Working of Blast-Furnaces of Large Size at High Temperature, with Special Reference to the Position of the Tuyeres"; "On Mining Machinery"; "On a Single-Lever Testing-Machine"; "On Governing Engines by Regulating the Expansion"; and "On M. Fromentin's Automatic Boiler-Feeder." Mr. Crampton was to lecture on his "System for Excavating the Channel Tunnel"; and Mr. J. Fletcher, "On Flameless Combustion."

The population of Lille have been distressed lately by the state of their water-supply from the Emmerin Springs; the water acquiring, especially after rains, a red colour, with bad smell and taste, and giving red deposits. The cause of this is the fungus *Crenothrix Kühniana*, Rabenhorst, whose filaments become charged on contact with aërated water, with a precipitate of sesquioxide of iron, then enter into putrefaction. Its unusual development is due to various causes. The soil has been prepared for it by industrial dejections, especially from distilleries, bringing abundant nitrates into the water-bearing beds (very superficial at some points). The springs, moreover, are near marshes and ponds. Last winter, having been rather dry, the aquiferous sheet was lowered about 16ft., and the spring rains suddenly raised it, engaging the vegetable and animal productions that had been developed in the moist earth. Once more, a part of the aqueduct passing through chalk, pierced with small holes, seems to have sucked in spores and filaments of the fungus whenever the current became somewhat rapid. Prof. Giard advises towns arranging their water supply to seek springs in the deeper strata (so as to avoid *Crenothrix*), to shun waters containing salts of iron protoxide (which is essential to the fungus), and to prefer the subterranean waters, the more aërated waters of lakes, far from all industrial works.

There is a strong tendency, in modern workshops, to bring steam force directly to each tool or machine, and there are signs that electricity will prove useful in the same way. An interesting application of the kind by M. Marcel Deprez, which he recently exhibited when lecturing at the Conservatoire des Arts et Métiers, is an electric hammer. This is composed of a solenoid about 40in. long, formed of a series of flat coils superposed and wire-connected—the whole forming a hollow cylinder, in which a soft iron cylinder, of 25 kilogrammes weight (the hammer), can move freely. With a circular commutator at the side, the system is, in fact, like a Gramme ring, only straight (with its collector). On the commutator are two brushes, at such an angle that they embrace about 10 of the contacts. Suppose, now, that at commencing, the soft iron hammer rests on its anvil, and that the current traverses the 10 lowest coils; the hammer will rise a little, and take a position in the region traversed by the current. On turning the commutator a certain extent in one direction, the current ceases to pass through the lowest 10 coils, and passes through the next 10 above; consequently, the hammer rises again. An opposite movement of the commutator gives the inverse effect—viz., descent of the hammer, which may be varied in speed by varied manipulation of the commutator brushes; indeed, the familiar effects of the steam-hammer can be well imitated.

M. Rousseau states, in a note to the Paris Academy, that while he was looking through his telescope on the morning of the 21st July, about 2 a.m., his vision seemed momentarily to lose distinctness, and he found that luminous sheets, like diffused lightning, filled for a moment the surface of the sky. He saw with surprise, too, diffuse flashes of the same kind, produced at about 20ft. from the ground. The phenomenon was repeated frequently during a quarter of an hour. There were no clouds.

Recently published statistics regarding the length of railways in different European states at the end of last year, show that Germany possessed 34,314 kilometres; Great Britain, 29,232; France, 27,585; Russia, 23,739; Austria, 19,126; Italy, 8,774; Spain, 7,839; Sweden, 7,431; Belgium, 4,123; Switzerland, 2,506; Holland, 2,296; Denmark, 1,696; Roumania, 14,174; Turkey, 1,395; Portugal, 1,219; Greece, 10. The total is 172,372 kilometres; in a straight line this is equivalent to thirty-five times the terrestrial meridian. The extent of new line made last year was 3,953km.; three-fifths of it in France (1,441km.). France counts 1 metre of railway per inhabitant (in this respect holding the first place); Germany, ½ metre. The total cost of European railways is estimated to be about 25 milliards, 855 millions of francs, the interest of which, at 3 per cent., is nearly 800 million francs per annum.

The Society of German cement-manufacturers recently held a meeting in Berlin, to consult on an attempt lately made in Germany, to bring into the market Portland cement mixed with other materials of less value. A powder of blast-furnace slag is chiefly used. The meeting considered that the effort in question was calculated to damage greatly the good reputation for solidity of the cement manufacture of Germany. Leaving the question open whether certain additions of small value to Portland cement, after burning, improve or deteriorate the quality, the Society agreed to consider that all such additions should be regarded and dealt with as adulterations where it was not stated on the barrels and sacks that such a mixture had been made. Only such additions, to an extent of 2 per cent., as are fitted to communicate certain properties to the cement—*e.g.*, gypsum, should not be regarded as adulterations. All cement works should be invited to agree to this, and the names of those that did not, should be published after October 1.

The electric resistance of glass at low temperatures has been recently measured by M. Foussereau. He tried three kinds of glass, ordinary glass, with base of soda and lime, Bohemian glass, and crystal. In all cases, lowering the temperature produced rapid decrease of conductivity —*e.g.*, ordinary glass at + 61·2° C. had a resistance (expressed in millions of megohms per cubic centimetre) of 0·705; at + 20° of 91·0, at − 17° of 7,970, this last representing nearly twice the resistance of a copper-wire 1 sq. mm. in section, reaching from the earth to Sirius. The hard Bohemian glass was 10 to 15 times more conductive than ordinary glass at the same temperatures, whereas crystal insulated 1,000 to 1,500 times better than ordinary glass at the same temperatures. The method was to send through a stoppered test-tube the electricity of a battery. This was collected in a condenser whose armatures were joined to a Lippmann capillary electrometer. The test-tube held and was immersed in concentrated sulphuric acid, into which entered platina electrodes. The outer vessel was in a glass envelope, the air in which was dried by sulphuric acid. The apparatus was put in an oil bath surrounded by a sand bath.

An interesting observation on tree rings is recorded by Prof. Bachelart in *La Nature*, during a visit to the ruins of Palenque, Mexico, in 1859. M. Charnay caused all the trees that hid the façade of one of the pyramids of the palace to be cut down. On a second visit in 1880, he cut the trees that had grown since 1859, and he remarked that all of them had a number of concentric circles greatly superior to their age. The oldest could only have been 22 years of age, but on a section of one of them he counted 250 circles; the tree was 60 to 65ctm. in diameter. A shrub, 18 months old at most, had 18 concentric circles. M. Charnay found the case repeated in every species, and in trees of all sizes. He concluded that in a hot and moist climate, where Nature is never at rest, it may produce, not one circle a year, as with us, but one a month. The age of a monument has often been calculated from that of trees that have grown on its ruins. For Palenque, M. Larainzar calculated 1,700 years, having counted 1,700 rings in a tree. M. Charnay's observation requires the number to be cut down to 150 or 200 years, making a considerable difference, 1,500 years. Prof. Bachelart asks whether M. Charnay took account of certain coloured rings which some tropical trees present in cross section, and which are to be distinguished from the annual circles.

At the works of Saint Chamond, in France, a new method has been adopted for annealing pieces of artillery of large calibre. A trench is formed, 22m. long, 13m. broad, and 16m. deep. In the middle is a pit of 4·75m. diameter, and 15m. deep, containing an enormous vertical tube with oil. The furnaces for heating the cannon are placed in the trench, and above them, at the level of the ground, are cranes for raising the piece from the trench and immersing it in the oil tube. Hitherto artillery pieces have been placed horizontally in a vessel of oil, and this method has the drawback of slightly arching the guns, whereas the new system produces no deformation.

Mosquito Oil.—A correspondent from Sheepshead Bay, a place celebrated for the size of its mosquitoes and the number of its amateur fishermen, recommends the following as a very good mixture for anointing the hands and face while fishing:—Oil of tar 1oz., olive oil 1oz., oil of pennyroyal ½oz., spirit of camphor ½oz., glycerine ½oz., carbolic acid 2drms; mix, and shake well before using.—*Drug Circular.*

Pearl Life Assurance Company.—The Eighteenth Annual Report of this Company records a great advance on any previous year's income, the net increase on the premium income being nearly 45 per cent. more than that of any previous year since the incorporation of the Company. 201,194 new proposals have been received during the year for which policies have been issued representing a new annual premium income of £101,967 10s. 5d. The total premium income for the year amounts to £110,283 10s. 4d. which represents an increase of more than £18,000 over the previous year's income. The annual premium income on the policies in force at the end of June amounted to £137,092 7s. 2½d. the amount being nearly double that of the year 1879.

Any one requiring sponge-cloths should send for a gross to Mr. J. R. Rhodes, of Barton Arcade, Manchester. His cloths are 22in. by 15in., good material, and only 11s. per gross.

LETTERS TO THE EDITOR.

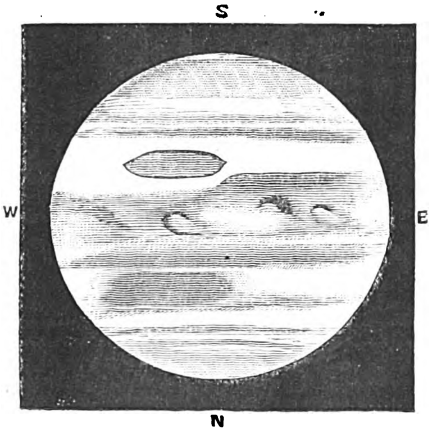
JUPITER.

[20380.]—On August 5th, 15h. to 16h., I obtained an excellent view of Jupiter. The brilliant equatorial spot crossed the central meridian at 15h. 4m., and at 15h. 12m. the middle of the great red spot was observed in transit. The former object moves so much swifter than the latter, that it gains 13m. 24s. (= 8·1° Jov. long.) per day, so that it is evident the two spots must have been in conjunction at about 0h. 44m. on August 5th. This observation enables us to compare their relative motion during the last few months with that derived in 1880 and 1881. In the *Monthly Notices*, Vol. XLII., p. 97-8, I stated that between Nov. 19th, 1880, 9h. 23m., and December 24th, 1881, 9h. 43m., the greater velocity of the bright spot had enabled it to complete nine revolutions relatively to the position of the red spot. The period of the bright spot was found to be 44d. 10h. 42m. 13·3s. Now, between December 24th, 1881, 9h. 43m., and August 5th, 1882, 0h. 44m., five more revolutions have been completed, with an average period of 44d. 17h. 24s., so that the time appears to have lengthened slightly during the present year. I believe the explanation is to be found in the fact that the slackening motion of the red spot has not been continued during the last four months.



Between July 8th, 1881, and March 30th, 1882, I obtained 63 observations of the red spot, and found that relatively to the times of passage of Mr. Marth's central meridian, computed on the period of 9h. 55m. 34·47s. (= 870·42° daily motion), the spot lost about 5m. or 3° of long. per month; for on July 8th and 10th the middle of the spot came to transit about 8 minutes after the assumed first meridian, whereas, on March 30th, 1882, the interval had increased to 48 minutes. Had this marked retardation been sustained during the last four months, the middle of the spot should now become central, 1h. 8m. after Mr. Marth's first meridian (*Monthly Notices*, June 1882, p. 391); but this is not the case. On August 5th, at 15h. 12m., the spot was exactly central, and the time may be relied on as very accurate, as the details of the planet were splendidly well defined. On this date the assumed first meridian passed the middle of the illuminated disc at 14h. 21·6m., or 50·4m. before the middle of the red spot, so that since March 30th the motion of the latter object has closely corresponded with the period of 9h. 55m. 34·47s. In other words, its velocity has been accelerated to the extent of 18 minutes, compared with that observed in the summer and winter of 1881.

Several new features are now visible on the planet. In the N. hemisphere, between the N. equatorial belt and the belt further N., there is a large dark mass connecting the two belts. It looks something like the red spot though not so well defined, and it occupies nearly the same longitude. It is about as far N. of the equator as the red spot is S. of it. This new marking is a very conspicuous object, and it will be interesting to find whether its period of rotation coincides with that of the red spot.

Another part of the planet has greatly changed since the last opposition—I refer to the region of the great south belt following the red spot. Under the *f.* end of the latter there has been seen, during the last two years, a narrow belt connected with the equatorial bands, and running a considerable distance along the southern outskirts of the great S. belt. This part of the disc is now a mass of dark matter. Under the *f.* end of the red spot the belt is apparently bulged out, so that the eastern side of the spot lies S. of a great cavity. The belt is very dark in this region and far to the eastward; but, on the whole, I believe the equatorial bands and the red spot are somewhat fainter than last year. The markings near the equator of the planet now exhibit signs of great disturbance, being broken in places and showing many dark and bright spots. The new spot N. of the equator, and the distortion of the great S. belt are now amongst the most conspicuous features of the planet, and I trust that some of your readers will examine them at an early opportunity.

W. F. Denning.

ζ HERCULIS—4·56in. / APERTURE.

[20382.]—I have read with much interest the letters which have recently appeared in the English Mechanic concerning Zeta Herculis, and I can assure Mr. Simms (letter 20213, p. 377) that there is not the slightest shadow of a doubt in regard to my divorcing Zeta Herculis in June, 1880, for I not only repeatedly did so myself, but both Mr. Masters and Mr. Weed had no trouble in making the same observation on several occasions, and this, strange as it may seem, was when we could not divorce Zeta Herculis with a 4½in. Wray. I mention these two facts in juxtaposition to show the utter ridiculousness of depending on that erroneous and antiquated formula, 4·56in. / aperture. It is hardly necessary to point out that, according to the E and A formula, the 4½in. Wray ought to have divorced it, and it ought to have been impossible with a 3½in. aperture; but the truth was exactly the reverse of this. It may well be asked, What was the cause of such a difference in the performances of the two glasses? This was due, in my humble opinion, to four things. First, the quality of the objective, the eyepieces, the eye, and collimation. Though all those causes may have been concerned, still, the main cause was the eyepieces. With such eyepieces as came with the 4½in. Wray, I should consider it a "large order" to divorce Zeta Herculis with 8½in. One of them made a flag-pole look as crooked as the handle of a jug, another we call the London fog, and I am afraid we condemned and sent back a fine objective, when the whole of our disgust ought to have been vented on the eyepieces. However, by discarding the whole coterie as useless, and getting new eyepieces, we are now pleased to say our 4½in. Wray begins to work as if it had no respect for that E and A formula. And why should it? That E A formula only represents the performance of ordinary objectives, with common eyepieces, under ordinary atmospheric conditions. It does not give the limit of good American objectives, and, in my humble opinion, our 4½in. Wray will split below it. Alvan Clark, a short time ago, promised to make Mr. Weed a 4in., on the very condition *that unless it split to* 1″ he was not to take it; the maker of my 3½in. offers to make me a 4½in., that unless it splits to 0·8″ I need not take it.

James H. Gardiner.

Newburgh, N.Y., August 1.

RIVETING CHINA, &c.

[20383.]—Queries relating to this subject have frequently appeared in the "E M.," but according to my ideas, the replies have been of a meagre and unsatisfying nature, such as left the querist in pretty much the same state of darkness as he was in before. As I promised lately, I here give such as are interested in the work the benefit of my little knowledge of it. It may be observed that it is an unusual subject for a watchmaker to write upon, but then, as I have said, I have had frequent opportunities of seeing the work done, and observing the methods adopted to secure success. It can in no way be called a branch of mechanics; but, as it is a matter with which householders are intimately associated, there may be many readers of these pages who may profit by a little instruction in the art of repairing and riveting china and glass. Glass-blowing and mending I have done on a small scale as a sort of pastime.

FIG. 3.

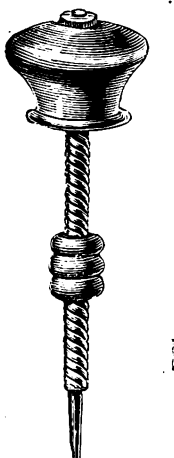

FIG. 11.

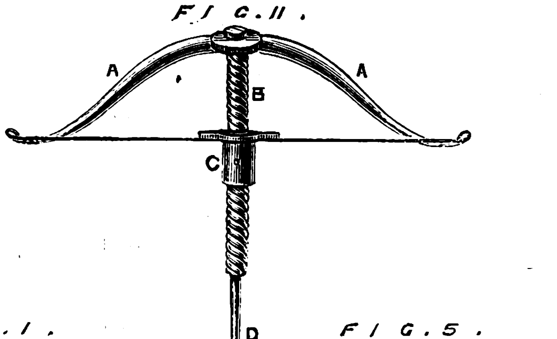

FIG. 1.

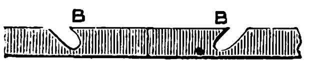

FIG. 5.

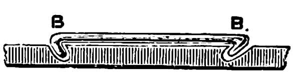

FIG. 4.

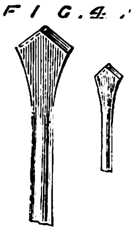

FIG. 7.

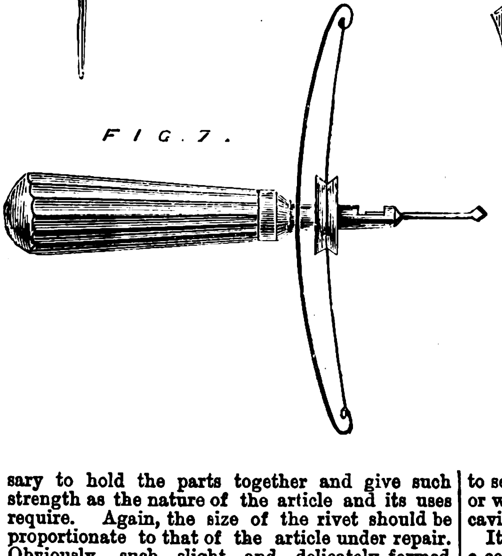

FIG. 6

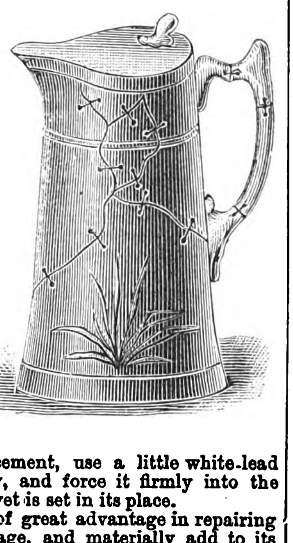

It has always appeared to me that an unnecessarily large number of rivets are invariably put in the broken articles by the itinerant menders who perambulate the country. It may be that the workman has an eye to getting as much as possible out of the job, or he is led away by a desire to make the article as strong as possible. It is charitable to allow that the latter is the correct supposition. Anyhow, I think for all ordinary requirements, a few well disposed rivets are quite as efficient as a large number crowded together in an unsightly manner. For a simple crack, two or three rivets are ample. A compound fracture necessarily requires an increased number of rivets. There is no great beauty in a rivet at any time, so no more should be used than are absolutely necessary to hold the parts together and give such strength as the nature of the article and its uses require. Again, the size of the rivet should be proportionate to that of the article under repair. Obviously, such slight and delicately-formed articles as are found in some tea and coffee-services, should not be fitted with such large rivets as would be necessary to hold together a punch-bowl or soup-tureen. Yet it is no uncommon thing to see the same sized wire used indiscriminately. The drills and wire should in all cases be consistent with the job. The term riveting is, to my mind, rather misleading, as, in fact, the mending is not riveting at all in its generally understood sense, because the holes are seldom or never drilled right through and the wire hammered over. The holes are drilled only partly through, as in Fig. 1, and at an acute angle, as will be seen in the drawing. The purpose of this will be evident, as by reason of the rivet-ends undersetting in the hole, the possibility of the rivet working out is almost nil. The drill should by preference be a diamond, mounted up as in Fig. 2, or in a somewhat similar manner. The diamond being soldered into a metal tube, slightly coned in shape, as at D. The top part A is a flexible spring, fitted with a drilled collar. The screw B is free to move, when acted upon by socket C, by moving which up and down, the part B is revolved, together with the drill. A common form of drill is represented in Fig. 3. This, I think, is known by the name "Archimedean." It is not so useful a form of drill as the other, because both hands are needed to work it, unless the handle is held against the breast. With the other form of drill one hand is at liberty to guide the drill and hold the article. In drilling, a finger should be placed at the spot operated upon, for the purpose of feeling when the drill-point is nearly through. Its approach will be known by a perceptible warmth and vibration (if I may so term it). It should not be allowed to come through or even to chip the enamel. Although a diamond-drill is almost a necessity for this kind of work, it may be done by a properly shaped and tempered steel drill, when assisted by a little spirit of turps as a lubricant. The cutting edges of the drill should slope in opposite directions, two facets only, as in Fig. 4, representing two sized drills. In starting the holes the drill may be guided by the fingers, or a piece of metal with a hole in may be held down in position as a guide for it. The wire used for riveting should be of brass or copper, well tempered, and accurately shaped and fitted. The rivets should have a little spring, so as to catch under the holes on the inner sides, as at B, Figs. 1 and 5. The rivet faces should be filed flat, so as to set close. For cement, use a little white-lead or well-made putty, and force it firmly into the cavity, after the rivet is set in its place.

It will be found of great advantage in repairing a compound breakage, and materially add to its strength if a little transparent cement, made of acetic acid and isinglass, is applied to the edges of the china before the final job of riveting; or, if time will allow, the broken parts should be firmly attached to each other an hour or two previously. The parts should all be perfectly clean, and be slightly warmed before applying the cement. If they are not heated, the cement gets cooled, and, instead of adhering, forms a hard, loose skin-like substance, which prevents a close fit, and is perfectly useless in its place.

The parts can be effectually and safely heated by immersing them in hot water, and wiping dry on removal. The job should be done quickly, and the parts brought together immediately the hot cement has been applied, as it sets quickly. All that exudes can be removed when cold. Fig. 6 shows an article much broken which has been strongly mended and made thoroughly useful again, with a comparatively small number of rivets. Fig. 7 shows a very handy form of bow drill, the handle of which contains the drills not in use, the end of it unscrewing. The socket of the drill is keyed into the handle, and revolves with the bow and wheel. For very large articles this form of drill is exceedingly useful, as it can be held in any position.

Glass goods are mended in a precisely similar way to china, extra care only being needed on account of the brittleness and thinness of the articles generally. Stems of wine-glasses may easily be joined together by melting the broken ends in a clear gas or other flame, and pressing together when perfectly plastic. The blowpipe will assist in getting the heat up. Glass is such a slow conductor of heat, that no fear of burning the fingers need be entertained, unless the worker is an immoderate time at the job, so that the parts can be held by the fingers without danger to them. When mending glass goods in this way, the surrounding air should be kept perfectly still, and all possibility of a sudden draught of cold air falling upon the heated glass guarded against. A draught of cold air upon the junction would prove fatal to it. The stem can be set upright while the glass is soft. Let all cool gradually.

Alfojoe.

SCIENCE AT SOUTH KENSINGTON.

[20384.]—Evidently, Sir, your article upon the above subject has disturbed Mr. E. Jackson's tranquillity of mind, and other people's, too, but in an opposite direction. No doubt each correspondent is giving the result of his own experience, and trusting that the controversy may be crowned with a good result. A few years ago the writer was "fortunate enough" to be a student at one of those science classes under South Kensington, and the subject under consideration was physiography! However many subjects are included in that "term" now we do not know, but at the period we are writing about it meant "physics, chemical elements, geology, astronomy, and physical geography"; and what is more surprising still, we were beautifully glided through the whole domain (?) of these various subjects in about twenty hours (that is, twenty lessons of one hour each). If the proper designation of such procedure as this be not "cram," we are at a loss where to search for an appellation wherewith to adorn it. We met weekly, or at least should have done, to receive our so-called "science lessons." The method of receiving them was as follows:—The students sat down each side of a long table, and the teacher (?) at the bottom end. After all were duly seated, the strict injunction came, "Take out your books, and turn to page so and so." Then the teacher would commence, and read over the various pages, the students of course looking at their books and following him.

Presently a student, whose curiosity was more acute than his neighbour's, would ask for an explanation of some rather obscure sentence before we proceeded further, to which came the stereotyped reply of "Never mind, you won't be likely to have a question upon that." (Probably a philosopher in embryo.)

Now, Sir, if such teachers are "not responsible" for the replies of their pupils, we very earnestly inquire who is? Mr. E. Jackson cannot accuse the pupils here of not paying attention to their lessons. The profound secret with the teacher was the discovery of all those points upon which he thought there would be questions asked, and a judicious avoidance of the remainder.

During the whole course of lessons we never saw a specimen of rock, and, as far as my memory serves me now, we never had a single experiment performed. One night, by way of a change, we had a small globe to show us the shape of the earth, and the distribution of land and water.

Such is the writer's experience of the Science Classes under South Kensington: the value of it we leave to your readers. **A. Manock.**

[20385.]—"Nun. Dor" is wrong in saying that I show that one half the instances I quote have gone astray from the very objects of the Science Department; I show nothing of the kind. The gentlemen I referred to were trained at South Kensington for the purpose of teaching, and this they have been engaged in ever since they left the school. "Nun. Dor" can satisfy himself on this point as regards my own case by referring to the "Science Directory" for any recent year. As the whole of "Nun. Dor's" argument is based on this misconception, now that I have removed the foundation, the superstructure falls to the ground.

Edward Jackson.

Birmingham, Aug. 12.

STONEHENGE AND SUN-WORSHIP.

[20386.]—I do not know whether the material of which Stonehenge is composed agrees with that of the eocene strata or not; but I fancy that it does not. I have stated that it is my intention to visit the place as early as possible, when I will see if I can detect the protruding rocks spoken of by our friend "Neo." I examined the stone about a year ago; but owing to a heavy storm overtaking myself and friends, we had to beat a hasty retreat, and I was not able to glean quite as much as might have been wished.

I will now exhaust my stock of information concerning the place, and shall not be able to state anything further until I actually visit these noble remains.

Stonehenge is situate about 8½ miles N.W. of Salisbury, and lies not far from an angle formed by the junction of two roads; one leading to Wylye (south), and the other to the north, through Shrewton and Heytesbury to Warminster. On advancing up the latter, we arrive at the avenue leading directly into the temple from the N.E., which is defined by a bank and ditch on either side. The first object which meets the eye is a stone about 16ft. high—"The Friar's Heel"—looking, as a writer on the subject has stated, like "a venerable Druidical figure, with long flowing beard, in an attitude of devotion, bending towards the sacred pile." Still advancing, we enter the area of the work, and find that it is surrounded by a ditch and slight *agger* of earth. This is outside the vallum; and the circumference is 369 yards. In a line with the "Friar's Heel" is a large prostrate stone, which bears the mark of tools, and once stood erect; it is supposed to be the altar on which the victims were immolated. It is 100ft. from the "Friar's Heel," and the same distance from the outside of the stone circle. From Vallum to Temple, and the inner diameter of the Temple itself, are both 100ft. The Britons (or other constructors) seem to have been partial to the proportion of 100ft. Before entering the temple we must observe two stones on the outer circumvallations—one on the south-east side, and the other on the north-west. There are two small tumuli on the opposite points, which are supposed by Stukeley to have supported two vases. The two stones just mentioned he assumes were altars. One of the tumuli, when opened, was found to contain burnt bones. The vallum and agger deviate at the tumulus opened from the circumferential partiality generally apparent, which leads to the deduction that this sepulchral barrow existed prior to the erection of Stonehenge. The trench surrounding the building cuts through one of the barrows containing no metals. Hence, it is again adduced that Stonehenge was not created until after the time of the origin of some of the barrows.

Perhaps, however—and it seems very probable—the trenches were dug by a small force of soldiers at some time or the other. The large stones already erected wanted but an entrenchment to form them into a capital little stronghold in days gone by. On the other hand, it may not be so. The burnt bones would indicate the latter.

The temple consisted of two aisles and two ovals, the latter constituting the "Cell or Sanctum." The outer circle is about 300ft. in circumference, and was composed of huge upright stones, bearing others placed horizontally on their tops, and mortised and tenoned together. "The horizontal ones touched each other and formed a continual corona all round the building." These stones, though irregular in shape, bear tool marks. Originally, there were thirty uprights, and as many imposts; of the former seventeen still stand, of the latter six remain.

The uprights average 16ft. high, and about 18ft. in circumference. The space given between each stone nearly corresponds with their width, which is about 3½ft. The entrance is slightly wider than the other intervals.

The inner circle consists of much smaller irregular stones, which show no marks of tools, and is distant from the outer circle about 9ft. Twenty stones out of a probable forty remain in this circle.

Next we notice the cell or sanctum, consisting of two ovals, a larger and a smaller one. The large oval was formed of five pair of trilithons. These rose gradually in size from east to west One of the uprights of the central trilithon has fallen, and is now in two pieces 26ft. in length. The other upright of this trilithon is 9ft. out of the perpendicular. Apparently, it is supported at the bottom by a smaller stone, which is ribbed or grooved. Sir R. Colt Hoare states, "The adhesion between them is just sufficient to swear by, and that is all." The tenon on the top of this stone is very apparent.

The trilithon next to the grand central one (just noticed) fell outwards towards the west in 1797, and in falling struck one of the stones of the outer circle. One of the uprights measures 21ft. 4in., the other 21ft. 3in., a very nice measurement if executed by an "unknown and long-forgotten race," who presumably had no means of hewing the blocks down to so marked an equality. The impost measures 16ft. The last trilithon (that on the right of the cell) has one upright still standing. The impost, and the other upright, have each fallen into the cell, and each has divided into three pieces. I have a guide before me, which I find a great assistance when visiting the place, obtained from an old person who watches these valuable old mysteries of the past. The inner oval consisted of 19 stones, of which 11 remain. They are inclined to a pyramidal form, and are smoother than the other stones. Within this oval is the altar stone.

The entire number of stones has been put down at from 129 to 140. The following opinions have been advanced as to the origin, &c., of this ancient pile:—

"The origin of this temple appears to have been as deeply involved in mystery in the twelfth as it is in the present century."—F. A. Blake.

"It is mortifying that the history of Stonehenge should still remain veiled in obscurity. . . . . All is darkness and uncertainty: we may admire, we may conjecture, but we are doomed to remain in ignorance and obscurity"—Sir R. C. Hoare.

Campden laments the obscured origin of this ancient pile "with much grief."

Inigo Jones states it is the ruin of a Roman Temple.

"The circle of Avebury, of which only a small portion now exists, may be considered as belonging to the remotest period is evident from its ruder character alone; but to Stonehenge must be ascribed a date long posterior to many of the barrows on the plain from the working of the stones, which could not have been accomplished without the use of iron."—Hatcher.

I agree with Mr. Hatcher on this point, and, consequently, I gave the opinion in opposition to "Neo," concerning the erection of the stones in the Neolithic age; but, referring to my extract from Sir R. C. Hoare, he is of opinion that *all* assumptions are useless. The pile might, as "F.R.A.S." has said, have been created in the Bronze age.

The late Rev. Ed. Duke classes Stonehenge with all similar monuments throughout the world, and supports "Neo" by assuming them to be sun-temples. "I cannot," he says, "but presume them to be the temples of the first heathen, dedicated to the sun."

I have now submitted all the material likely to lead to a just conclusion, although we must despair of having arrived at any really satisfactory expoundment. Ages upon ages have doubtless gone by since these stones were erected, perhaps an age before the Roman invasion; but it is hard for me to evade the idea that iron was used, and I cannot therefore carry its origin further back than the Druids. We know that iron was used in this country when the Romans landed, for their chariots were fitted with scythes.

We must allow for decay when considering the workmanship developed on this ancient monument, the decay of centuries; but whatever be the amount of attempted elucidation, whatever be the extent to which we carry our expostulation, I really do not think we shall arrive at a true verdict, or even at an assumption of any intrinsic value.

H. Stooke.

RAILWAY SIGNALS.

[20387.]—I do not think that such a change of system in the working of signals proposed by "Nun. Dor." would be any advantage. He states that by the present system a driver proceeds unless obstructed; so he would if the system was changed as proposed. In the present arrngement, the all-right is a positive order to come on, so is the danger a positive order to stop, and each is a direct and positive signal.

I agree with "A Driver," that there should only be two signals, the all-right, the old caution, at an angle of 45°, and the danger, at an angle of 90°. I think it would be better to take the angle from the centre of the arm; for if the sides of the arm are parallel to the centre, they would be at the same angle. Also, the all-right light to be green and the danger red. Should the signal indicate any other position, either in the position of the arm or the colour of the light, it should be treated as danger, and the driver to proceed slowly to the next signal-box. Two or three degrees in the position of the arm either way I don't think would matter, but beyond this a signal to be considered danger.

I think that the signal-posts should be fixed on the side that they are best seen, on a straight road on the left, but on curves on the side that the signal will first be noticed. To have them all on one side would necessitate having a separate post for the up and down signal, instead of using one post for the two, which is now done in a great many cases.

In his last letter (20367), Mr. Stooke speaks of the expansion of the wire altering the angle of the arm. Could not this be obviated by a weighted compensating lever? Also, I think the variation of the angle due to the wearing of the axle and axle bearing, could be adjusted by set-screws in the bar which the counterbalance weight falls upon, so as to be able to adjust the fall of the weight; or a shackle, with a right and left-handed thread, could be introduced in the connecting-rod, so as to be able to lengthen or shorten the rod.

J. G. Moon.

[20388.]—"Nun. Dor." (letter 20344) suggests an alteration in signalling, the practical value of which is anything but apparent. In the first place, the suggested alteration is a mechanical disadvantage. In a large number of cases the semaphore arm would have to be moved 90° where now 45° suffice. This means that double the amount of wire has to be taken up by the lever—a serious consideration in a distant signal, raised, say, 20 times in the course of an hour. Again, the normal position of the arm being 90°, the signal must be perfect in its action, and expansion and contraction in the wire counteracted, or the "all right" signal would vary some 20°, according to the temperature; and the arm, when not difficult for the signalman to put on, would look untidy, and be misleading at an angle of some 10° or 15°, and some difficulty might be experienced at night with the coloured glasses.

Were the mechanical defects surmounted, the system would have to be universally adopted, or not at all; it would be scarcely fair to ask a driver to work his train under two systems diametrically opposed, and then hold him responsible for an accident caused by his mistaking the signal. Even let the system be generally adopted, I do not think that the expense incurred would be compensated by any advantage gained.

Cora.

[20389.]—The "radical change" which "Nun. Dor." advocates with regard to signals has certainly an advantage in the fact that the arm would "fall to danger" in case of a wire, rod, or other portion of working gear breaking; but, surely, would not the very confusing alteration involved in the adoption of his arrangement be in itself sufficient to be fatal to its actual use?

In the new-pattern signals on the G.N.R. the arm has a continual tendency to return to danger by gravity, because it is pivoted at its centre, and above the horizontal centre-line of the arm; therefore, in these signals, counterweights are not used when the post is near a signal-box, the weight of the arm and rod being sufficient to overcome the friction of a short distance of wire on pulleys. The G.N.R. has also a good arrangement with regard to the night-glasses. In whatever position on the post these may be, the working gear is so contrived that they are *raised* when the signal is taken off, and so help its return to "danger" by their weight. This arrangement is the reverse of that of some companies, the glasses with them having to be kept raised when the arm is at danger in cases where the glasses and arm are on the same side of the post.

Both for the sake of uniformity and clearness, an angle of 45 for a "go ahead" signal would be the best to adopt universally; except in the G.N.R. projecting semaphores, which are most clearly distinguished when the arm is parallel to the post.

Some of the companies are discarding arms swung in a slot in the wooden posts, and are pivoting them on the outside of solid posts. Of these are the Metropolitan (Harrow Extension), North Staffordshire, and Great Northern, the latter's being all projecting.

Tittesworth.

[20390.]—I do not agree with "Nun. Dor's." proposal to reverse the method of working the signal-arm. We want a conspicuous signal for "danger;" and to obtain such, we must keep the arm in a horizontal position. We *do* give a "positive signal to come on," by giving "clear," and if the arm falls into the post, I have already said the condition is treated as "danger." I do not see what else he can require.

"A. S. H." states the arm should not go lower than 45°. I have stated that this represents "clear"; but we allow the arm to go to 85° as an allowance for expansion. Signals should, if possible, be placed on the left-hand side of line; but engineers have *reasons* when they do otherwise—or, at least, they should have. Our correspondent will observe that green, instead of white, lights are in several places being provided.

Two slight errors have crept into my last, due to bad scribing presumably. After word "off," top of column, page 523, please read, "or when the wire breaks." For the word "curve" in last paragraph, please read "arm."

H. Stooke.

THE VIOLIN MUTED.

[20391.]—In his letter, "The Violin Muted," p. 452, "Fiddler" very properly inquires into the results which would ensue, if the resonator, instead of being fixed near the neck, would communicate in the region of the F holes with the back. If "Fiddler" merely wishes to have the freedom of the top, this is already insured at present, as the hole through which the screw passes is large enough to avoid interference between resonator and top. But a more important question comes up here—viz., how the resonator is to be attached to the back through the F holes. Before settling upon the distance from the neck where the screw should pass, I made a number of experiments to determine the correct distance, and I found that the nearer I came with the screw to the bridge, the less volume I obtained; but I did not take time enough to determine whether the loss of sound was due to a pressure on the back, or to the shortening of the free end of the resonator. The fact is, with this new mode of stringing, an endless change of experiments is before an observant experimenter, and as I very soon will put the resonator in the market, I will enable those interested to make all possible trials. Now permit me to give another information. There is a pardonable tendency on the part of many violinists to discard beforehand the idea of a violin without end to end pressure, as aimed at by me. I am prepared, after some successful experimenting, to offer a compromise, and I now restore a *portion* of this end to end pressure, but under a different form. The latest development combines the merit of the vibrating string holder with light bridge pressure, and end to end tension. Such a violin will be sent to "Fiddler" in about a week, and I dare to anticipate that he, and your other correspondents, will be able hereafter to concede a fulfilment of my promises.

E. Berliner.

Boston, Mass., U.S.A., Aug. 1.

COLOUR.

[20392.]—I am sorry I have not opportunity to write in reply to Mr. Geo. Smith's letter (20373) more fully; but the quotation he gives from Tyndall's "Light" he certainly understands differently to myself. Tyndall says, "On the screen are now 10 coloured rectangles." I understand this to be 10 differently coloured. He then says "by judicious management one of these colours is rendered yellow, the other blue." I take it the remaining eight rectangles are stopped out altogether, and certainly do not think that Tyndall says or implies that blue and yellow contain all the colours of the spectrum. He distinctly says: "I deflect one portion of the colours and leave the residual portion," as Mr. Smith says; but this is clear language in a different sense to the way Mr. Smith understands it, and in this experiment blue and yellow do not contain all the colours of the spectrum, but the "residual portion" only when part has been deflected.

I beg to suggest an experiment with polarised light and a double image prism, whereby two discs of green and red or yellow and blue can be made to overlap, and where they overlap are white in the case of the blue and yellow.

I do not differ from Mr. Smith's statements as to the result of looking through coloured films or glasses at various objects; but I submit these experiments, however interesting, are beside the question.

I agree with him that no natural colours are pure. With regard to the one-tenth of white light mixed with nine-tenths coloured, destroying all trace of colour to the eye, Mr. Smith in my opinion makes an important qualification this week. (I hope he did not understand me to charge him with wilful misstatement.) He says now that "if an aperture of one-tenth be cut in a coloured disc and the disc be rapidly revolved, the effect will be a white ring on a coloured ground." Just so; because the comparison is made with the deeply-coloured portion, and this kills the colour on the apparent white ring: but if the one-tenth be cut away from centre to circumference, and revolved with a totally uncoloured ring left for comparison, it will still appear coloured enough to the eye for all the one-tenth admixture of white light. Why I spoke so confidently on this point was because of the known fact that every object we see reflects back to the eye more than one-tenth of white light mixed with the colour we perceive. I will venture to say that the brightest and most vivid colour reflected by any object is mixed with more than one-tenth of white light, and therefore such mixture does not and cannot extinguish the colour.

The undulatory theory would lead me to expect that very various combinations of rates of vibration would be undistinguishable to the eye. A great many combinations would produce white light, or other combinations green, or blue, or violet, and these might be undistinguishable, from the pure monochromatic colours of the spectrum, as far as the eye is concerned, just as 10 and 2, or 9 and 3, or 8 and 4 will make 12, and if we only saw the total without means of analysing, we could not tell how it was made up. Neither does the unaided eye help us with colours or with white light, but the prism enables us to ascertain the components, and to tell whether vibrations are simple or compound.

E. Holmes.

COLD-WATER SOAP—ALUMINIUM—MELLOGEN—ACETIC ACID—ARSENIC—ARSENIC IN WALL-PAPER—COTTON.

[20393.]—In reply to query 47388, page 436, headed "Cold-Water Soap," this term is usually applied to soaps containing more or less sodium carbonate. Such soaps lather pretty well with hard water. They must not be confounded with soaps manufactured by the cold-water process. I have no knowledge of the particular brand of soap mentioned by the querist.

I fancied "Zelia Naien" really desired information about the production of "Aluminium" (query 47416); but it appears (page 436), that he has mastered the most difficult part of the problem, and now only wants a solution of minor details. I sincerely congratulate him, and the more so as his supplementary discovery of a (cheap ?) method of reducing magnesium and other metals without the aid of sodium is scarcely secondary in importance to the economical reduction of aluminium itself. In writing of the inventor's "hopeful method," I intended to refer to the probable value of it.

I am unable to suggest any formula representing the production of "Mellogen," and far less do I "know" the reaction which occurs.

"Acetic Acid" (query 47524, page 484) is most readily assayed for strength by titration with standard alkali in the manner described by E. S. Beavan, on page 507. Tables of densities of acid of various dilutions have been constructed by Mohr and by Oudemanns. According to the latter chemist, Mohr's observations were made on an impure acid, containing about 5 per cent. of water, although Mohr's figures appear to be those from which the alleged strength of the B. P. acid has been calculated. Careful experiments made by me some years since (*Analyst*, III., 268) proved that serious inconsistencies existed in Oudemann's "Table of Densities." The part referring to 28 per cent. of acetic acid is fairly correct, but the densities of diluted acid are seriously in error. Entirely distinct from the above considerations, there is the fact that acid containing 79 per cent. of $C_2H_4O_2$ is at its greatest density (1·0748), the gravity decreasing both by dilution and concentration. "Phosphorous" will find both Mohr's and Oudemann's tables in Vol. I. of my "Commercial Organic Analysis," together with details of other and better methods of determining the strength of acetic acid.

"Arsenic solution" (query 47576, page 508) is a nasty thing to keep one's fingers in. Why does not the querist wear the indiarubber finger-stalls used by photographers, &c., and obtainable at any india-rubber shop? Or he can extemporise similar protections by wrapping guttapercha tissue round his fingers, and making the joints tight by warming before the fire and pressing?

In answer to query 47261, entitled "Arsenic in Wall-Paper," "Beetle-Crushers" writes": "I suppose, from your query, you understand something of chemistry." From his reply, I suppose "Beetle-Crushers" does *not* understand anything of chemistry. His answer is utter rubbish. Fancy his expecting the arsenious oxide or arsenite of copper to inflame spontaneously in chlorine gas, and recommending this as a test for its detection! Fancy, further, his stating that sulphide of ammonium will give a yellow precipitate, with a solid arsenical compound, and especially with arsenite of copper! Oh, poor, neglected, and forgotten Montaigne!

The readiest way of detecting arsenic in wall-paper is to roll up a strip, some few square inches in area, and warm it with dilute hydrochloric acid till the colouring matter is dissolved. If a strip of bright metallic copper is not darkened when boiled for a few minutes in a portion of this solution arsenic is certainly absent. If the copper becomes covered with a grey coating, another portion of the liquid may be treated with zinc, free from arsenic, in a hydrogen apparatus, and the evolved gas kindled after the air is expelled. On depressing a cold piece of glass or porcelain on the flame, a hair-brown deposit will be produced if arsenic were present. The best method to obtain an idea of the amount of arsenic present is to treat the acid solution from (say) 20 sq. in. of paper with tartaric acid and excess of caustic soda; then pass sulphuretted hydrogen to precipitate the copper and lead; filter, and acidulate the filtrate, when a yellow precipitate of As_2S_3 will be obtained, and may, if desired, be collected, washed, dried, and weighed.

"Cotton" (query 47655, page 532) may be tested for jute by treating it with chlorine or hydrochloric acid and potassium chlorate. The chlorinated fibres are then washed and treated with a solution of acid sulphite of sodium, when those derived from bast (jute) will acquire a fine crimson tint, the cotton being unaffected. **Alfred H. Allen.**

Sheffield, August 12.

FAURE'S ACCUMULATORS.

[20394.]—In your "Scientific News" in this day's (August 11th) Mechanic, it states that a watchmaker in Paris lights his shop with 24 Swan lamps worked by 24 Faure accumulators.

Turning to page 523, in same number, I find the following:—The E.M.F. of a Faure accumulator is two volts. The E.M.F. required for a Swan incandescent lamp is 45 volts; so that two dozen accumulators are required to light one lamp.

It is a pity that people write about what they know little about, causing such absurd and misleading statements to be made.

Some time since I called at the office of the Faure Accumulator Company, in the Strand, and asked the obliging attendant how many cells were required for one Swan lamp. He replied, four; and, as I presume that he would know something about it, I can only conclude that your correspondent, "E." (page 523) knows nothing about it, and that the French watchmaker knows more than both put together. **Caloric.**

CROWN-GLASS ACHROMATISM.

[20395.]—The letter of "Orderic Vital" (20356) has caused me the greatest astonishment.

He says, "f_2 must be less than f_1; for, if not, the convex achromatism would exceed that of the concave when the lenses are in contact, and the error would be increased by separation." But why so? How can he prove that the error would be increased? He gives us no proof, and does not even give a hint as to how he arrived at his conclusion. On the other hand, the real way to ascertain whether it is so or not is to form a general expression for the aberration of the rays after passing through two lenses. Call it u, and call the distance between the lenses a, then find $d_a u$. If this is *negative*, as I find it to be (quite irrespectively of any numerical relation between the convex and concave), up to a certain value of a, it shows that as a increases u diminishes, f_2 being supposed numerically greater than f_1, and, therefore, possibly it may diminish till it becomes 0.

To ascertain whether it does so or not, put the value of u equal to 0, and we shall obtain an equation between a and f_1 and f_2, and the blue and red rays will come to a common focus according as the values of a are possible or otherwise. The equation of condition which I find is

$$(f_1 - d)^2 + f_1 f_2 = 0 \quad \ldots\ldots\ldots\ldots \quad A$$

As long as $f_1 f_2$ have different signs the roots of this will be always possible, whatever be the numerical relation between f_1 and f_2, so that f_2 need *not* be less than f_1. "O. V.," however, is unquestionably right in saying that in order that the focus to which rays converge may be a real one, f_2 must be greater than f_1. This fact I have carefully borne in mind in all the combinations that I have tried.

These things being so, when "O. V." says, in effect, that achromatism is impossible, it is tantamount to saying that eqn. A is wrong. Will he kindly favour us with what he supposes to be the right one—i.e., one which will indicate that f_2 must be less than f_1 in order that u may increase as the separation of lenses does.

In fact, if f_2 and f_1 have different signs, there will be always two values of a, which will make the aberration vanish, and if f_2 is reg. and greater than f_1, the attentive reader will see that one of these values corresponds with a real and the other to a virtual focus.

The fact then that $a = 0$ contains possible roots is in itself sufficient to show without differentiating that the assumption, for such I must call it, that u increases with a unless f_2 is less than f_1, quite falls to the ground.

We might verify eqn. A as follows:—By a well known optical principle, if the course of rays after immersion is reversed they will pass over the same ground as those that entered. If these rays diverge from a point whose distance from the concave lens, which we will still call f_2, and emerge from the convex lens parallel to the axis, these emergent rays, if their course were reversed, would pass through the point whose distance is b. Let c be the conjugate focus to b, then, see Parkinson's optics, $1/c - 1/b = 1/f_2$, or $f_2/b = f_2/c - 1$.

But the condition for coloured rays emerging parallel is—

$$d = \frac{f_1 + f_2}{2 + f_2/b} = \frac{f_1 + f_2}{1 + f_2/c}$$

by the eqn. just found.

Now, since in the above equations the rays are supposed to emerge parallel to the axis of the lenses, it is evident that they must pass through the focus of the second lens, which shows that f_1 is *numerically* $= c + d$, or $c = f_1 - d$, but as c is obviously a negative quantity being measured in a direction opposite to that of the rays, while d and f_1 are measured in the same, so that we must put $c = d - f_1$; and if we substitute this for c in the last equation and then clear it of fractions and transpose all quantities to the left side, we find—

$$(f_1 - d)^2 + f_1 f_2 = 0$$

which is identical with it, so that parallel rays entering lens f_1 would converge to the same focus as that from which the rays diverged above. Also, it may be shown that in both cases the same condition, viz., that $f_1 - d$ is less than f_2, will have to be observed.

In deference, then, to your excellent correspondent, "O. V.," I have reconsidered the whole question to the best of my power. But I may say that, previous to writing about the matter, I probably had bestowed upon this particular question more hours than most of your readers have minutes; and after a careful review, I can find nothing in what I have written that needs correction.

I would respectfully endeavour to impress upon all who would write upon the subject the necessity of working out the question for themselves; otherwise, those who, without doing so, can throw any light upon the matter will be few indeed. A friend of mine, who was certainly the first mathematician of his year, when he presented himself at the schools on the second day of examination, was told that his papers on the first day were so admirable that he should have a first class without any further examination—a thing, I believe, that had never before happened; yet he told me that *he was never sure that he understood a demonstration* until he had worked it out for himself.

In conclusion, I may say that I will try to get a telescope made according to the plan I am advocating chiefly — i.e., where rays converge to a common focus; though I am afraid that this will neither easily nor quickly be done. As far back as last November, an optician, in whom I had much confidence, undertook to make a telescope upon the old idea of achromatism—e.g., where the rays were made to emerge parallel. Its plan was this: Front lens, plano-convex, radius of curved surface, 13½in.; other lens, plano-concave, radius 19½in., the flat sides of both turned towards the eye; distance between lenses, 6½in.; length of telescope, 45½in.; diameter of convex lens, 3⅛in., and of concave, 2⅜in. Instead of which I received one of 34in. in length, and with 10in. between the lenses. The consequences of which mistakes may easily be imagined without being described.

W. G. P.

THE PRESSURE OF WIND.

[20396.]—I do not appreciate the distinction which Mr. Romanes (p. 527), draws between "the pressure was 49½lb." and "the pressure on the square foot was 49½lb."—if that "square foot" is the distinction. Just as when boiler-pressures are spoken of, pressure of pounds per square inch is understood, so in the case of wind-pressure it is understood to be pounds per square foot. But the exact words which have now thrice appeared in the English Mechanic, leave no possible room to doubt that the 49½lb. was on the square foot, especially as we can take the still higher "53lb. on the square foot on October 14th" (the Astronomer Royal).

I do not comprehend such an expression as a "velocity of 53lb. on the square foot," and fail to see why the opinion of so eminent an engineer as Mr. Hawkesley should be taken in preference to an obstinate fact. The primary object of my previous letter was to point out that if the recorded pressures were accurate, tables in which the pressure is calculated by some formula were useless, and as they are, misleading. When Mr. Romanes says it does not seem to strike me that the anemometers might be at fault, he has surely forgotten the second and third sentences in my letter on p. 501. It is partly because I want to know whether the instruments used for measuring the wind-pressure at Greenwich are at fault that I wrote, and to repeat, I say "one would think there can be no difficulty in arranging an instrument to record with accuracy the exact pressure" (p. 501). No one supposes that we have on the surface of the earth such a "storm" as Mr. Simmons experienced; nor would it be necessary to build a house situated at the foot of Blackheath-hill so strong as one placed alongside the observatory. All the same, it is of great importance to learn what is the actual pressure of the wind at any given moment; or assuming the formula to be correct, to take the velocity for one second as one of the data, not the velocity for one hour, which being made up of alternate gusts and intervals of calm, cannot possibly give the maximum pressure at any moment. I thought I had made it quite clear that it would be advisable to take the actual pressure, and not that found by any formula. Perhaps some of your readers can give some definite information as to the actual pressure—now that it seems the Astronomer Royal must take a back seat behind Mr. Hawkesley; and meantime I assure Mr. Romanes that the question is one which is by no means settled in the minds of engineers and architects. By what means is the wind-pressure measured at Greenwich?

F. M. S.

STRING VIBRATIONS.

[20397.]—The "E. M." of Aug. 11th (p. 524), will be famous hereafter in connection with "Fiddler's" discoveries regarding vibrating strings. Certainly, a string vibrating seems to move as a whole, "the greatest impulse being at the centre; but away from that point, the oscillation line seems blurred." But I have been given to understand that a string vibrated also in sections —½, ⅓, &c., of the whole length, and that this secondary vibration goes on at the same time that the string moves as a whole. "Nodes" are those points about which the oscillation takes place.

I am sorry I have not the "E. M.," and cannot follow the subject through previous letters. I see "Fiddler" falls foul of Mr. Schucht for saying that vibrations are communicated through the nodes. As a "node" is a stationary point as regards the section of the string which it ends or begins, it seems to me that the vibration cannot be so transmitted as long as they are simple. But a violin string does not give only one set of vibrations; its motion is the sum of the vibrations of different sections; so that any given node will be at the end of one section, and at the same time in the continuity of another section.

My knowledge of acoustics is small, and I have no book to refer to just now; but as far as I remember, a solid body touching a vibrating string produces a point of no vibration, *i.e.*, a node at the point of contact. Similarly with the soundboard of a violin; the soundpost can only transmit at the most the vibration of those sections whose nodes do not coincide with the contact node produced by the soundpost itself. But this action can only be conceived with the oscillations of those fibres which pass over the post. The rest of the soundboard is unaffected by it as regards the transmission of vibrations to the back.

But, beyond this transmission, the post has an action on the soundboard as a whole, forming a node in it, determining its mode of vibration.

The post, then, has two actions; it transmits vibrations passing across it to the back of the violin; it gives an increased effect to the tone produced by one section of the string by determining the vibration of the soundboard in a definite direction. Variety in the tone of "harmony" to which this ascendency is given, is the cause of the variation in the tones of different violins. I agree with "Fiddler" in thinking the post unnecessary, if the soundboard be moved the right way: I would rather say if it be cut in such a way as to give ascendency to the favoured harmony. But the post seems to me to give a ready method by experiment of adjusting the vibration, when the soundboard is not so cut.

I don't quite follow "Fiddler's" line of argument just at this point. He says if a soundpost be not used the violin will sound louder, *soit*; but further, he says, "and without a node." Given two sounds of the same pitch and timbre, these have the same harmonies, the same nodes. Why, then, "without a node"? The node must be present, whether it be determined by the contact of post with a badly cut board, or by the varying thickness of the board itself. Then why should a "harmonic formation," consequent on a node, according to "Fiddler," weaken the tone? Does it not sound with the fundamental, and, by its combination with that and its fellow harmonic, produce a note of definite timbre? The drift of the following words I can't understand; his "therefore" seems, as far as I can guess at the sense of the premises on which it follows, visually, not logically, to me decidedly misplaced.

"Fiddler's" confidence in himself and his "fledgling" is delicious. A useful instrument "has only to be made the right way to vie with the production of the old masters." "The bass of our new violin is perfected."

"Fiddler's" reasoning again becomes shaky, but here more from insufficient basis than from "pure cussedness." Up to Saturday, I had believed that a drum did not give a musical note.

In the harp and piano the impairment of tone by the unscientific soundboard is so slight, as compared with that caused by the imperfect scale, that a soundpost more or less is of slight importance. The banjo is hardly worth consideration. "Fiddler" seems to think his nut of a series of soundposts hard to crack. Would not the result of their combined action be the determination of a definite mode of vibration, &c.? To sum up, the soundpost acts by transmitting a certain number of vibrations to the back; an action of slight importance. Secondly, by (indirectly) giving ascendency to a particular harmonic—a result which is achieved in "Fiddler's" violin by his skilled hands cutting out the soundboard on mathematically calculated lines.

One question more: Will "Fiddler" be good enough to explain his theory of string vibrations? and, if possible, without so much "gas" as his present letter contains.

Aug. 13. **Nur ein Geiger.**

ON THE CONSERVATION OF SOLAR ENERGY.

[20398.]—The very brief epitome of Dr. Siemens' "Solar Hypothesis" which I represented in these pages did scant justice to the subject, I am aware; but, still, I do not think any statement there can be held responsible for Mr. J. H. Schuct's remarks in your issue of the 11th inst. Mr. Schucht speaks about the idea of shrinkage involved in Dr. Siemens' theory as being opposed to the "laws of nature and against logic," when regarded as being perpetual. He seems to forget that it is only as a counterbalancing action that Dr. Siemens uses shrinkage—"in some measure counterbalancing the expenditure of energy produced at the expense of solar radiation."

"If the oxygen can be dissociated by radiant solar energy, while in a state of extreme attenuation, I cannot conceive how they can come back to the sun's photosphere without combining." I do not know what this sentence of Mr. Schucht's means, when it is considered with reference to Dr. Siemens' theory. What Dr. Siemens supposes is, that a process of interchange is constantly going on; the aqueous vapour and carbon compounds in space, being dissociated on reaching the sun, are compressed into the solar photosphere at the poles, while a current of the same vapour reassociated, is sent out at the equator. That this outflow must take place can be shown on mathematical grounds, the only condition being that space is not empty.

Many questions of a very interesting character have been raised respecting this hypothesis by Dr. Sterry Hunt, Prof. Fitzgerald, and others, in *Nature*, and I refer Mr. Schucht to the last and present volumes of that journal for the correspondence on this subject, where he will find how the objections to the theory, so far, have been met by Dr. Siemens.

Worthing, Aug. 14. **C. H. Romanes.**

GRAVITY ESCAPEMENT CLOCKS.

[20399.]—Sir Edmund Beckett and others interested in Horology, will be glad to know of the progress of the gravity escapement in the United States.

Messrs. E. Howard and Co., of Boston, the celebrated watch and clockmakers, have been using this escapement in their regulators and tower-clocks for some six or seven years past, and value it highly. On a recent visit to their office in this city, I had the pleasure of seeing a very fine turret clock, using the double 3-leg gravity escapement, and striking the hours and quarters. The workmanship was first-class, and the style of the whole thing indicated durability and time-keeping qualities. Their principal regulator was also a 4-leg gravity, and put in an elegant case with mercurial pendulum, altogether as fine a regulator as I ever saw.

Messrs. Howard told me they had made "3-leg gravities," for the *Tribune* building, for Dr. Hall's Church on 5th Avenue, and for the Standard Clock of the "Grand Central Depot," all of this city. They did not give me the rates of any of these clocks, but said they went as well as was expected.

The "City Hall," of New Haven, Conn., has one of the "double 3-leg" clocks, under charge of Prof. Waldo, of Yale College Observatory, who states that it averages *closer than the great Westminster Clock*, having run for several months on a rate *not exceeding* 47-100 *of one second per week* (0·47 sec.) I have written to Prof. Waldo for particulars, but have not yet received them.

Sir E. Beckett ought to be gratified that his clocks go so well and are so much appreciated in the United States, and I have no doubt he is.

Roi ne Puis, Souza Je Suis.

THROWING OIL ON THE WAVES.

[20100.]—In his recent speech in the House of Lords, Lord Sudeley gave an interesting résumé of the chief evidence in favour of the assertion that oil thrown upon waves will "quiet them." That phrase is not more correct than to speak of the oil rendering the sea smooth. All that can possibly be asserted or supported by the existing evidence is that oil to a certain extent prevents waves breaking, and as every waterman and seaman knows, it is not the rolling masses of water that are dangerous, but the waves that break on board. According to Lord Sudeley, the use of oil is not a new discovery, but one that has been tried for years, with more or less success. From the earliest days it is mentioned as well as recorded in Scripture; and it is well known that the inhabitants of the sea-coast of Syria were aware of it in past ages. We know also that in Pliny's time divers made use of oil to smooth the surface, and so produce a more steady light at the bottom. In more recent times, in 1757, Franklin's attention was drawn to this subject, and experiments were made by him of various descriptions. In still later years, many experiments have been carried on, and papers have been read at different institutions on the subject. It is also well known that seamen engaged in the whale and seal fisheries, and also fishermen in Shetland and on the coast of Scotland, have more or less employed this method for a great many years. The experiments at Peterhead will be fresh in the memories of all. It seems to me that if oil has any useful effect in preventing the sea from breaking inboard, a good deal must depend on the kind of oil used. Paraffin oil, for instance, would, I should think, be of little use, from its want of viscidity—the property on which the phenomenon would appear to depend. An oil of the consistence of thin treacle would presumably give the best results. I do not know what oil Mr. Shield used at Peterhead, but his experiments were not at all conclusive, for although the white crests and the spray were controlled, the waves persisted, and after a time the oil was swept away. Lord Sudeley said that in some of the trials which had been made for using oil to calm the surf, and thus enable boats to land easily, curious and very contradictory evidence had been obtained. In the first place, it was considered by very competent authorities whether oil could be used with advantage where there was a force of wind amounting to a whole gale, which might be put down at 10—whether, in fact, it could be used with any advantage against a force of wind exceeding 6. The general opinion was that in a heavy gale it would be of no use. Again, in the second place, experiments had been tried with the oil for landing boats through surf which had proved entirely unsuccessful, owing to sharp currents and tides setting the film of oil along the shore, and thus preventing it being of any use. Further, it had been found very doubtful if, when the wind set full upon the shore, and a high surf was raised, it was possible to prevent the oil being washed rapidly out to sea. A rush of water back from a surf was usually supposed to return as an under current, or as it was technically called the "under-tow," in which people were very often swept away. It had been found by experiment that there was also in most cases a very strong surface current drawing out, and in one instance the oil was swept out so quickly to sea that it was perfectly useless. Some of the experiments seemed to point to the fact that oil could be very well used round a ship to allow boats to approach. There was an idea, which seemed well worthy of trial, to the effect that small bags of oil should be attached to life-buoys, which could be pricked at the moment of throwing them overboard, so as to calm the surface of the sea round them. There could be no doubt that cases constantly occurred of all trace of a lifebuoy being lost after it was in the water; whereas, if there was a smooth oily surface round it, the probabilities were that it would be distinctly seen from the ship, and also give the person overboard more chance of seizing it.

The Board of Trade has definitely declined to undertake any experiments with oil, thinking it their duty not to waste public money; but they are collecting all the authentic cases of actual saving of life, and any trustworthy evidence as to the effect of oil upon sea-waves, with the view of embodying them in a report to Parliament. There seems no doubt—Lord Sudeley admitted as much—that under special circumstances, and to a certain extent, oil can be used with advantage on bars, and in landing boats on broken water; but the Board are not sanguine that any remarkable discoveries will be made by the experimenters who are trying, or about to try, the effect of oil. Can any of your readers say which is the best oil for the purpose, and give the reason why? The cost of oil would no doubt be considerable, but when a fleet of fishing boats are running for harbour, if the bar can be smoothed it will be certainly done if a few tons of oil will do it. **J. O. N.**

ABBE'S APERTOMETER.

[20401.]—In reply to "Antares" (No. 20277, p. 429), regarding the use of Prof. Abbe's apertometer, I have tried every method of measuring apertures that has been suggested for some years past, and have found none so convenient and reliable as this apparatus.

In measuring a large number of high-power apertures, dry, water-immersion, and homogeneous-immersion, I found it advisable to use a microscope with a rotating stage, preferably the Continental form, in which the tube rotates with the stage. On the cylindrical edge of the apertometer disc I pasted thin tissue-paper, to avoid the glare of light. Placing the microscope vertical with the disc upon the stage, I adjusted the lamp-flame in the horizontal plane of the disc about 12in. off. Care was used to see that when the auxiliary lens was fixed to the lower end of the draw-tube (forming, with the usual eyepiece, an "erecting" or terrestrial eyepiece), no diaphragm or other obstacle prevented the lens from being slid sufficiently far down to take up the real image formed by even the highest powers. Inasmuch, too, as the principle of the apertometer assumes that the whole telescopic field of the objective, when used as a telescope, represents the aperture when used as a microscope, we must be careful that the diameter of the auxiliary lens, or the diaphragm of the eyepiece, does not cut down the telescopic field, as would be the case if either of these were less than the active diameter of the objective lenses—in other words, as stated by Prof. Abbe, "for observing the *limits* of this telescopic image, the whole must, of course, be within the field of the auxiliary microscope." That is why the auxiliary lens supplied by Mr. Zeiss is a low power of large diameter, and why the eyepiece itself should also be of low power.

"Antares" opens a question with reference to the precise utility of the homogeneous-immersion formula, which has not yet been treated of authoritatively. He asks whether this formula is to be regarded as useful only where apertures greater than the limit for water (1·33 N.A.) are required? I think experience has demonstrated that all incident pencils from one refracting medium to another of much greater refracting power, beyond the cone 140° in the rarer mediums, make unfavourable angles—angles that cannot be effectually dealt with, and this applies the more the greater the difference between the media. For instance, in a strictly dry lens the aperture between the cone 140° in air (= ·94 N.A.) and 180° (= 1·0 N.A.) is practically of little use; in a water-immersion lens the cone between 140° in water (= 1·25 N.A.) and 180° (= 1·33 N.A.) is likewise of but little service; and equally in a homogeneous-immersion lens the cone between 140° in the immersion fluid (= 1·43 N.A.), and 180° (= 1·52 N.A.) is practically useless. Prof. Abbe has arrived at the conclusion that the limit of useful aperture is a much lower figure than 1·43 N.A. With our present means of construction, however, the lenses which exhibit the finest definition with direct oblique illumination that would utilise 1·25 N.A. are not those lenses of precisely 1·25 N.A., but of higher aperture. It would thus appear that in order to get a well-corrected outer zone of 1·25 N.A., the lens must really have a larger aperture to cope successfully with the difficulties of the marginal aberrations. It should be observed that by the homogeneous immersion formula the higher apertures (say those beyond ·94 N.A.) are more successfully corrected, because the path of the rays is more regular, and can thus be more definitely calculated. This is clearly evidenced by the superiority of definition seen with homog. imm. lenses, when, by the conditions of the object and the illumination, the effective aperture is reduced well within the limits that have already been attained by the water-immersion formula: it is then seen that for all apertures greater than 1·0 N.A. the homog. imm. formula is to be preferred. I believe it is now generally accepted among expert manipulators that the water-imm. formula has seen its best days, and the time is not far distant when it will be entirely superseded.

I note, in passing, a misprint under (2) in the second paragraph of "Antares'" letter. He is made to say that with a homog. imm. of 1·47 N.A., when the aperture was measured with water as the intermedium, he recorded 1·25 N.A., whereas, obviously, under this condition, the record would be 1·33 N.A.—the refractive index of water. Such a lens might be used for testing the refractive indices of all fluids less than 1·47. For very large apertures, a flint-glass disc is advantageous.

So recently as 1876, at the Loan Collection Exhibition, Prof. Abbe used a rectangular plate of glass (as figured in Nägeli and Schwendener's "Das Mikroskop") for the graduations of his apertometer; upon his being shown a semi-cylinder made by Tolles, of Boston, he at once saw the improvement that could be made by putting the graduations on a semi-disc instead of the rectangular plate. Let me now suggest that graduations should be continued on the cylindrical edge so as to permit a direct reading with the auxiliary microscope. **Akakia.**

SCREW-PROPELLERS.

[20402.]—As several of your correspondents take an interest in the problem of screw-propulsion, I send you the following account of Osborne's propeller, in the hope that some of your readers can give further information. The fin-propeller was recently exhibited at the Lambeth Baths, fitted to an iron vessel about 6ft. long. This model was fitted about midships and below the water-line with a rectangular plate, placed parallel to a longitudinal vertical plane at each end, and in its centre line this plate is coupled by a crosshead to a rod passing through the sides of the vessel, and being connected inside to the piston rod of one of the two steam cylinders, placed crosswise in the vessel and having their piston rods extending through both cylinder covers. The cranks of these cylinders being set at right angles to each other, the blades will receive a reciprocating motion, each end moving alternately to and from the sides of the vessel, which latter is by this means propelled. Mr. Osborne does not confine himself to this mode of attaching or working the fin-propeller, he proposes to use one at the stern of vessels, working it up and down instead of sideways, and to attach smaller fins to the side of the vessel to increase the propelling power and give ready means for steering and turning the vessel, which can be very easily done with these propellers by increasing or decreasing the speed of one of the pistons. For vessels of longer dimensions, Mr. Osborne proposes to arrange his fin-propellers in such a manner that they may be drawn up close to the sides of the vessel when not in use, and thus be quite out of danger. Shots fired at the blades would, should they be able to have any effect below water level at all, only perforate the blades without materially affecting their working, unless they were struck at the joints. The little model, which is only 6ft. long, and heated by spirit-lamps, was worked with 30lb. pressure, and run at a speed of about 200ft. per minute; the motion in the water was but very slight, and the vessel itself moved exceedingly steady. Mr. Osborne has brought the invention from South Africa, where his model has been making several trips of over an hour's duration on Simon's Bay. **C. F. E.**

SMALL DYNAMOS.

[20403.]—I am sorry "Tried" did not sign his own name, so that one would know whom he was trusting to. However, "Tried" does not in the least alter my opinion that at present there is not a machine that an amateur can successfully make and use. I am sorry that I feel compelled to disbelieve his statements. I wish I could do otherwise; but when he writes what must be absolutely false, one cannot believe his statements. Will our readers refer to the two extracts which I have taken from "Tried's" letter (29349). "The machine being driven from a *foot lathe* produced current enough to light up, *well, five* 10-candle-power incandescent lamps (mine are the italics). I must add that there were only five in the shop, or else we should have put *six*." Now, then, for the other quotation:—"I took it to my own place, and having *steam power* at hand, put it to what I calculated about a *quarter horse*. I found that running at about 1,700 revolutions per minute it drove at their full power *six five*-candle-power lights." Now, anyone with one grain of sense will see in a moment that with something like *four* times the power, only one-fourth the effect is obtained. To put the statements side by side we have—

Foot-lathe lights six *ten*-candle-power lamps
Quarter horse ,, ,, five ,, ,, ,,

I think it is quite unnecessary for me to write a single word more. Those who have made up dynamos have, I know, in ninety-nine cases out of one hundred, met with disappointment. I have received through the post a number of letters from amateurs who have been deceived, and others who have been led astray by false recommendations, and so long as I am permitted to write to these pages I shall honestly state my own convictions, and even if I sometimes have to appear harsh. I will ask "Tried" one question—Will he, on his honour, declare that the dynamo he refers to, did light up five (I won't say even six) *ten* candle-power incandescent lamps to their full power by the motion obtained from a foot-lathe, at which one man was treading? He says that in the above experiment "the lamps gave *as much light* as they should do." **W. J. Lancaster.**

LEGAL REPLIES.

[20404.]—(47639.)—By the Gun License Act, 1870, amongst persons exempted from taking out a license I find the occupier of any land, or any person by his order, using or carrying a gun for the purpose of scaring birds or killing vermin on such lands. It is, therefore, clear that a license is not necessary for the purpose of killing birds destroying fruit in a garden, which, indeed, would also seem to come under the general exemption, as being used in a dwelling-house or the curtilage thereof.

(47644.)—If a trader is so unwise as to take business premises as a yearly tenant, and to spend his money on improving them without having a lease by which he would have some certain period of tenure, I fear he must take the consequences. The owner of a freehold or a leasehold property has a perfect right to sell it as and when he likes, and he is in no way bound to give any notice of that sale to the yearly tenant, although, of course, it is sold subject to that tenancy. In the case put, the proceedings seem to have been quite regular, and "Ignoramus" has no remedy. It is usual for the vendors to give the purchaser an authority to receive the rent from the tenant in possession—and, doubtless, they have done so—but no other notice is necessary. The purchaser stands in the same position with regard to the tenant as did the former owner, and he can, therefore, give him the same notice to quit or pay an increased rent. This being only a yearly tenancy, there can be no question of compensation for business premises.

(47649).—If a solicitor has money in hand belonging to his client, and he will not pay it over, or take proceedings as instructed, the best way to bring him to book is to issue a summons at the Judges' Chambers of the High Court, calling upon him to show cause why he should not pay over the money so received, and tax his costs, if there be any to charge the client. If the client knows what money has been received by his solicitor, he can of course sue him for the amount. The Law Institution would only interfere in serious cases of fraud, or the like. If a solicitor neglected to sue for a debt after being instructed, and the debt was thereby lost, an action for negligence would lie against him, provided the facts were strong enough to prove such negligence.

(47667).—Partnership.—This is a very curious question, but it is of course possible for two traders to become partners as to their premises only and as to nothing else. As between themselves, any agreement they may make will be valid, and will govern their liability one to another. But if they hold themselves out as partners to third persons, they then become, as regards the world, liable for the acts and debts of each other; and this liability cannot be got rid of by any means whatever, presuming a partnership to exist. People who act as their own lawyers generally live to regret it; and such an agreement, with a sixpenny stamp, would be drawn by a respectable solicitor for two guineas; if under seal, there would be a ten shilling stamp required, which would be charged extra. I cannot undertake to answer general questions as to the law of Ireland, though in most respects that is like the law of England.

(47668).—LEASE.—Lawyers' costs differ; but three guineas, including the necessary 5s. stamp, would be a fair charge for drawing up the lease mentioned. A covenant could be inserted forfeiting the lease if the premises were assigned without the lessor's license; but I never heard of a clause of forfeiture for parting with the possession of the lease itself. Such a provision would certainly be unusual, if not absurd; but it would not be impossible. If it is meant that the forfeiture should happen upon the lessee's parting with the possession of the property, that would be a usual and perfectly valid covenant; but it would not prevent his depositing the lease, and I doubt whether a clause aimed at preventing this deposit of the lease itself would have any effect.

Frederick Wetherfield, Solicitor.
2, Gresham-buildings, Guildhall.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46748.]—**Sharpening Carpenter's Saws.**—It is, I think, stated alternate teeth as there shown, and of course the saw must be reversed, and according to sketch, the front of tooth with the set to you and the back of the one from you.—JACK OF ALL TRADES.

[46828.]—**The Guerin Brake (U.Q.)**—The Guérin Brake was tried upon the Tynemouth Branch of the North Eastern Railway, and referred to by Colonel Yolland in his report to the Board of Trade, 1858. It was fitted to carriages, and was put in operation by the compression of the buffers as soon as the train received a check from the steam being shut off and the tender-brake being applied. It could not act on the rear of a long train, and did not protect it in case the coupling-chains broke or became detached. Like the Stephenson Brake of 1832, it was subject to difficulty in backing the train. The Nasmith Brake, tried on the Leeds and Manchester Railway, 1839, a similar system tried on the South Western Railway by Major Robbins, 1852, the Guérin, and many others, are repetitions of Stephenson's Brake of 1832. In reply to the second part of the query, Mr. McConnell applied "steam brakes" to engines, but he was not the inventor. A patent was issued to Robert Stephenson bearing date at Westminster, 7th October, 1833, No. 6484, "Locomotive Engines," in which his steam brake was fully described and illustrated. It was applied by admitting steam to the brake cylinder. He also pointed out that "the same effect may be produced by admitting water from the boiler," and that the same cock may have a double passage to allow steam or water to escape (to release the brake) when in an opposite position, or to shut both when turned into an intermediate position. This brake was first tried on the Liverpool and Manchester Railway, and in March, 1834, it was fitted to an engine named "Samson" upon the Leicester and Swannington Railway. It appears to have been in use but a very short time upon this latter line.—CLEMENT E. STRETTON.

[46859.]—**Indigo-Blue Dyeing.**—Since writing last I have learned who Mr. J. Ormiston is, and I feel rather flattered being told by a person of such experience that "it is simply an impossibility" to dye (as I stated I can do) 700 yards serge with 12lb. indigo in a woad vat. This is my usual day's work; 700 yards of the serge I speak of weighs from 480lb. to 500lb. Knowing the great difficulties experienced by woollen manufacturers in procuring the services of good woad dyers, and rightly or wrongly setting some value on my knowledge of woad vats, I am anxious to know if Read, Holliday, and Sons', or any other patent process, is likely to supersede woad vats, and would be thankful for an answer to one of my queries as to the cost of dyeing the above 700 yards by Read, Holliday, and Sons' process. Mr. Ormiston asks me to give an idea of the depth of colour. Navy blue is generally understood to mean a full deep blue, such as regular yachting serge. I will take the liberty of writing to Mr. Ormiston, perhaps before he sees this. One thing is certain: that no better or more permanent blue for woollen goods can be dyed than that of the woad vats when properly worked.—BLACKWATER.

[47174.]—**Pedal Reeds.**—Fig. 1 is an outline sketch of the instrument, which is 47½in. high, 47in. front, and 29in. deep to back, and weighs about one-third of a ton. Such a height as this, I conclude, "J. H. T." does not design for his instrument, so that it would be difficult to pack into a lower one what is to be seen in Fig. 1. In this it will be seen that wind from feeders passes up the front part and down the back part to the pedal note box. As the distance between manuals and pedals is inconveniently great, and further complications arise from the method of Fig. 1, I would recommend the adoption of Fig. 2, which saves a great deal of woodwork, and lowers the instrument and manuals by 8in., and by having a projecting keyboard, the convenience would be the same as is adopted in an organ. Fig. 2 shows the feeders put under the feetboards (as is sometimes done), letting the wind directly into the pedal note box, and from thence trunks carry it to the wind-chest above. The pedal note pallets open underneath this box, which is not more inconvenient, seeing that in either case the instrument has to be tilted against the wall to get at the said box.—J. H. HUXLEY, Barry-road, S.E.

FIG. 1.

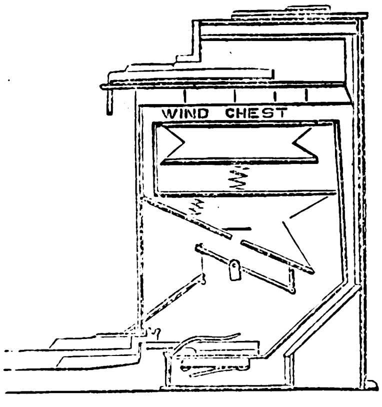

FIG. 2.

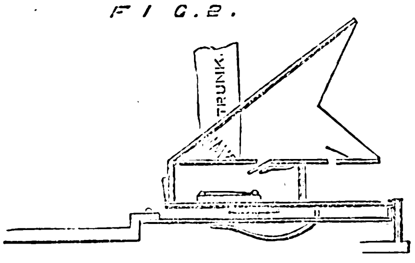


[47219.]—**Text-book of Physiography.**—As Mr. A. J. Smith "is acquainted with both Huxley's and Geikie's manuals," we may, in addition, introduce to his notice "Dr. Young's Physical Geography Advanced" (Collins and Sons), and "The Elements of Physiography," by J. J. Prince (John Heywood). The latter, although prepared more especially for the elementary stage, may not be altogether useless for the advanced.—A. MANOCK.

[47322.]—**Injured Thigh.**—For 2d. you can purchase a box of pure Venice turpentine. It is very sticky, and must be poured on to a linen rag and placed on the wound. It will spread itself. Then place on the top of this a simple bread-and-water poultice, fresh night and morning. The turpentine must not be pulled off, but left until it comes off by itself, which it will do after a day or two; then wash with warm soap-and-water, and add another. Do not try to get away the sticky part about the wound; it will do no harm. The better it grows the longer the turpentine will be coming off. Repeat both poultices till quite well; then, if the place is tender, merely put oiled cloths on (salad oil). Also a cure for boils.—SYMPATHISER.

[47323.]—**Steam Launch.**—Has "Ajax" looked through his back Nos.? There are several specifications for yachts and launches—one so recently as p. 286 of this volume—and many notes about them.—LOCRIS.

[47327.]—**Colouring Steel without Heat.**—I believe the colour is nothing more than lacquer. Common kind would be made of shellac dissolved in methylated spirit; others probably of mastic, alcohol, and a little camphor. For colour, use Prussian blue; if orange, the brown shellac will be about right. Should think that several readers could supply you with the actual recipe, though I believe the manufacturers of tools consider their varnish a special secret. The thinner and tougher the coat the better. If no one else helps you, I will see whether I can find anything out for you; but not being personally mixed up with manufactures, it will be only second-hand.—ESSAR.

[47330.]—**Leaking Vats.**—It is not easy to answer this query; but, to prevent the shrinking, cannot you fill up with water instead of leaving it empty? The only remedy is to line the joints with indiarubber (if that will stand the liquids), and bolt up very tight. One might possibly suggest something else if the kind of liquid had been stated.—ESSAR.

[47350.]—**The Baths of Wildbad.**—There may be some special virtue in the waters of Wildbad, but it would certainly be very expensive to bring them over here, and probably in cooling they might lose some of their virtues. Personally, I should attribute much of the salubrity of Wildbad to the pine forests in the vicinity, and I suspect that any kind of wholesome water (provided it were used as frequently as the baths) would answer as well. It may be rank heresy; but you take it for what it is worth.—NUN. DOR.

[47352.]—**Ink—Sealing-Wax.**—You might try printer's ink (good) to which a little glycerine had been added; or to good black writing-ink you might add a paste of ivory black and gum-water, worked up thick, until you made the writing-ink of sufficient consistency. The sealing-wax should preferably be made in a bright copper pan; for colour use powdered verdigris. Either pour into moulds, or roll into shape on a warm marble slab, with a piece of polished wood as a block.—T. P.

[47359.]—**Broadwell's Breechloading System.**—You can learn all about Broadwell's system in his patent specifications, or in some of the engineering papers of four or five years ago; but as to Krupp's use of it, perhaps you know that Krupp denies using it. There was a long controversy on the subject in *Engineering*, I think, about two years back.—T. P.

[47369.]—**Preserving Mosses.**—I believe drying in hot sand is the best way of preserving all kinds of plants, including flowers.—NUN. DOR.

[47434.]—**Lathes.**—In answer to "Miner," I see that he has a desire to have metal bearings to his lathe. That being the case, I should recommend good gun-metal, well-fitted; but I prefer hardened-steel collar and mandrel, as there is nothing to equal them for wear and freedom in running. If "Miner" can favour me with a call, I will personally explain all he requires.—J. H. EVANS.

[47448.]—**Ritchie's Induction-Coil.**—"B. H." (No. 47448, p. 460) says he does not understand my description of R.'s coil at p. 16, No. 859 (Sept. 9, 1881), in the matter of the battery connections. My sketch showed the two tubes, each put, like a cap, over its own end of the primary coil. It is easy to see that the two ends of the wire might escape where the open ends of the tubes meet; but there are a few objections to this. I should drill two small holes in the closed end of one glass tube, and bring the primary ends out thence. It is easy to see that, if the coil be of the upright variety, only one glass insulating-tube is needed, the two wires being brought to the lower end of the coil, and into and through the wooden base. The contact-breaker or vibrator is a small, independent, electro-magnet, wound with wire the same as that of the primary, and set upon the base, near the coil, its wire being connected with battery so as to be in the primary circuit. There is no way of building a coil so good as this "section" plan, which has been followed by Messrs. Ritchie since 1857; but, like other good things, conscientious and faithful work must be used. A little hurry, a little carelessness, a few feet of poor wire put in instead of waiting till good could be had—any slighting work like this will spoil the coil. Take plenty of time, wind close and slowly, insulate thoroughly, and, if the wire is good, the coil ought to work.—ROI NE PUIS, SOUZA JE SUIS.

[47463.]—**On Change-Wheels.**—I may state that the best rule I know of is—multiply the number of teeth of driven wheels by number of threads of leading screw per inch, and divide by number of teeth in driving wheels; the result is the number of threads per inch the wheel will cut. All difficult threads must be done in this manner. The nearest wheels to cut 31 threads with a leading screw of 4 to the inch are: 20 and 55 driven, and 85 and 100 driven, which cut 30 10-11; this is near enough for all practical purposes.—T. F. GELL.

[47463.]—**Change-Wheels for Screw-Cutting.**—To "TRY AGAIN."—You will approach 31 threads to an inch by selecting the nearest number that you have to some multiple of 31; thus, as your train goes as high as 125, then the 125-wheel will be only different by one tooth from 4 times 31. Now, taking my old rule, which I believe to be stated in the simplest possible terms—viz., multiply the number per inch of your leading screw by the distance apart of the threads you require, thus:—

$$\frac{4}{1} \times \frac{1}{31} = \frac{4 \times 4}{124} = \frac{24 \times 4}{124 \times 6}$$

then—

Mandril.		Stud.	Screw.
40	—	60	
—		24	124

would be the exact train required. Now, as you have not 124, substitute 125, which will give a thread of 31¼ to an inch, a difference scarcely perceptible.—J. K. P.

[47464.]—**Wood Shrinking.**—"Anxious to Know" should put his iron rings on his wheels when red-hot, and instantly plunge them into water, when the iron will contract. In fact, the same way as iron tires are put on carriage-wheels, only on a smaller scale.—H. Dixon.

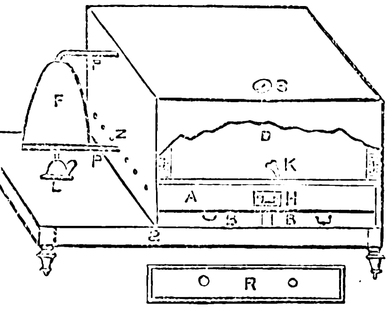
[47491.]—**Magic-Lantern Slides.**—I think Mr. Lancaster's remarks on this subject are intended to apply to those who know nothing of painting; but anyone who can paint a little in water-colours will soon be able to colour transparencies; at any rate, I found it a pleasant occupation during the long evenings last winter, and my pictures are as good as any I have seen in the shops. The colours I used were moist water-colours—Prussian blue, crimson lake, Italian pink (a yellow), and burnt Sienna. These are about all the transparent colours, and from them any other colour can be produced by mixing in various proportions. My transparencies were taken from engravings of Stanfield's sea-pieces, which make very good subjects for the magic-lantern. These were not printed very dark, in order that the colours might have their due effect; the common fault of coloured transparencies being a want of colour in the darker parts—such as trees, deep shadows, &c. It is also an improvement, before copying the engraving, to chalk over certain parts where bright colour is required in the copy; for instance, a fisherman standing up in a barge is to have a bright red cap, which is to stand out from a grey background. In the engraving this contrast is represented by variations in the depth of tint, but by making the cap white with chalk the transparency will have a little space of clear glass where the red cap appears, and this can be filled in with colour. The chief difficulty will be found in laying on light tints over a broad surface, such as the sky, middle distance, &c.; here an ordinary paint-brush or camel's hair pencil is useless, as it leaves all sorts of marks and blotches when used on glass, and I have found the following method very successful: take an ordinary dinner plate or two, and having placed it face downwards, paint over a portion of the white surface with a good strong tint of Prussian blue, not using too much water; then, over other portions of the plate or plates, paint with mixtures of colour to produce the various greys, purples, &c., required for the clouds, and allow to dry. If dried at the fire, allow to cool. All these tints should be of full strength, and appear almost black on the plate. We must then prepare several "dabbers," which are made by cutting out little circles of kid glove the size of a halfpenny, placing little balls of cotton wool in the centre of these and tying up with thread—the smooth side of the glove to be outwards. Hold the transparency in the left hand with a sheet of white paper behind (at a little distance from the picture), and with the fingers of the right hand hold a dabber. Now breathe hard upon the Prussian blue on the plate, and dab on it with the dabber; then instantly make a dab on the transparency, having slightly breathed on it, which will transfer a little circle of blue from the plate to the sky of the picture. Repeat this process till you get a series of these circles covering the sky; then breathe on the picture, and dab all over the sky gently. This will produce a flat tint, if properly done; but the tint will be very light—about the right thing for a blue sky; and it may be shaded off to the horizon by dabbing more in that portion of the picture. Clouds may be produced by using a wet brush, and wiping off the wetted parts with a cotton handkerchief, and then the greys and other tints dabbed on. I should have stated that the transparency should be varnished before the colour is applied with the ordinary negative varnish. It is wonderful what beautiful cloud effects can be produced by this method; and Stanfield's pictures have generally some cloud effects which can thus be reproduced. Having completed the broad effects of colour of the lighter tints, should we require to paint over them or to deepen them, it will be necessary to protect them with a coat of varnish (Canada balsam in turpentine); but do not varnish any part that is not to be painted over again, and do not use the varnish too thick. The colour can then be put on with a brush using a little ox-gall, and softened with the dabber. All dark and bright colours must be varnished with the Canada balsam to make them transparent; but the sky and other light parts are best left unvarnished, as the slightest speck of dust attracted by the varnish is very visible on the lighter parts.—M. I. C. E.

[47518.]—**Balance-Wheel Cutting-Tool.**—I am sorry our friend "Alfojoe" has not the tool, so that he can give "T. F. A." a sketch. I am very much pressed for time, or I would try and send a sketch from the tool I have to sell for a friend. Although the tool looks somewhat complicated, it is not so when in use, although it would be a complicated tool to give a correct sketch from. The tool I have has a division-plate for all the numbers of teeth from 7 to 19; several differently-shaped cutters, so that any kind of teeth can be cut—that is, any angle of escape-wheel teeth. With additional straight cutters, any other wheel could be cut in this tool, providing the division-plate is calculated for a given number of teeth. Example.—If a wheel of 45 teeth is required, each space of the 15 divisions can be marked into three; or, in the same way, we might divide the 19 by 4, and cut a 76-wheel, &c., &c. "T. F. A." can have further particulars by writing to me.—Edward Roberts, 27, New Bond-street, Leicester.

[47553.]—**Problem in Dynamics.**—On p. 530, fifth line from bottom, for "through v" read "through half v." Fourth line from bottom, I should be E.—C. H. Romanes.

[47553.]—**Problem in Dynamics.**—I think that C. H. Romanes is not correct. How could the monkey move the ball at all? For, although he climbs the rope, at no point or time can he exert a downward pressure greater than his own weight. Hence there would always be an upward pressure on the ball equal to its own weight, and no more, and the ball would not rise. If I am in error, will C. H. Romanes kindly state where, and oblige?—Tam O'Shanter.

[47555.]—**Incubator.**—Explanation of Sketch; 2, separate stand; B, tin trays to hold damp sand; A, drawer with perforated zinc bottom to hold eggs; N, handle that folds flush with drawer front; D, tank to fill with boiling water through screw plug S; I, oak sawdust, packed round sides and top of tank to keep in heat; K, tap to draw off water; F, circulating boiler to keep water in tank at required heat, 104°; L, lamp; P P, pipes leading to tank; Z, holes through case and drawer, with pegs to fit for ventilation on 19th day; R, separate front to inclose drawer and trays.—Cetewayo.



[47570.]—**Bronzing Cardboard.**—First make a sieve by glueing a piece of fine muslin or butter-cloth all round a frame, made of deal, 4in. square 1½in. deep, to put the bronze in, next make some glue-water rather thinner than cream, and strain through a fine cloth or muslin; put the glue-water in a basin, and place it where the lid should be on the tea-kettle; place the kettle on the fire to heat the glue (hotter the better). Have your cardboard quite flat; put on the glue-water very quickly and evenly with a 2in. flat camel-hair brush; go over the card with the sieve in your left-hand, tapping the sieve gently with the fingers of your right-hand, it will be ready for dusting in an hour's time; try a piece of card about 14in. by 12in. for a trial.—Practical.

[47572.]—**Midland Tank-Engines.**—There have been 10 six-wheel coupled tank-engines built, which number from 1552-1561. They have cylinders 17 by 24, and wheels 4 by 6. These engines have very short chimneys, and short domes with spring balances on the side of the boiler. The engines which "Meteor" means are bogie tank-engines. He is right with dimensions, but was mistaken with the numbers. 1532-1546 were built for local traffic about Manchester, Bradford, and Bristol. 1547-1551 are fitted with condensing apparatus for the Metropolitan districts. All these have been built at Derby Midland Locomotive Works in 1881 and 1882.—Camomile.

[47576.]—**Arsenic.**—"Prevention is better than cure," and I should strongly recommend B. T. Ord to procure a few indiarubber finger-stalls. They can be obtained from any photographic dealer for a few pence, and will completely protect his fingers from injury.—T. S. H.

[47580.]—**Nightmare**.—Nothing is easier than to prevent, or cure, this distressing and often dangerous malady. This disease is a symptom of indigestion. The persons liable to it are those who indulge in the extravagance of heavy suppers, particularly if their stomachs are in a weak condition. One way to cure it is as follows:—Go to bed without any supper, or take very little, and what little is taken, let it be food easy of digestion. Avoid all intoxicating drinks, and anything that is likely to lie heavy on the stomach. When in bed do not lie on your back, and make a habit of early rising. Get as much fresh air as possible. Always make it a rule to rest an hour or so after taking your supper. I do not think any medicine is necessary, as this disease proceeds generally from abusing the stomach. Nightmare is easily prevented, and is only a punishment for people who are careless in their diet.—G. Fryer.

[47580.]—**Nightmare.**—I am very happy to be able to impart some valuable information upon the subject of nightmare, in return for a few useful hints conveyed to me through your columns. I purposely waited to learn the character of the replies to the query in yours of the 3rd inst.; but there seems to be no new remedy devised. At one time I never dared to fall asleep upon my back, so subject was I to fearful dreams. Subsequently, I found that I could not sleep upon my left side, and I was compelled to adopt the back as the only change, fighting the while against sleep. Now, the shape of the head being oval it follows that the back of the head or one end of the oval resting upon a pillow, causes an unnatural position, to the entire destruction of easy respiration, which, if it does not always produce nightmare, serves to render night hideous as a companion. The remedy is simple, and to this discovery I am indebted for many peaceful nights whilst lying on my back. Place the pillow under the nape of the neck, so that the head may slightly hang over—it may rest upon the bolster. The windpipe now has the passage fully open, and breathing is unrestricted. All I require, in return for my discovery, is a recumbent memorial—the statue to be embellished with representations of Melton Mowbray pies, pork sausages, crabs, lobsters, and tenpenny nails.—Fred. W. Brearey, Maidenstone Hill, Blackheath.

[47586.]—**Pure Silver**.—To obtain the silver chemically pure you dissolve it in pure slightly diluted nitric acid, when it will cause the acid to become green. When dissolved, pour the clear liquid out, and add to it a solution of common salt as long as a precipitate falls. This precipitate will be chloride of silver, which, when washed and dried, must be melted in a crucible with anhydrous (without water) carbonate of soda. Chloride of sodium and silver will be the result after the mass has been stirred with an iron rod and the temperature raised to a very bright red. The silver will be found at the bottom of the crucible as a brilliant mass.—T. Delbridge.

[47586.]—**Pure Silver.**—Absolutely pure silver is very difficult to prepare; but if the querist understands chemical operations, I will give him the method employed by Prof. Stas in the determination of its atomic weight. Silver, pure enough for all ordinary purposes, may be obtained from his scrap by dissolving in nitric acid (aqua fortis), diluting with water, and adding a solution of salt as long as a white precipitate of silver chloride is produced. This white precipitate is then washed well with hot water about a dozen times—pouring on the hot water, allowing to settle, and pouring off. It is afterwards dried, mixed with twice its weight of dry sodium carbonate, and the mixture fused in a clean crucible; the button of silver so obtained may then be cleaned with a little dilute sulphuric acid, and scoured with clean white sand.—T. S. H.

[47590.]—**Honours Chemistry.**—The calculation given by the querist is one of the simplest. The volumes must first be all reduced to 0°C. and 760mm. pressure; but as nothing is said about pressure, except in the first case, we may conclude that it is normal, and the only correction to be made is in the case of the first volume, at 4° and 537·4mm. The corrected volume of air employed becomes:

$$851{\cdot}4 \times \frac{1}{1 \times 0{\cdot}003665 \times 4} \times \frac{537{\cdot}4}{760}$$

or:

$$851{\cdot}4 \times \frac{273}{273 \times 4} \times \frac{537{\cdot}4}{760},$$

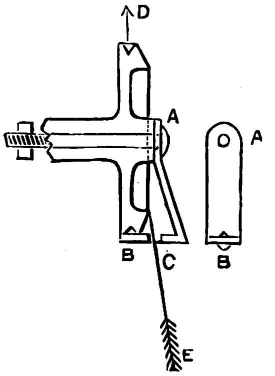
according to the usual formulæ. Call this volume of air V_1. Now the volume of gas which disappears on explosion is $657{\cdot}06 - 374{\cdot}73 = 283{\cdot}33$; but this consists of $\frac{2}{3}$ hydrogen and $\frac{1}{3}$ oxygen, therefore, the oxygen present in volume V_1 of air is $\frac{1}{3} \times 283{\cdot}33 = 94{\cdot}44$, and the percentage of oxygen $= \frac{94{\cdot}44 \times 100}{V_1}$.—T. S. H.

[47597.]—**American Organ.**—"J. P. C." had better put away the idea of enlarging his one-row American organ, particularly as he wishes to add more reeds, which will incur the necessity of a larger bellows, which will also require a larger case to hold it. Some little space will also be required for the mechanism of the octave coupler.

There are three octave couplers applied to the various American organs. One is made to couple up, its action being to bring down its respective note an octave above. This is the ordinary octave coupler. There is also another octave coupler, which actuates so as to bring down each respective note an octave below. Another coupler, known as the divided octave coupler, is so constructed as to bring down the corresponding note an octave above in the treble portion, and those of the octave below in the bass portion of the organ. Let "J. P. C." first decide as to the exact size of the instrument he wishes to construct, and the number of rows of reeds he wishes to have, then, no doubt, he will have the assistance of our able correspondents, as well as every assistance which I can afford him.—G. Fryer.

[47598.]—**Electrical.**—In the beginning of the article it says that a di-electric in allowing electricity to pass through itself may undergo slow inductive decomposition. Consequently, the + ly charged ball, A, acts by induction through B on D, thus charging D − ly and repelling + to C. While so doing, however, A slowly electrifies the part of the side of B nearest to it − ly, and repels the + to the opposite side. This + electricity then neutralises the − ly charged brass ball, D, thus causing the leaves of the electroscope to collapse. As it is only strong enough to electrify the part of B nearest to it, the experiment can, of course, be repeated when a fresh part of B interposes.—T. Delbridge.

[47599.]—**Drilling Bicycle Hubs.**—Take a piece of coach hooping about $\frac{3}{4}$in. by $\frac{1}{8}$in., and bend as shown in sketch; bore a hole in at A for centre-pin, and at cranked end at B a small one for a wire centre to be riveted in. After your hub is lined off and centred, put a longish-pointed drill into the lathe, and just run this drill in the depth of countersunk between centres all round; then apply the angle-piece as shown, and drill a small hole for your back-centre the required angle for back-centre at C, and then proceed to drill them all through, shifting this piece every hole to bring them square, or rather more lineable; see B E.—Jack of All Trades.



[47603.]—**Plating with Gold inside and Silver outside.**—Silver-plate your cup, then pour gold solution, previously heated, inside the cup, and suspend the gold anode in the centre of the cup, attach the negative wire to the handle of the cup. The gold solution must be exactly up to the brim.—J. E. A.

[47604.]—**Bicycle Tires.**—Having been in the same difficulty as "Apprentice Boy," I shall be glad to help him out in the same manner as I was helped out myself. The following is the simplest way to fix a loose tire. Powder or roll into a pencil-shape some of the cement, put it under the tire, then hold a spirit-lamp underneath until the cement oozes out; then tie a piece of string round the tire and rim, and let it remain according to the length of time given in the "Instructions," for the cement. The spirit-lamp will not burn the paint at all which hot-irons do. A spirit-lamp may be made very cheaply, as follows:—get a "Liebig" or similar jar, with a bung in it, bore about four holes in the bung and insert a glass tube in each, and with a few inches of wick and two or three pennyworth of methylated spirits, the lamp is complete. I use glass tube 1-6in. diameter; but I daresay any other material will do. The tubes should be in a straight line across the bung.—Geo. Reavell, Alnwick, A.B.C.

[47607.]—**Kitson's Steam-Brake.**—In my reply, Vol. XXXIV., p. 145, I mentioned that Kitson's steam-brake was not tried at Newark, in consequence of the Midland Company's engine and tender No. 892 not arriving at the trial ground. The following is the official description of the brake prepared for the information of the Royal Commission:—Kitson's steam-brake acts merely on the wheels of the engine and tender, and not upon the train. It consists of two oscillating cylinders—one underneath the foot-plate of the engine, and the other underneath the foot-plate of the tender, the pistons of which are connected with the brake rods. To put on the brake, steam direct from the boiler is applied to one side of the pistons only, the other sides being open to the atmosphere. Strong spiral springs at the backs of the pistons liberate the brake-blocks immediately the steam is exhausted. A simple two-way cock upon the front of the fire-box simultaneously admits the steam to the cylinders, and closes the exhaust-ports, or *vice-versâ*. By means of another cock, steam may be admitted at will to both engine and tender, or to each separately. The brake-blocks are of cast iron, hung from the framing, and are applied to one side only of the driving and trailing-wheels of the engine, and to both sides of all six wheels of the tender. Provision is made for working the brake with an ordinary hand-screw if necessary. Pipes are arranged so that a water-jet can be turned on to the engine tires. Experiments were made on the Derby, Castle Donnington, and Trent line, September 22nd, 1875, and February 9th, 1876, with a train consisting of engine and tender, No. 892, both fitted with Kitson's steam brake, four carriages without brakes, and two guards' vans with ordinary hand-brakes. The results obtained, when compared with the stops made by engine No. 815, fitted with Le Chatelier's counter-pressure steam apparatus, upon the 21st September, 1875 (details of which will be found in Vol. XXII., p. 119), conclusively proved to all present that brakes upon engine-wheels produce far more retarding power than an engine reversed, and full steam against it, even with the Chatelier tap open. —Clement E. Stretton.

[47610.]—**Defective Sewing Machine.**—It is difficult to advise without seeing, as the stitches cobbling underneath may be caused by various means; firstly, see that the upper thread is rightly threaded, and that the tension of same is sufficiently tight; secondly, the take-up spring, through which thread passes just before reaching needle, should have sufficient spring to take up any loose thread, sometimes these springs get loose and require tightening; thirdly, see that the needle does not jar or burr against the presser-foot, or against side of needle-hole in plate; fourthly, see that presser-foot holds the work firmly; to ascertain this, raise the needle and lower the foot, now place a sheet of thin paper under the foot, and if foot is rightly adjusted, you will not be able to draw the paper from between very easily without tearing the paper; fifthly, see that you have shuttle threaded right, possibly, you may have the shuttle threaded too tight; lastly, see that the feed-motion feeds the work forward, as the needle repeatedly going down in the same hole would cause cobbled stitches; you can ascertain this by placing material in machine and working it round as if for ordinary work, but without any cotton in needle. If you cannot get on, should be glad to correspond, if you will advertise address. Perhaps the machine is out of time, that is to say, the needle and shuttle might not be in right time.—E. Martin.

[47613.]—**Photographic Camera.**—To Mr. Parkinson.—In my own practice I use an improved tourist-camera, with horizontal and vertical sliding-front, improved double swing back, hinged focussing screen, and will take pictures horizontal and vertical. You will find this camera the most useful for an amateur's practice; by having an extra front you can adapt your portrait lens, without causing the slightest inconvenience. The cost of a first-class camera with three double slides, would be, $\frac{1}{4}$ plate, £4 10s.; $\frac{1}{2}$ plate, £6 6s.; 1-plate £7 15s. I would not advise you to purchase anything but a first-class set of apparatus; if you do not care to go to the price, purchase a second-hand set of first-class manufacture.—James Parkinson.

[47628.]—**Private Study of French Language.**—You should have lessons of a good teacher so as to acquire the language conversationally. If that plan does not suit you, join a corresponding class, to which Miss Walker, St. George's Hall, Randolph-place, Edinburgh, will introduce you. If you want to study quite alone, get Chardenal's 1st, 2nd, and 3rd French Courses, prices 1s. 6d., 2s., and 3s. 6d.; "Le Petit Précépteur," 1s. 6d.; "French Verbs at a Glance," by Beauvoisin, 6d.; and Chambers's "French and English Dictionary." The corresponding classes are one guinea per quarter.—Maggie Brune.

[47623.]—**Electro-motor.**—The armature A consists of round iron bar, with the pole pieces, P P, fixed on the ends, exactly as shown in Fig. 1. B B are field-magnets, with poles arranged as shown in Fig. 2, which is a top view. The pole pieces of field-magnets are of the shape shown in Fig. 3. When the armature revolves, it encounters no dead point, being either attracted or repelled during the entire revolution. The commutator reverses the current just as the edges *d d* of the armature arrive at the edges, H H, of field-magnet poles. In most electro-motors, that period of the armature's revolution during which it passes the field-magnet poles is wholly wasted; but in the above motor, owing to the relative shapes of the latter, and the poles of armature, this part of the revolution is the most useful of any, as the armature is then nearest the attractive poles, and so subject to the greatest pull. In Trouvé's motor, the length of the armature from pole to pole is extremely small, wherefore it cannot be powerfully magnetised, and there is also but little leverage. The armature of above motor must be of good soft iron. Should any difficulty be experienced in making the field-magnet pole pieces, they may be of cast iron. Any point that is not clear I shall be glad to elucidate.—Conrad.

FIG. 1.

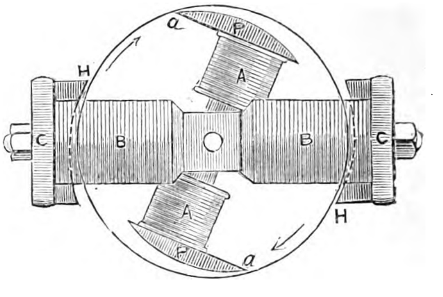


FIG. 2.

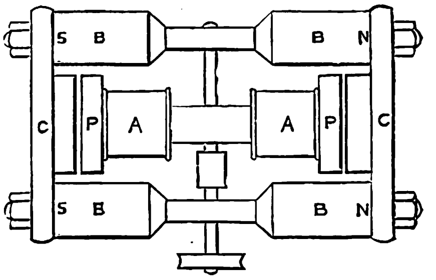

FIG. 3.

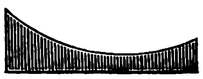


[47630.]—**Brakes.**—There is no question as to the answer to this. A wheel touches the rail only in a point; but a brake block covers a wider surface. It is commonly said that friction is only a function of pressure, and has nothing to do with surface. I believe that to be to a certain extent erroneous; but, as you will see, if a wheel is skidded, the point is quickly worn down to a "flat," and the surface being highly glazed, the wheel slips over with the minimum of friction. On the other hand, when the wheel rubs against the block, the latter wears like the tire, uniformly, and a greater surface must be worn away before either tire or block has the highly polished glaze of a "flat"—in fact they never do glaze. Finally, I think you will find that Capt. Galton, in the trials he made on the Brighton, demonstrated by mechanical means that the greatest friction was produced when the wheels just rubbed past the blocks, and I think it was mainly from the facts learned in those experiments that the Westinghouse brake was so arranged that the driver could manage to always keep it just short of skidding. Skidding is an abomination, as it wears flat places, which increase the thumps on the rails, and necessitate frequent turning up of tires. No engine-driver worthy the name will allow his fireman to stop the wheels if he can help it.—Nun. Dor.

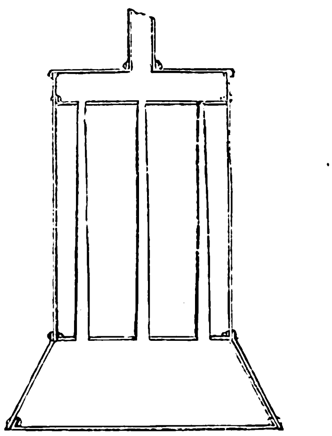
[47630.]—**Brakes.**—To Mr. H. Stooke.—If your correspondent will refer to the details of Captain Galton's experiments, Vol. XXVII., or to my pamphlet on "Railway Accidents," he will find that skidding should be avoided, as the best results are obtained by applying the brake-blocks to the wheels with a pressure as high as possible short of the point which would cause them to skid. The rotation of a wheel is arrested as soon as the friction between the brake-block and the wheel exceeds the adhesion between the wheel and the rail.—Clement E. Stretton.

[47632.]—**Model Loom.**—"Diana" is right in thinking that a model loom would be of great assistance to him in learning tweed designing; that is, if he can work one and make the necessary changes. But I would advise him that he can learn tweed designing in half the time it would take him to make his loom, except he has a mechanic's shop at his elbow. If he has no knowledge of looms, it would take the whole of the 24 pages of our paper to give the instructions he asks for, and he would have a lot of questions to ask as to details the following week. Designing and pattern-weaving are two separate things, and "Diana" can learn one without the other. If he will say what he has done, what he is doing, and where he is stuck, I will help him out, either through the Mechanic or privately; but I don't wish to give instructions that will be useless to him, except he has some knowledge already. If he still wishes to go on with his loom, it would be well if he would state what kind of loom he wishes to make—Jacquard, Dobbie, Barreltapits, revolving or drop-boxes for shuttles: or whether he would make the necessary changes by hand.—W. Stuttard, Breeze-lane, Liverpool.

[47640.]—**Unipolar Induction.**—This experiment is a modification of Ampère's revolving bucket apparatus, in illustration of his magnetic theory. It is fully described in most treatises on electromagnetism of the date 1830 to 1850; but not in the modern textbooks. See for an illustrated account of all the apparatus of this kind in "Sturgeon's Researches," or the older editions of the Encyclopædia.—J. Sutcliffe.

[47642.]—**Silicate of Soda.**—I think this will suit inquirer. Take 1 part silicate of soda, 7 parts water, boil for one hour, decant the liquid and mix thoroughly with 2 parts kaolin. Use this as paint: it will dry with a polish and keep damp out of outside-wall.—Raj Mistry.

[47647.]—**Boiler.**—I should suggest that a pair of 2in. cylinders would be better for a boat 4ft. long, 6in. beam, and the dimensions of boiler for such would be 6in. in all (vertical), a smoke-box ½in., boiler 4in., diameter 3in., fire-box 1½in., increasing in diameter from 3in. at top to 4½in. There should be 9 tubes, ⅛in. diameter at the top and ¼in. at the bottom; the ends should be turned down over the tube-plates, thus holding them firmly together. This boiler should be able to stand a pressure of 40lb. to the sq. in. Fill it up about two-thirds with water. This boiler should be made of copper, and burn spirits of wine. It will work a pair of 2in. stroke cylinders very well. Sketch is exactly quarter-size.—Amateur Engineer.



[47651.]—**Examination of Malt.**—To E. S. Beaven.—1. Estimation of Grape-Sugar and Dextrine.—If "Phœnix" has not already prepared his Fehling solution, let me recommend him to keep it in two parts. It will then keep good a much longer time. In order so to prepare it, dissolve 34·64 grammes of pure copper sulphate in distilled water, and make up to 500cub. centimetres. Keep this solution in one bottle. Then dissolve 173 grammes of Rochelle salt and 65 grammes of caustic soda, and make that also up to 500cc., and keep in another bottle. For each estimation use 5cc. of each solution. The 10cc. will be equivalent to ·05gm. grape-sugar. Before using the test solution dilute 10cc. with 40cc. water, and boil. If any precipitate forms the solution is useless. To prepare the malt extract for analysis, take 50cc. of the 1 in 10 extract previously obtained, and dilute this to 500cc. This will be a suitable strength for estimating the grape-sugar. Measure carefully 10cc. (as above) of the Fehling sol. into a white porcelain evaporating-dish, add 40cc. distilled water, and raise to boiling point. Then run in the diluted extract from a graduated burette, one or two cc. at a time (boiling up after each addition) until the blue colour of the Fehling sol. is destroyed, and all the copper precipitated as red oxide. This operation you will find requires some nicety of manipulation, and the point at which all the copper is just precipitated is not easy to arrive at without considerable practice. It is best after boiling up to allow the precipitate to settle, and then gently tip the dish on one side in a good light, and note if any shade of blue remains. For perfect accuracy, it is necessary to test the hot solution for copper as follows:—Take out with the point of a pipette a few drops of the clear solution, and filter through a very small piece of Swedish filter paper; add a drop of acetic acid and a drop of potassium ferrocyanide. A brown colour indicates that copper remains unreduced, and more malt extract must be cautiously added, and the testing repeated, taking care to use a clean filter and test-tube. The whole operation must be performed as quickly as possible, as the red sub-oxide has a slight tendency to redissolve. The quantity of extract used is now read off from the burette, and is equivalent to ·05gm. grape-sugar. Supposing 16cc. of diluted extract have been required, then (as each cc. equals ·01gm. of malt), ·16gm. of malt yields ·05gm. grape-sugar, or 31·2 per cent. Some analysts recommend adding three or four times the quantity of strong ammonia solution to the Fehling, instead of water. The reduced oxide of copper then dissolves, and a clear solution is obtained. I have performed the process many scores of times both ways, and consider the old method most reliable, although not so easy; but "Phœnix" can have particulars of the other if he likes. Now, as to the dextrine. I presume "Phœnix" has Bale's or some other table giving the proportion or true lb.-weight per gallon of solid extract corresponding to the specific or apparent gravity of the wort. Supposing his original 1 in 10 extract had a gravity of 1,027 (which it will if the malt is good), the table shows this to be equal to ·697lb. per imperial gallon. Now, as his malt is in the proportion of 1lb. to 1 gallon (an imperial gallon of water weighing 10lb.), this is obviously equivalent to a solid extract of 69·7 per cent. of the malt. Deduct from this 31·2 per cent. (the assumed percentage of grape-sugar), and the remainder is dextrine, plus soluble albuminous matter. To determine the dextrine directly, take 100cc. of the diluted (1 in 100) extract, and boil it for two hours in a flask with 2cc. of sulphuric acid; this will convert the dextrine into grape-sugar. Estimate as before with Fehling. Deduct grape-sugar already found, and the difference is dextrine in terms of grape-sugar, which must be diminished by one-tenth to give the actual dextrine. I should have said that I am in the habit of boiling the wort previous to diluting it for the above determinations. Of course, it must afterwards be cooled down to 60° F., and made up to 500cc. The albuminous matter, which does not coagulate, but remains in solution, will be found by difference, and ought to be under 4 per cent. 2. Mashing Heats.—What does "Phœnix" mean by "calculating upon the amount present?" The grape-sugar and dextrine are not present in the original malt. They are formed by the action of diastase upon the starch of the malt in the mash-tun, and the proportions in which they are formed depend upon the temperature of the mash. I cannot pretend to give "Phœnix" instructions in practical brewing, but I will give him a few general facts as to the relation between heats and the formation of grape-sugar and dextrine. And first I would note that I believe many brewers regulate their process of mashing entirely by varying the heats of their liquor, irrespective of the actual heat of the mash itself. Now, it is the mash heat that is of importance, and the heat of the liquor is only a means to that end. It has been proved that the best temperature for the conversion of starch into dextrine (which constitutes the first part of the mashing process) is 145° to 147° but that a considerably higher after-temperature is needed if it is required to convert a large proportion of the dextrine into grape-sugar; 165° to 167° appears to be the most favourable heat for this transformation. Practice and theory unite, therefore, in fixing 145° to 147° as the proper initial temperature of the mash, and according to the extent to which the heat is afterward raised will be the proportion of sugar to dextrine. I have myself obtained experimentally 36 per cent. of grape-sugar, and 24 per cent. of dextrine by maintaining the infusion at 167° for three hours. In practice, this could scarcely be done unless there was a coil in the underback where the conversion would go on at the temperature mentioned just as well as in the mash tun. Finally, the printer has obviously made a mistake in representing you as mashing 5qrs. of malt with 2½ barrels of liquor, but I cannot possibly feel what the taste of your customers may be, and should say, moreover, that the process of fermentation had more to do with modifying the character of the beer than even the mashing has. If, however, a very full bodied, or, which is the same thing, a dextrine beer is wanted, the temperature should not go much, if any, above 160°; but if, as I expect, a saccharine beer which will undergo a ready fermentation and come round quickly is required, I should say that the mash might with advantage be 10°, or nearly so, higher: that is, of course, after starch conversion has taken place. Let it be understood that I refer solely to mash temperature. The mashing is a purely chemical operation. The regulation of liquor heats to obtain a given mash heat depends so much upon the age of the malt, the temperature of the air, and even the position of the tun, that experience is the only possible guide.—E. S. Beaven.

[47653.]—**Oiling Fish-lines.**—Take a piece of flannel, and when your lines are stretched, apply boiled oil, to which a little camphor and turps is added. You can stain it with what you like, and it will dry very quick if the oil is good boiled linseed oil.—Jack of All Trades.

[47654.]—**Printing.**—I know of no work specially devoted to colour printing (letter press), but I imagine all the usual guides to presswork contain a few lines about it. There is really nothing in it, so far as the type is concerned. Suppose we have a prayer-book, with red initial-letters and a red border line. The black type is set up in one forme with the initial-letters omitted; the red type is set in another forme, and in this case consists of the initial-letters and the border line. The compositor's business is so to arrange the types in the two formes that if a sheet of paper is laid accurately to gauge-marks the red letters will fall exactly in their places. The only real difficulty is in the paper, for if after the black is worked, the paper is allowed to dry, the red letters will not fall exactly in their places. If you can see one of Lloyd's Registers of Shipping, you will find numbers of words and signs worked into that; but being done on machine, the register is not quite perfect, though very close. In press work, where the sheets of paper are placed on pins, it is comparatively easy to insure the red falling into proper position. I should mention that there is a method of working advertisement pages in four different colours. Suppose, for instance, a page of this paper divided into quarters for advertisements, it would be possible at one impression to work four colours. That is done by having a four-celled ink-slab, each cell in line with its share of roller and type; then, as the roller has no lateral motion, it will take up on each of four portions a separate colour, and ink the four portions of the page with different colours. Obviously, that can be done to very great nicety; but a little space is necessary between each colour. Before lithography reached its present perfection, a capital imitation of the spectrum was worked from a wood block and printers' inks. The table had a rack each side, and the roller was fitted with spur wheels working in the rack; further, the roller was of greater circumference than the spectrum was long. The inks then being carefully placed in proper order on the table, the roller was passed over, and being regulated by the wheels and the rack, the same part of the roller always fell on the same part of the table. At the press, the block from which the impression was taken had a similar rack on each side, and the roller being placed to a gauge-mark always inked any given part in exactly the same manner. Some excellent copies of the spectrum were thus produced; but, necessarily, the process was more expensive than even the multiple working of the chromo-lithograph. Finally, let me tell "J. D." that while separate colours are, in letterpress, invariably produced by means of separate formes, in the cheap coloured pictures he sees, the tints are often produced by working one colour over another; thus, to make a green, yellow would be worked over blue. Don't imagine, however, that blue and yellow *make* green, as some paradoxers would persuade you; it is only certain combinations of pigments that make the colours which seem just now to puzzle some people immensely. I wonder often whether their eyes always see alike, for pressmen's don't always.—A Practical Printer.

[47655.]—**Cotton.**—Jute is the best of several Indian herbaceous plants, generally Corchorus capsularis and C. olitorius. It consists exclusively of bast-cells, whose greatest diameter in the first-named plant is 16 millimetres, and in the latter 20 millimetres. The fibre is strongly lignified by saturation with moisture. When fresh it has a silky lustre, and white to flaxen colour; but with age it darkens very much, and in a damp atmosphere becomes a deep brown. Cotton is the seed hair of several species of Gossypium; each hair is an individual cell, whose maximum diameter fluctuates between 12 and 42 millimetres, contracting slightly towards the centre, diminishing towards the base, becomes conical towards the tip, and the cell-walls are very thick. W. Binns and friend may easily distinguish the fibres under a good microscope, if they cannot do so by pulling them apart and examining them closely with the naked eye. The weft may be all composed of jute, as is sometimes the case, and it would have made no difference to them if used as bought, without dyeing. The great characteristic of jute is the unequal solidification of the cell-walls, which distinguishes it at once from other fibres. Cotton consists of almost pure cellulose, is unaffected by aniline sulphate, coloured blue by iodine and sulphuric acid, and ammonio-cupric oxide causes it to swell up and finally dissolve. Jute, by treatment with phloroglucine and hydrochloric acid, becomes blood-red, and treated with sulphate of aniline it becomes intensely yellow. I think its affinity for colouring matter is quite equal to that of cotton; but, of course, treatment suitable for a fabric of cotton alone cannot be expected to give satisfactory results on a cotton-jute fabric. Any further information if desired, or I would examine a piece of the cloth.—W. Stuttard.

[47657.]—**Railway Signal-boxes v. Thunder and Lightning.**—I have some useful information on this subject. You shall have it soon.—H. Stooke.

[47664.]—**Brake Failures.**—To "A. S. H."—The failure to which your correspondent refers and about which he remarks there has been "considerable controversy," occurred on 7th July. Upon that date the up night Scotch express was worked in duplicate, the second portion being drawn from Leicester to London by an engine (823) fitted with a steam brake and the Midland modification of the automatic vacuum brake, better known as the "two minute brake." The report of Col. Rich upon the Portskewet Pier accident has most distinctly pointed out the danger to be expected from the use of brakes which leak off, and the frequent failures which occur to this brake upon the Midland and Great Western railways ought to receive the serious attention of the directors of those companies. Mr. Reynolds, in his book on continuous brakes, states, page 183, "that we ourselves are convinced that if the Midland Company abolished the use of the steam-brake on their engines there would be a serious accident in less than a week." This is well-known to be the general opinion upon the railway, and it would not surprise any person who understands the dangerous "leaking off" system to hear of a serious accident being caused by the failure of the two-minute brake; in fact, such an accident has been expected for some time, but so far it has fortunately happened that upon the occasions when failures have taken place and trains have run past stations and junctions, the line has been clear, so that no collision ensued, but there is a very great fear that this may not always be so, especially when the mishap occurs at a crowded junction like Kentish-town, as was the case upon a recent occasion. Under these circumstances we cannot be surprised that the engine-drivers complain about this very inefficient brake. —Clement E. Stretton, Saxe Coburg-street.

[47669.]—**Grapes.**—It is a very rare thing to get the Sweetwater to ripen without bursting. Have you been applying liquids too long to the root and keeping house dry?—Jack of All Trades.

[47670.]—**Study of Electricity.**—Our friend "Sigma" would have to write a volume to answer your query fully. Get "Preece's Telegraphy," "Culley's Handbook," "Ferguson's Electricity," and from them learn the nature of electricity, and the construction of instruments. Cost of the three books not more than 30s., I believe.—H. Stooke.

[47671.]—**Institute of Chemistry Examinations.**—You may sit in May next for either elementary or advanced certificates. The only restriction placed by the Department is, that you confine yourself to one—that is, not to answer questions from both elementary and advanced. Hence, it is impossible to take the elementary and advanced certificates of same subject in one year. —F. G. S.

[47673.]—**Electric Lighting.**—I should use the "Lampe-Soleil" in preference to any other form of arc light. I have carefully examined it, and for simplicity, steadiness, whiteness of colour, and general perfection, it is not approached by any other form of arc light that has been yet brought out.—Caloric.

[47673.]—**Electric Lighting.**—It is impossible to get an arc lamp of the candle-power you mention, three of which would only require 1 h.-p. of engine. The nearest approach to it would be either a small Jablochkoff (the purchase of which you would soon repent) or a Joel semi-incandescent lamp. You would be able to produce from 2 to 3 of the latter, of about 50 candle-power, from 1 h.-p. As regards the "Lampe-Soleil," I am afraid it would not answer your purpose, as each lamp of 1,400 candle-power (so-called) requires at least 2 h.-p. What I should advise you to take, if you wish to illumine a large room, would be an arc lamp of the Brush pattern of about 1,900 candles (2,000 without globe), to drive which 1¼ h.-p. would be ample.—John Bull.

[47674.]—**Electrotyping.**—It is quite possible to accomplish your design, with care; soak the plaster-cast in wax, and brush over with dry and pure black-lead. You had better make a rough experiment to get a thin shell of copper, when you have done so, begin again and try for your ⅛in. thickness, it will take several days, perhaps weeks. —J. Sutcliffe.

[47678.]—**Scratched Plate.**—The only way to remedy this is by regrinding and repolishing, which would cost as much as new glass.—E. Holmes.

[47681.]—**Painting Stove-Poles.**—Glass-paper off with coarse paper and coat with patent knotting. But your poles should be warmed first and perfectly dry.—Jack of All Trades.

[47681.]—**Mill.**—See answer to 47642.—I am not quite sure whether it will stand the heat on the stove-poles.—Raj Mistry.

[47682.]—**Electro-Magnetism and Magneto-Electricity.**—Oersted's discovery was the action of the galvanic wire in producing motion of a magnetic needle. Faraday then showed by experiment that this action was owing to the north and south magnetic poles having a tendency to move round the wire in opposite directions. Arago then discovered that conducting bodies in motion produced motion in a magnet. And finally, Faraday showed that the movement of conducting bodies under the influence of a magnet produced a current of electricity, and in consequence this produced heat. It would take too much space to describe the experimental illustrations of the above. Only a few are given in the small popular treatises of the present day.—J. Sutcliffe.

[47683.]—**To Electricians and Mechanicians.**—You may enlarge your battery by the required number of porous cells, and use as a double-fluid Bunsen; if you, however, prefer the bichromate double-fluid cell, cut the zincs to 7in. by 2½in., and use them inside the porous cells, and the carbon in the outside jars, with small lumps of carbon to increase the surface; set up the 50 cells in two series as one battery of 25 cells; this will give you the best effect. Amalgamate the zincs, and do not try any mechanical agitator; such a thing can easily be made by what is called a water-tumbler, but it would be no use. An accumulator battery is not suitable for your purpose any way.—J. Sutcliffe.

[47688.]—**Painting.**—Give it two coats of moderately dark lead colour, and three or four of black. Ivory black or drop black must be used in both, as it is lamp-black that has so much grease in it, and so difficult to manipulate on account of the manufacture and spongy texture, and will remain for years with grease sweating out of it if in the sun, unless it is put into a crucible and subjected to a red heat; it is the most difficult paint to get to dry properly. Mix your lead colour with one of boiled oil to four of turps, and your black with gold size and about four of turps. See that each coat is laid on uniform, and not too thick, and thoroughly dry before another, and just slick it over with No. 1 or 1½ glass-paper every coat before applying the next, to keep the face free from lumps, blisters, or having the face-measels.—Jack of All Trades.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last C. E. Stretton has replied to 46828.

Edible Snails.—Snail gardens are common throughout Europe; that at Ulm, in Wurtemberg, sending out no fewer than ten millions of the largest species—*Helix pomatia*—to be fattened in other gardens before being sent to various convents in Austria for consumption during Lent. The proprietor of another "snailery" at Dijon is said to clear about £300 a year by his snails. In this country snails are sent in large quantities from the Licolnshire fens to Covent Garden Market, where they bring about 6d. per quart. Their use in medicine, however, is not unknown in this country; and they have been for centuries prescribed, as cod-liver oil is, for consumptive patients. They are also said to be employed in the manufacture of cream, forming when bruised in milk and boiled, an excellent imitation of the genuine article.

QUERIES.

[47684.]—**Tin-plate Working.**—I want to make some tinware, notably a number of canisters of one size. What tools shall I need? Please give technical names, and price. I can use a bit fairly, but cannot turn up edges. About what quality of plate should I use? Any information as to buying plates, sizes, &c., will be appreciated.—Geo. Chapman.

[47685.]—**Photography.**—To Mr. W. Henderson, Jun.—Kindly state how the marks caused by freckles may be removed or obliterated from a dry plate negative, and oblige—South Tower.

[47686.]—**Legal.**—J. B. became a bankrupt 41 years ago, and died, leaving five children. The debts were £5,800, part of which were paid, some of the creditors having accepted a composition of 8s. 6d. in the £, while others received only 4s. 5d., and awaited more. Balance-sheet showed £900 still owing, but £700 has since been paid, and another £500 is now expected to be. Is it of any use the children putting the matter in the hands of a solicitor with the view of getting some part of this money, and what chance of success?—J. E. B.

[47687.]—**Legal.**—Will Mr. Wetherfield give me advice in the following matter?—My father having died leaving a will, bequeathing me the rents of six houses for my life, afterwards to my children. A short time before his death he borrowed £200 on note of hand, giving the deeds of my houses for security, which the executors are endeavouring to make me pay. Now, am I compelled?—as he leaves his furniture, stock-in-trade, &c., to be sold, and after paying all debts, funeral expenses, &c., the remainder to put out to interest till his grandchildren attain the age of 21 years.—A. S. B.

[47688.]—**Remelting Pig-iron.**—Supposing I melt 215½ tons of old cast-iron railway chairs, and 163½ tons of ordinary pig-iron together, and produce 348 tons of castings, may I assume I am doing this with as little loss as possible? It will be seen the loss in this case is 200lb. per ton, which seems rather heavy. What is the average waste in remelting pig-iron?—Sefton.

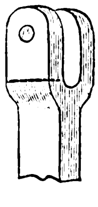
[47689.]—**Steam Tricycle.**—I am about to make a steam tricycle, and would feel obliged if any of "ours" could answer the following:—1. What dia. of cylinders would I require? 2. Size of boiler? 3. Is petroleum as fuel more economical than coal? 4. Could I carry quantity sufficient to last four hours?—Glasgow.

[47690.]—**Enamelling Photographs.**—Will any of our able photographic correspondents kindly explain the method of enamelling photographs, as I wish to try my hand at one or two which I have in my possession?—G. Fryer.

[47691.]—**Siemens Dynamo-machine.**—Will any reader oblige by giving particulars of the Siemens small shunt machine, and gauge of wires on armature, number of sections and lengths, size on field-magnets and length, to enable an amateur to construct a machine to be driven by a ¾-horse engine, to light a small workshop? Engineer.

[47692.]—**Garden Produce.**—To Mr. Wetherfield.—I am employed by the Local Board of Health at a weekly wage, with free house and garden, but have got notice to leave their service, and the crop on garden is not ripe, and I want to leave it on the garden till it is ripe. Can I claim to do so till it is ripe? If not, it will be a loss to me to take the crop up at present.—Anxious to Know.

[47693.]—**Printing Press—Fractured Staple.**—Can any one of our readers tell me the best way to repair a fracture in the staple of a printing press, in the position shown in the annexed rough sketch? The line of the fracture is shown by the dotted line. I have had it temporarily repaired, and cannot have it removed off the premises. It is a super-royal Columbian press, and the staple is in one large casting. The plan must be within the capabilities of an intelligent blacksmith with ordinary tools.—Country Johnny.



[47694.]—**Taking Top off Violin.**—I am going to fix a resonator on my violin, as described by Mr. E. Berliner in No. 882, p. 568. Would "Fiddler," or any other correspondent, kindly help me?—Cremona.

[47695.]—**Legal.**—To Mr. Wetherfield.—You will much oblige a subscriber if you will inform me the number of years a building must have been built against the gable end of a neighbour's building, and over and before a wood-shuttered opening before a right to the same by Statute can be claimed?—A closed door has been in my garden for some years in disuse, and stopped up. The owner of the property has removed the door, bricked it half up, and put a window and sliding ventilator in other part of the doorway. Has he a right to do it?—A Constant Subscriber.

[47696.]—**Wheel Cutters.**—To "Jack of All Trades."—I want two circular cutters for cutting teeth in wheels $^{5}/_{32}$in. and $^{3}/_{16}$in. pitch. Can you inform me the best way to make them?—A. T.

[47697.]—**Roundabouts.**—Would some one tell me how to contrive a set of hobby horses or roundabouts, the same, I mean, as are seen at fairs, and what wood is best suited to carve the same from?—A Constant Reader.

[47698.]—**Bunsen Battery.**—To Mr. Lancaster or Others.—I have some Bunsen cells which I put away one night without cleaning, simply emptying out the porous pots, washing the carbons, and standing out the zincs. On looking at them again, I find the acid in the outer pots evaporated, leaving behind, at the bottom of the jars, a substance of almost a white crystalline appearance about 1in. thick. This deposit is freely soluble in water. The zincs are quite rough, and covered with small white spots on the inside, and on the outside with some soft substance—both of which are insoluble in water. The p.p.'s are covered with white feathery crystals (sulphate of zinc, I presume). Will you kindly inform me what the various substances are, and how to clean the zincs and the p.p.'s? Also, whether the zincs will want reamalgamating before further use? and oblige a—NOVICE.

[47699.]—**Distillation.**—Will any correspondent kindly give the particulars of the process of distilling peppermint, and other similar herbs?—C. T., Horological House.

[47700.]—**Collimation.**—Mr. Gravatt's method for checking the line of collimation is as follows:—The line of collimation of a level is correct when $C'' - C' - (A'' - A')$ equals $2\ \{B'' - B - (A'' - A')\}$ A', B', C', being level points at equal intervals, the instrument being placed midway between the stations. A'', B'', C'', being heights taken at the same stations, respectively), the instrument being placed in front of A undisturbed for the three observations. I should feel obliged to any correspondent who would demonstrate as simply as possible in what manner this becomes a check upon the line of collimation.—T. C., Horological House.

[47701.]—**Platinum in Smee's Cell.**—Would platinised platinum be as good in a Smee form of cell as the usual platinised silver? I have a notion that mercury would not attack it so readily as it does the silver. Is it so? Can it act on it, and may I expect equal constancy and greater durability (at greater cost, of course)? Would "Sigma," or any other kind subscriber, oblige?—PLATINUM.

[47702.]—**Shoemaking.**—I have noticed of late that shoemakers are putting lapels on boots without any stitches. Can you oblige me by telling me how it is done, and what sort of cement is used?—J. C.

[47703.]—**Darkening Mahogany, &c.**—Can any correspondents inform me how to fumigate mahogany or oak wood in making furniture, which gives a deep rich colour and tone to new wood?—S. W.

[47704.]—**Hydro-Kinone.**—In the "E. M." for the 28th July last, under the heading "Recent Advances in Photography," Capt. Abney mentions hydro-kinone as a new developer, having many desirable qualities. Would the lecturer, or any other reader, kindly give instructions and formula for using same?—PHOTO.

[47705.]—**Incandescent Lamps.**—Can I light up a small room for a few hours each evening with fifty Leclanché cells (pints)? If so, what power should I get? Also, which would be best lamp, also price?—MEDICUS.

[47706.]—**Plumbing.**—Will any of your readers kindly inform an amateur plumber how he would set about making an obtuse or right-angle 4in. bend of sheet lead?—ANXIOUS TO KNOW.

[47707.] — **Cylinder and Boiler for ½-h.p. Engine.**—Would some reader of the "E. M." tell me the size of cylinder for ½-h.p. engine, and describe boiler for the same?—AMATEUR ENGINEER.

[47708.]—**Cast-iron Pipes.**—I should feel obliged if any reader of the "E.M." would kindly give a formula for calculating the thickness of cast-iron pipes for waterworks? Also, the usual commercial lengths these pipes (spigot and socket) are cast, from 3in. to 24in. internal dia., the depth of socket of each size, thickness of joint, and quantity of lead required to make such a joint, and (if possible) the mean weight of each pipe?—ETNA.

[47709.] **Compressed Lime Crucibles.**—Can any reader give information of how such crucibles are prepared, the kind of lime used, and pressure necessary? I have the use of a small hydraulic press, giving a pressure of 20 tons: Is that sufficient?—T. S. H.

[47710.]—**Tables of Spectra.**—Would some correspondent give me full titles and prices of some good tables of spectra, marked with wave-lengths, such as Capron's or Lecocq de Boisbaudran's, and state which is considered the best?—T. S. H.

[47711.] — **Electrical Measurement.** — Would "Ll.B.A." kindly inform me if the following calculations are correct?—

$$C \times E \times 0{\cdot}00134 = \text{h.p.}$$
$$C \times R = E.$$
$$E \div R = C \text{ in ampères.}$$
$$E \div C = R.$$
$$\text{c.p.} \div \text{h.p.} = \text{c.p. per h.p.}$$
$$\text{Where c.p.} = \text{candle-power.}$$

Also, what is the difference between volt-weber and volt-ampère?—STUDENT.

[47712.]—**Largest Dynamo and Coil.**—Will any reader kindly tell me which is the largest dynamo ever made, and the name of maker? Also, which is the largest induction coil? Where are they at the present time? If possible, kindly say length of spark of coil, and strength of dynamo.—ELECTRICIAN.

[47713.]—**Aniline Dyes.**—What are the usual adulterants in picric acid, naphthaline, Bismarck brown, aniline black, and Hoffman's violets? How may the same be ascertained?—PRO BONO PUBLICO.

[47714.]—**Tests.**—Will some of "ours" kindly give me a method of ascertaining, quantitatively, the amount of potash in the chromate and bichromate of potash?—PRO BONO PUBLICO.

[47715.]—**Transit of Venus at Marseilles.**—Will your correspondent, "S. G.," who has given particulars of Transit at Jamaica, be so kind as to do the same for Marseilles, which, in point of clearness of atmosphere is probably about the best part of Europe for observation?—A. K.

[47716.]—**Faint Stars.**—Can Mr. Sadler recommend a catalogue of stars which would be of use in identifying them down to the 8th or 9th Mag., at least, and can he give any hints which would be of use in making them out with an equatoreal? It would be a great convenience if the catalogue gives R.A. in time, and D., not N.P. D.—BRAIN.

[47717.]—**Problem.**—I should be pleased if you correspondent, E. J. Markham, Esq., will kindly favour me with a solution?—

given— $$\frac{1 + x^5}{(1 + x)^5} = a, \text{ to find } x.$$

—ANXIOUS.

[47718.]—**Stains in Woollen Goods.**—Can any one tell me how to remove stains of peppermint from a scarlet wool table-cover, without injury to the latter? Also, beer-stains in a light green wool table-cover?—W. H. F., Fareham.

[47719.]—**Ague.**—Will Dr. Edmunds inform me what is the best diet for a person tormented with continued ague, in spite of all quinine, strychnine, arsenic, &c., &c., &c., &c.?—UNHAPPY JACK.

[47720.]—**Oil-Stone.**—There is some kind of spirit which will soften a piece of Turkey when clogged, and gummed with oil. Will someone kindly name it? I cannot recall the name, nor the book in which I read of it.—S. P.

[47721.]—**Studying for the Medical Profession.**—I am at present engaged in a large mercantile business in a country town, but have an idea of adopting the medical profession in the course of a year or two. I wish to know how I can best prepare myself by private study, what languages are necessary, and what examinations I will have to pass. Could I get attached to the Local Infirmary, and what length of time will it be necessary to spend at the hospitals? My age is 28 I have received a fairly good education, and have a knowledge of chemistry.—DELTA.

[47722.]—**To "Sigma."**—What would be the difference between two Smee's cells (as regards E.M.F. and quantity), one with 32in. of platinised silver, and charged with dilute sulphuric acid, 1 to 8, and one with 64in. of platinised silver; and charged with dilute sulphuric acid, 1 to 16?—NOVICE.

[47723.]—**Restoring Engraving on Silver Plate.**—We have some silver articles which have been in use for many years, and we now find that the old engraved lines have been filled up and silvered over to to make a plain surface. The latter has worn off, and we wish to remove the filling, so as to restore the engraving. How can it be done?—OBLIGED.

[47724.]—**Silvering Mirrors.**—How is the heat applied in the new process of silvering looking-glasses? I believe it is done by steam, but shall be obliged for a diagram of the apparatus.—C. H.

[47725.]—**Water-glass.**—Could any reader tell me how to make water-glass, so that when an article is coated, and then baked, it would have a coating of glass?—J. G. MOON.

[47726.]—**Tin-Plate Working.**—About two years ago, I inquired in these columns how to cut out the base of a spout to be fitted to a water-can. Mr. Davies said that full instructions would be given by him under "Plumbing," but they have not yet been discovered. Will some reader kindly help me?—TIRO TIRONUM.

[47727.]—**Boot and Shoemaking.**—I want very much to have a full description of tools used by bootmakers (not machines), and the manner of their employment, with an elementary description of how to sew on soles. The books recommended by Mr. King are useless to a—TIRO TIRONUM.

[47728.]—**Electrical.**—To "E."—Can you tell me about the number of alternations in the direction of the current of the "alternating" dynamo necessary to light up an electric candle steadily?—CANDLE LIGHT.

[47729.]—**Dyeing Hose.**—I wish to die ladies' hose, &c., old gold colour. Could any of your kind readers assist me?—BLANCHE MAY.

[47730.]—**Labels for Plants.**—Can any of the "E. M." readers kindly describe the labels for plants, for which the Society of Arts have just awarded prizes?—K.

[47731.]—**Killing-Bottle.**—Can any correspondent inform me of a way to make a good killing-bottle for insects? I have one about 3in. by 3in., in which is placed 1oz. of cyanide of potassium, covered with a layer of plaster of Paris, mixed to the consistency of cream. This bottle is too slow in its action: the insects become quiet about ½min. after admission, but it requires quite 5min. to kill them, and if taken out before that time they recover. I have heard that there are bottles that kill the insect almost immediately after being placed in them. If any of the readers of the "E M." know of such, and method of making, will they kindly insert an answer?—J. MOULT.

[47732.] — **Coil for Lighting Gas by Electricity.**—To "SIGMA."—Some time since I asked a question concerning the above, but got no answer, and I now wish to repeat it, and to call Mr. Sprague's attention to it, if he will oblige me so far. There are many successful systems of lighting gas by electricity in which are used a Leclanché battery, 2 to 4 cells; an induction (resistance?) coil, on an open circuit, broken at the burner, and closed and reopened, at the burner, to light the gas, the spark at breaking the circuit being very large and bright, and, I suppose, being from the so-called "extra" current. The coils are small, but do their work well. I desire to know how the coil is wound: Is it simply a coil of fine wire, developing a spark by the mutual action of the various coils on each other (extra current); or, as I have heard, a regular induction coil, so joined up that the primary is joined to secondary to put both in the same circuit. Will Mr. Sprague satisfy my anxiety to know the facts?—ROI NE PUIS, SOUZA JE SUIS.

[47733.]—**Switch for Telephones.**—Will some of the readers of the "E. M." assist me in the following?—I have erected a pair of telephones, A and B. They consist of microphone transmitter, pair of receivers, and bell each, and they are connected in the ordinary way by a line wire about ½ mile long, with an earth at each end. They work very satisfactorily, and I am now desirous of introducing a third telephone, C, which involves, extending the line wire some 100 yards beyond B, into another house. I am at a loss how to join up the third telephone, so as to make them all intercommunicable. Will some one suggest a switch or other arrangement?—F. C. M.

[47734.]—**Microscopic.**—Being desirous of studying the infusoria, I wish to know (1) what is the form of microscope? (2) Is the binocular necessary? (3) What is the best stage for following the motions of living objects? (4) What objectives and what aperture will be best, and (5) Is it not possible, by using the deeper eyepieces, to make a good 4-10 do all the work? And if so, where can such an objective be obtained? £12 would be the utmost I could afford for the microscope stand alone.—O. O.

[47735.]—**Cataract.** — Will any kind reader give advice as to the following? My father, when 67 years of age, became perfectly blind with cataract in both eyes, and his brother also a few years earlier; grandfather also lost one eye. Is this complaint hereditary, and is there any known remedy or preventive? My eyes (age 45) up to within the last twelve months, have been very good, and I could read the "E.M." comfortably 8 or 9in. off. Now I have to hold the paper 18in. away, and soon get tired, and put on spectacles, which, I am afraid, weaken the sight if used for long together. I apparently can see a long distance as well as ever. Any advice as to what to do to retain my sight and avoid cataract will be thankfully received.—ARCHITECTUS.

[47736.]—**Legal.**—To MR. WETHERFIELD.—Will you kindly give advice on the following matter?—I own a piece of land, which I have let to a man in the following manner: I drew up agreement in writing myself, what I thought at the time would answer for a lease for seven years, which was considered good enough by both of us. It stated plainly that the rent was to be paid one-half on Lady Day, and the other half on Michaelmas Day in each year of the seven. There is no seal or stamp on the paper: it is simply signed by both of us in the presence of witnesses, with their signatures attached. He has paid some of the rent, according to agreement, and had proper half-yearly receipts; but this last 18 months he has allowed to become in arrears. He keeps promising to pay, but does not do so. Which would be the best and cheapest way to compel him to pay me? Can he, under such an agreement, defy me in this way, or relet until the seven years have expired, or can I give him six months notice if the agreement is not valid as a lease? If he has a lock on the gate, can I put another over it until it is paid? The rent of the land is £9 per annum, and he has occupied it now four years on Lady-day last.—ONE DOUBT.

[47737.]—**Black Shellac Varnish.**—Will some of "ours" kindly inform how to make shellac varnish, black? I have tried lamp-black and Prussian blue, and also aniline black; but without success. The varnish I want to make black is made of 1 part orange shellac, dissolved in 5 parts meth. spirits.—RAJ MISTRY.

[47738.]—**Analysis of Paint.**—How can I eliminate oil from paint, and at the same time estimate the amount of oil and water which a sample of paint my contain before proceeding with the rest of the analysis?—OXIDE.

[47739.]—**Tallow.**—How can adulteration in tallow be detected either by analysis or otherwise? Perhaps some of your numerous readers will kindly give me a few hints on the above.—OXIDE.

[47740.]—**Boiler Query.**—Having made a vertical steam-engine, 1¼in. stroke, mounted on a thick brass boiler, riveted and soldered, 10in. high, 5 diam., I want to heat it with an atmospheric gas burner, having made one with ¼in. pipe to the elbow, with fine vent-hole, from the elbow upwards ¼in. tube (inside diam.), terminating in a ring 3in. diameter, with 15 holes. This does not seem to get steam up any quicker than an ordinary batswing burner, and the gas escapes a little at the air-supply hole, although I have tried different size supply holes both for air and gas. Is the fault in the angle elbow, or the ¼in. tube not sufficiently large? Any information would be esteemed a favour. Also for heating it effectually where gas cannot be obtained, if possible by unscrewing gas apparatus and using that hole (⅜in.) only, as I would rather not alter stand to push a lamp in. Being a complete model and driving model machinery, I want to exhibit it publicly, therefore should be pleased with early reply. Boiler is mounted on iron bed-plate fixed to a mahogany base, having a hole clean through for air supply, &c.—STARLIGHT.

[47741.]—**Winding Engine.**—Will someone kindly help me to an explanation of the formula given on p. 596, Vol. XXI.? Say how the figures 12, 3 15, and 37·7 are obtained, and oblige—W. W. H.

[47742.]—**Tenant's Liabilities.**—Last Michaelmas I let a house. I have never yet received any rent, as my tenant says, having taken the house by the year he is not bound to pay rent more than once a year. Is this so, or can I claim the rent every half year? Also, is the tenant bound to leave the house in good repair? It was a new house, and he is the first occupier. We have no agreement.—LANDLORD IN DOUBT.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Aug. 16, and unacknowledged elsewhere:—

T. Mercado.—Rev. W. J. E. Rooke.—J. Hutton.—Jas. Perry.—Rev. J. J. M. Perry.—A. Manock.—A Would-be Piper.—Galvanometer.—Disinfectant.—Chlorine.—R. Gilbert.—Tin Plate.—Indigo Planter.—Patent Plate.—A. S. L.—A. J. Smith.—Arqudante.—Boxwell.—A Subscriber.—Constant Reader.—Dolomite.—Douglas.—J Harrison.—Etna.—Caius.—A. M. R.—W. L.—H. W.—Amateur Electrician.—Grapho.—Prismatique.—A Fellow of the Royal Astronomical Society.—J. C. King.

G. B. T. (How would you get the air out again? The pressure of the air would force the piston down in one cylinder, but not if that was connected to a beam and had to drag another piston up against atmospheric pressure. For you have on one side 15lb. per sq. inch less friction to pull up 15lb. plus friction.)—Paul Pry. (They are made of peroxide of manganese, carbon, and rosin, and subjected to a very heavy pressure in the moulds.)—C. H. (A solution of a tincture of the Pyrethrum roseum is said to be a protection against the bites of mosquitoes.)—An Amateur Electrician. (Put your question direct to one of the opticians who advertise in our columns; but tell him exactly what you want to do—don't bother him about a "photo-electric microscope.")—H. Hayes. (We do not know of such a work.)—J. S. (Indiarubber dissolved in bisulphide of carbon or mineral naphtha.)—Obliged. (We understand now that you wish to remove the filling so as to restore the engraving. It is most likely silver solder that has been run in, and if so could be removed by the careful application of heat, but only a practical workman could do it. Nitric acid would dissolve the silver itself. We insert a query for you.)—Young Electricity. (See reply 47496, last week. You do not say how long the coil is; but as to the spark, see p. 289, last volume.)—Unmusical Joiner. (Full instructions for making American organ were given in Vol. XXVI. Harmonium in back volumes. For prices of fittings, you must obtain the price lists from the sellers.)—Semper Fidelis. (If you had given us a description as well as a photograph, we might have been able to have determined it; but as it is, we can only suggest that it is some arrangement for drawing purposes, probably for use with the microscope.)—Round Turn. (Does it? At any rate, such questions must be put to an intelligent schoolboy.)—Sugar. (The blood was used for clarifying, but nowadays it is dispensed with, animal charcoal effecting all that is desired. The albumen was the useful part.)—Novicio. (When you write again, use an ink with less gum in it, and don't fold up the letter until dry. So far as we can understand the query, we can say that oxalic acid will remove ordinary ink.)—Questator. (Must search the records, or get some agent to do it.)—W. R. C. (We really do not know what sciences a "mackanic should chiefly study to become a member of the South Kensingention science and art department," nor "what would be is profession when leaveing"; but on application to the Secretary you can obtain the Directory, price sixpence. You can also obtain the Whitworth prospectus, free, on application to the secretary of the Science and Art Department, South Kensington.)—Finem Respice. (We cannot undertake to indicate the "best" textbook; but we think that Greenwood's "Metallurgy" (Collins), and Goodeve's "Steam-Engine" (Lockwood), would suit you.)—Was-heil. ("Model Yachts and Boats") L. Upcott Gill), is a useful book. You will find many hints in back volumes, and the lines, &c., for a schooner fully set out in p. 309, Vol. XIII.)—Learner. (If you will refer to recent back numbers you will find a series of lessons on dry-plate photography, and many replies as to developing.)—A Seven Years' Subscriber. (We quite agree with you that an answer to your questions would be interesting to many. It is for that reason we have frequently devoted considerable space to the subject during, say, the last seven years. Suppose you look at pages 237, 261, 285, 308, 381 of the last volume, and the indices of the other volumes you have.)—E. D. (Fully described in No. 849, p. 396.)—W. S. Brown. (We should be glad to give the description of the milling machine.)—Scheneider. (£2 12s. 6d., at Doctors' Commons, at the Archbishop of Canterbury's office, or of local surrogates.)—Wm. Fellows. (If the circumstances are as you state, we do not think your master can either legally or reasonably expect you to make good the damage, or refuse to pay you your wages.)—Country Architect. (A full and complete series of illustrations of the new Courts of Justice, from the drawings of the late architect, G. E. Street, R.A., are now appearing in the *Building News*. The first batch appeared in the number published June 30.)—L. L. (A good process to clarify liquors is said to be the following: To each two gallons of the liquor add 150 grains of starch, 75 grains of dry egg-albumen, and 75 grains of sugar of milk, previously macerated in a little water until the two last ingredients are dissolved. The liquors clarified by this method are said to become quite brilliant, and to acquire a pleasant taste.)—Housewife. (A solution of bichromate of potassium and glue yields a superior cement for broken glassware. Moderately strong glue or gelatine solution is mixed in a dark place or in a photographic dark room, with a small amount of concentrated solution of bichromate of potassium. The edges of the fracture, which have been thoroughly cleaned, are then coated with a thin layer of the mixture, strongly pressed together, and kept close by tying with twine, or in some other manner. The glass is then exposed to sunlight for some hours. This causes the cement to become insoluble even in hot water.)—B. J. L. (We do not know what the "original maker's" receipt is, but here are two for making eau de cologne. 1. Oil of orange flowers (Neroli), 4 parts; oil of lavender (Mitcham), 4 parts; oil of rosemary, 8 parts; oil of lemon, 8 parts; oil of bergamot, 16 parts; tincture of musk, 1 part; acetic ether, 1 part; water, 158 parts; alcohol, 800 parts. Add the oils, tincture of musk, and acetic ether to the alcohol; then add the water, and set the mixture aside in glass-stoppered bottles, until it has become perfectly clear and limpid. Draw off the clear liquid, or filter it through paper. 2. Oil of orange flowers, 3oz.; oil of rosemary, 2oz.; oil of orange, bitter, 5oz.; oil of lemon, 5oz.; oil of bergamot, 2oz.; alcohol, deodorized, 6 gal.; water, distilled, according to strength required. Dissolve the oils in the alcohol; to five gallons of the mixture add slowly and while stirring, enough distilled water to render the liquor very slightly opaque. Then add the reserved gallon, which should render the liquor clear again, and set the mixture aside for several weeks. Finally filter.)

CHESS.

All Communications for this department must be addressed to the Chess Editor, at the office of the English Mechanic, 31, Tavistock-street, Covent-garden. W.C.

For every succeeding Eight Words	**0**	**6**

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

Holloway's Ointment and Pills.—For bad legs, gathered breasts, and scrofulous sores. these are genuine specifics. The grateful and earnest gratitude of thousands who have been raised from prostrate helplessness and a condition loathsome to themselves and others, renders it quite unnecessary to enlarge in this place upon their extraordinary virtues.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 8d. for the first 24 words, and 3d. for every succeeding 8 words.

Wanted, all the back numbers of the "**Electro**-Metallurgist and Electric Light Journal." Exchange.—J. C. T. Carter, 3, Castle-street, Reading.

Organ Bellows and Windchests (new and second-hand), in good condition, ready for wind and pipes.—Address, William Johnson, No. 12, Moxley near Wednesbury.

Splendid pair of **Horns**, 6ft. from tip to tip, and 11in. at base. Exchange for good 52in. Bicycle; or what offers?—Address, W. T. P., Poundisford, near Taunton, Somerset.

"**English Mechanic**," 114 to 557, in parts and numbers. What exchange?—A. Harris, Wavendon, Woburn, Beds.

Fret-cutting. Circular Saw, Turning, and Drilling Machine. What offers in exchange, value fifty shillings?—Webber, 34, Arundel street, Strand.

"**Imperial Gazetter, England and Wales,**" twenty two parts at 2s. 6d., bound, gilt, six volumes. Exchange Bunsen Batteries, Incandescent Lamp, offers, Electrical Light Apparatus.—J. Trackson, Norwich.

Horizontal **Engine**, new, 1½ bore, 3in stroke, link motion, reversing gear. Take 5in or 6in. slide-rests—D. Alexander, 22, Market-place, Forfar, N.B.

"**English Mechanic**" in exchange for "Graphic," "Illustrated," or "Dramatic News." Papers even a month old accepted.—E. B. Fennessy, Pallasgreen, Limerick.

Organ Pipes. Stopped diapason and flute, wood. Principal, Twelfth, and Fifteenth, metal; for what offers?—M. Rayner, Pavement-street, Cleckheaton.

Wanted, powerful **Hand Punching Machine** in exchange for one small Horizontal Engine and Boiler, complete, half horse-power.—J. Bilsborough, Alderley Edge, Cheshire.

Concertina (Anglo), 30 or more keys, or **Portable Harmonium** wanted in exchange for Violin in case, and cash.—Hewson, 12, Great Crown-court, Haymarket, W.

Violin, in case, with bow, value £5. Exchange for good Telescope on stand, or good model engine and boiler. Difference in cash.—Hewson, 12, Great Crown-court, Haymarket, W.

Magic-Lantern, mahogany bodied, Lime Light Apparatus, and quantity of Slides, cheap, or exchange. List and particulars on application.—F. B., 15. Southgate-road, Wood-green.

Piano (Cottage) Wanted, must be cheap, in exchange.—All particulars to W., 69, Norfolk-road, Essex-road, N.

48in. **Wooden Bicycle**, saddle and bell, complete, nearly new. One brass boiler on stand, 2 by 4. Useful exchange.—Samuel Baker, Robin-lane, Pudsey.

Set of Vertical **Engine Castings**, 2 by 4 cylinders, bored and turned, also copper boiler, 6 by 3½. Useful exchange.—Samuel Baker, Robin-lane, Pudsey.

Whole-plate walnut wood **Camera and Portrait Lens**. Would accept first class half-plate View Lens in part exchange.—Tanner, North Parade, Horsham.

One octave set of **Beech Pedals**, suitable for organ or piano, in frame complete. What offers?—Tanner, North Parade, Horsham.

THE GEOMETRIC SLIDE-REST.

By J. H. Evans.

THE present forms a most interesting subject for all amateur turners, inasmuch as an unending variety of patterns may be produced, some of the most beautiful character, especially those with fine lines. This instrument was invented by Capt. Padsey Dawson, a gentleman of great mechanical ability, and a very fine ornamental turner. The slide-rest was patented in 1870, but I regret to say that, owing to its being somewhat costly, the patentee was not in any way a gainer by it. As I am about now to explain the instrument, I trust it will be an incentive to some of our amateur ornamental turners to have it added to their lathe; and if they are already possessed of the spiral apparatus, it will not be, of course, such an expensive addition after all.

FIG. 1

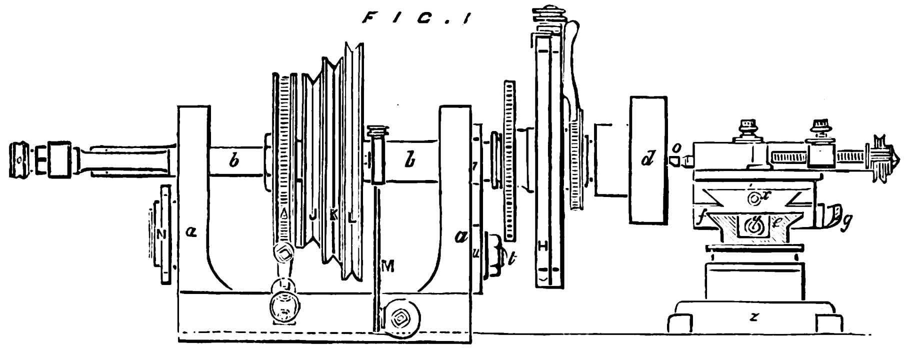

FIG. 2

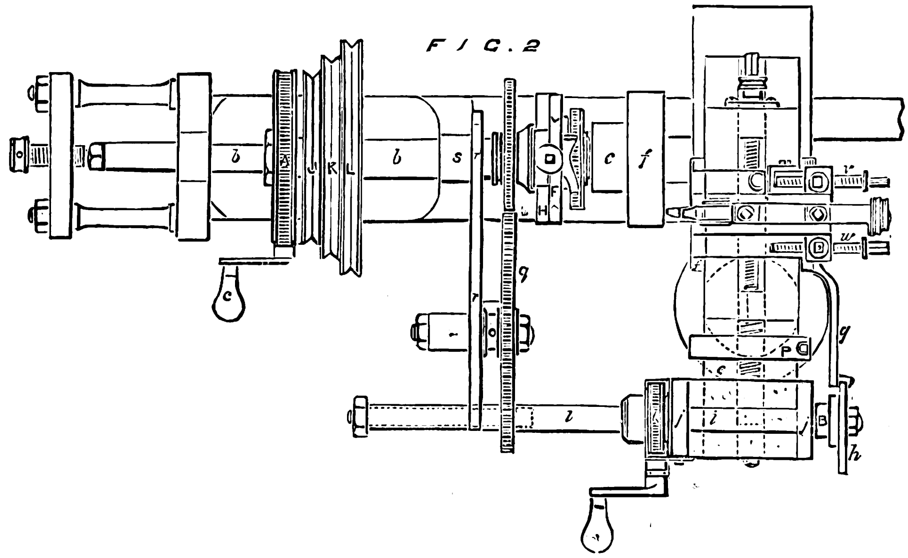

FIG. 3

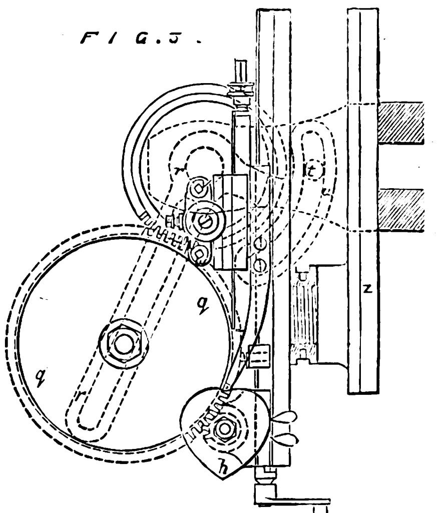

FIG. 4

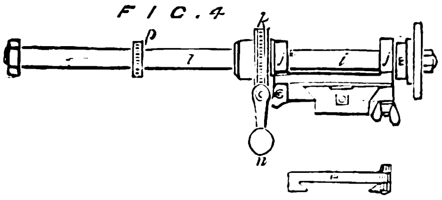


The invention relates to the arrangement of apparatus for producing figures, designs, and devices of an ornamental and geometrical nature upon wood, metal, and other materials, also to the employment of cams, templates, or pattern-plates in a special manner upon a lathe, which templates, &c., effect the automatic movements of the upper slide of slide-rest, and so give motion to the cutter or tool that is being used. Although this apparatus can be readily adapted to almost any lathe, it was designed more especially for such as are generally known as ornamental turning lathes.

As will be seen, the geometric slide-rest works in connection with the spiral apparatus, and it is by the different changes of the various wheels that such a vast number of patterns can be executed; for instance, if the simple eccentric cam is placed on the transverse arm, and the wheels used are 144 on chuck, 16 and 120 on double arbor, gearing into a 24 on the spindle, the effect would be quite a different thing to using the same wheel, and either reducing or increasing the eccentricity of the cam, or to use the same eccentricity and place the 144-wheel where the 120 was used, and so on. I am quite certain that it is impossible for any one ever to work out the uses of such a tool, as they are perfectly inexhaustible.

To proceed. The apparatus is made on the same principle as the ordinary slide-rest for ornamental turning, with the exception that it has two slides; the upper one carries the tool-box or holder, in which the tools, such as eccentric cutter, drill, spindle, and universal cutter are held, also, of course, the fix tool for line patterns. The tool-holder being the ordinary standard size, any of the ornamental cutters, in fact, can be used with the apparatus. The top slide has two screws in the usual way, one to traverse the tool-carriage and the other to form the stop for the depth of cut. The lower slide has a spiral spring in the place of the ordinary screw, which is secured to the right-hand end by a steel pin; the other end of the spring passes through a small hole in the end of the lower slide, and is kept in its place by a small nut on the end of it, and when the slide is pressed against it it oscillates from the elasticity of the spring. At the back of the tool-box, under the adjusting-screws for regulating top slide there is an arm firmly fixed to the metal part of lower slide, and at the end of this arm or lever a small steel rubber is fixed, made so as to revolve freely. This when at work acts against the edge of the various templates that are used.

On the left hand of the lower slide is a transverse slide, which moves to any part of the slide, and can be fixed with a thumb nut wherever required; this slide carries a spindle, and the end nearest the lathe-head is turned down to fit any of the change-wheels and pinions, which are held on their places by a steel nut and washer; the large wheels are filled up with a loose pad with a small hole and a large washer, just in the same way as they are used on an ordinary slide-rest.

The motion is given to this spindle by a tangent-wheel and screw when the revolving-drill is being used; but when the fixed tool is in use the motion is given by a winch-handle on the end of the spindle, and the tangent-screw, of course, thrown out of gear. On the end of the spindle opposite to that which carries the wheels a metal flange is fitted, which carries the various templates, guides, &c.

In order to make the apparatus more easily understood, I have given two or three illustrations of it, and by reference to the various figures in the drawings it will, I hope, become perfectly clear to our readers as far as its application to ornamental lathes is concerned. Figs. 1 and 2 represent a face and plan-view of it respectively, A being the mandrel-frame and B the mandrel, fitted in the usual way to hardened steel collars, H, Fig. 1, being the eccentric chuck, the only difference in this part being that I now make them with tangent-wheels instead of ratched-wheels; D represents the material about to be worked upon, and is held in a cup-chuck. In front of the lathe-head, Fig. 1, is seen the slide-rest Z, being the shoe into which the socket of the lower slide is fitted; the slide C is planed up in the usual way, and on to it is fitted the metal slide F; this must be made to slide evenly and freely, in order to be acted upon by the spring; the slide L is also fitted to the one F, but this is actuated by a screw X for adjusting the tool to various positions and parts of the work.

The slide-rest is, of course fitted to a cradle in the usual way. Letters R and U, Fig. 1, show where the radial arm is fixed, T being the nut and screw to fix it in the position required. **M** is the index peg, as seen in the drawing, but this, although shown, cannot be used when the apparatus is in motion, as the pulley is constantly on the move. N shows where the eccentric action is obtained for throwing the metal conductor into gear with the steel guide for screw-cutting. J K L represent the pulley; A with a star illustrates the segment apparatus.

We now come to the plan, Fig. 2, which gives a representation of the apparatus as connected to the spiral ready to work, and it will be readily understood by careful reference to it. Fig. 4 shows the metal-piece J, which is fixed to the slide E, in whatever position it is wanted by the thumb-nut, *i* being the spindle which passes through the same, having on the one end the metal flange B, to which is again fixed the cam H, and when deep cutting is required to be done the tangent-wheel K is used in order to create a slow and more powerful motion. On the other end of the spindle *i* a nut is fitted to fix the various wheels on, the distance being made up by numerous metal washers to bring the wheels into a line with those on the radial arm. Referring to Fig. 2, they will be seen in gear. Having so far put the apparatus together, the wood D should be surfaced over with the top slide, a fixed tool being placed in the top slide; and while this is done, it is better to put a strong tension on the spring, and place the fluting stop P against the end of the slide. When the work is surfaced, over the stop P may be removed and the cam H brought to bear against the small steel roll on the arm *g*. We will take as a beginning the plain eccentric as a cam, and if this is set out to about ⅜ eccentricity, and one whole revolution of the tangent wheel taken, the action of the whole apparatus will immediately display itself, inasmuch as it will be clearly seen that, while the mandrel is making its revolution, the tool-slide is moved backwards and forwards by the cam bearing against the projecting arm G. Very beautiful patterns are thus produced, and as I have before said, the variety is unending. The cams that up to the present time have been most used are the plain eccentric, the ellipse—two of which placed across one another produce most beautiful effects—and the heart shape. I have worked considerably at these, and find that I can get a different production at almost every move; and that one of the most difficult things to obtain is a reproduction of any particular pattern, unless the settings are most accurately taken—that is, the exact wheels, precise amount of eccentricity of the cam, and the adjustment of slide of eccentric chuck, if it is used. Fig. 3 shows a face view, the dotted lines giving the position of radial arm and wheels in gear, also the heart-shape cam. When only very fine line patterns are required, the tangent-wheel K may be thrown out of gear, and a winch-handle placed upon the end of the spindle behind the cam, and the motion obtained by it. When using the plain eccentric cam, this motion is very regular; but when such cams as have undulated edges are used, the tangent-screw is quite necessary to get a smooth cut and to prevent an uneven pressure occurring through the cam slipping suddenly into a deep recess of the cam.

To cut deep mouldings round the various figures, such as 3, 4, or 5 loops, the drilling instrument O, Fig. 2, is used, and having a variety of drills fitted to it, increases its its capabilities; and it is, as I say, more essentially necessary to use the tangent-wheel when deep drilling is being done. The fixed tool, however, is used when fine-line patterns for printing from are required, and the tool should have the under side well cleared, as the work itself has to turn sharp corners, so to speak, and if the tool is at all thick, it forces it to cut away the sharp corners of the different patterns. Another way to vary the pattern is to use the fluting stop P; when this is arranged so that the slide when brought forward by the spring butts against the stop, instead of completing its movement, the end of the pattern cut becomes square, or rather of a very slight curve, according to the diameter of the pattern, but quite a different termination to what it would if the stop were removed; the top slide can also be adjusted by its screw, so that any number of cuts upon a surface may be made, each one differing from the other. If I wrote for a month upon this subject, I could tell little more, but one practical lesson would clearly illustrate what it will do; it is certainly much easier to work than the geometric chuck, and will produce an equally interesting variety of patterns. The inventor, who devoted a considerable amount of time, has, in conjunction with other apparatus, produced some most beautiful effects, and although Capt. Dawson has spent so much time upon it, I am sure he will agree with me that it is not yet half worked out. I am indebted to the Captain for my knowledge of the apparatus, and I trust that some of our readers will take advantage of it also, as it is an addition worthy of any ornamental lathe, and will afford quite as much amusement as a geometric chuck.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE summer meeting of the Institution of Mechanical Engineers was held last week in Leeds, under the presidency of Mr. Percy G. B. Westmacott, who in his address took a survey of the progress of engineering during the last half-century, and called special attention to the waste of power still going on, notably in the form of the smoke nuisance. The address, however, was mainly devoted to pointing out that just as railways had not ruined canal or road traffic, so any contrivances for cheapening the cost of transit either by land or water would act directly towards increasing the prosperity of the country. The president's address was followed by the reading of an interesting paper on the "History of Engineering in Leeds," by Mr. A. H. Meysey-Thompson. Then followed a paper which gave rise to an instructive and animated discussion, although it referred to so apparently simple a subject as the position of the tuyeres in blast furnaces. The author, Mr. Cochrane, gave a number of valuable details showing how by drawing back the tuyeres, using high temperature of blast, and increased area of hearth, considerable economy had been effected in two furnaces—the average consumption of coke per ton of iron had been reduced respectively to 18·35 and 18·45 cwt. The author has made experiments as to the temperature in the furnace, and he finds the highest at a point about 14in. from the nozzle of the tuyere, the temperature diminishing towards the centre of the hearth. Mr. Lowthian Bell opened the discussion on this paper, and commended the spirit in which Mr. Cochrane had investigated the benefits of increased capacity of furnace and blast of high temperatures; but he failed to agree as to the reality of the results alleged to be obtained, and regretted that Mr. Cochrane had not furnished analyses of the gas discharged from the furnace, which are an infallible criterion of the working of the furnace. Mr. Bell agreed with Mr. Richards as to the great importance of high-blast temperatures in low furnaces; but where the latter are high, he considers that the heat can be obtained by the combustion of coke in the usual way. He did not wish to deny that Mr. Cochrane might make iron with even less than 18cwt. of coke per ton; but to reduce the consumption to between 16cwt. and 17cwt. would involve the use of blast at a temperature of about 2,500°, and no stoves are known which can yield this temperature, and blast so heated could not be conveyed in iron pipes. The discussion extended into the second day, and the president, in closing it, pointed out that any thing that bore on the economical production of iron was of interest to mechanical engineers. It is obvious, however, that a discussion of matters which can be settled only by practical experiments is a waste of time; and if Mr. Cochrane can make iron with less coke than anybody else, it is so much to his advantage, and his rivals might either copy his practice or adopt their own in silence. Possibly, however, the discussion will serve to draw attention to the subject, and lead to other experiments having for their object the development of economy. The next paper was read by the secretary on "Mining Machinery," by Mr. Henry Davey, of Leeds, and this also led to a lively discussion, chiefly on the best means of preventing colliery explosions. Mr. Davey, writing of underground application of power, expressed the opinion that compressed air, though very convenient, was not very efficient—the useful effect being only from 25 to 33 per cent. of the power employed to compress the air. Hydraulic engines give, under suitable conditions, an efficiency of from 50 to 60 per cent., and are preferable to compressed air; but in Mr. Davey's opinion it is possible that mechanical operations underground which do not require more than small powers, may eventually be performed by means of electricity transmitted from a dynamo at the surface. He, however, thought that the gas-engine, or rather the hot-air engine, worked by quick combustion of gas, was likely to play an important part in mining, as well as in other spheres of industry. Mr. Davey's views as to the uses of compressed air were naturally criticised by several speakers, for it is obvious that in all mining operations there is a special advantage in the use of air, which, having done its work, can be discharged in a cold state into the atmoshere of the mine. In the case of water there is obviously a loss of useful effect, as the descending column is barely sufficient to force the water up again, and the effective power in the mine is consequently less than that indicated by the pumps at the surface. Several speakers advocated the use of compressed air, and Mr. Jeremiah Head drew attention to the better ventilation of mines. In two papers read at the meeting reference was made to the gradual replacement of the old furnace system of ventilation by fans, which latter are considered to leave nothing more for the engineers to do. Within the last twelve months, however, there have been at least twelve explosions attended with terrible loss of life, and Mr. Head believes that the use of the fan increases the risk of explosion. If a colliery owner learns that there is a fall in the barometer, all that he can do is to set the fan working quicker, which has the effect of still further relieving atmospheric pressure in the mine, and actually induces the exudation of gas from the coal in greater quantities. Mr. Head suggested that the proper method of ventilating mines would be to force air to the extreme ends of the workings, and allow it to flow back as it could, by which means a pressure would be kept on the face of the coal, and the dangerous gas would be prevented to a certain extent from escaping. Mr. H. Smith asked if it was not possible to discover some material possessing "chemical sponginess" which would absorb the fire-damp, and render it inert; but the suggestion was met by an expressive "shake of the head" only. The general result of the discussion may be said to be that air-engines are more convenient, but less economical, than hydraulic apparatus; and it is strange that their convenience being acknowledged, no one should have pointed out that they afford a means of working a mine by means of a pressure of air instead of by exhausting the air and creating a current which is supposed to sweep fire-damp out of the mine, but unfortunately does not. Mr. Davey thought that ultimately electricity would be utilised in mines, but some of the speakers pointed out that there must always be great risk of sparks exploding any mixture of gas and air which might happen to be near the wires. Still, we may hope with Mr. Davey that the time is not far distant when tall chimneys will cease to pour out "blackness" over the towns and fields, and that coal will eventually be consumed entirely in the shape of gas, or be burnt under pressure; but we are afraid it will be some time before he gas-engine becomes the universal prime mover, and electricity is utilised as the means of transmitting power.

A paper, by Mr. J. H. Wicksteed, of Leeds, on a "Single-Lever Testing Machine," was read by the secretary. The machine described is a fifty-ton of the steelyard type, in which the novelties are the travelling of the weight beyond the fulcrum on to the short end of the lever until a point is reached where the long end is balanced; the arrangement of a non-pendulous travelling weight of which the centre of gravity moves along a centre line drawn through the point of support and the point of attachment of the sample; and the indifferent equilibrium of the whole, which is attained by arranging the weight of the lever and all its attachments symmetrically above and below this centre line. Several members who have seen the machine at work spoke of the delicacy with which it tested and of the rapidity with which it could be operated, Mr. Head, indeed, saying that he could not conceive of anything simpler, quicker, handier, or more accurate. The other papers read were "On Governing Engines by Regulating the Expansion," by Mr. Wilson Hartnell, and on the "Fromentin Boiler-Feeder," by Mr. John Hayes. Prof. Rucker delivered an address "On Lighting and the Transmission of Power by Electricity"; Mr. Crampton lectured on his hydraulic system for excavating the Channel Tunnel automatically; and Mr. Fletcher repeated his lecture "On Flameless Combustion." Mr. Crampton's method of excavating the tunnel is, in some points, novel. The advance of one yard per hour in a tunnel 36ft. in diameter involves the removal of 170 cubic yards, or 250 tons of chalk; and a simple calculation will suffice to show that the removal of such a mass from the face of the working to the surface is no light labour. Mr. Crampton proposes to use hydraulic engines, which will work under a pressure of about 700lb. per square inch. The quantity of water used will be about three times the weight of the chalk *débris*, which will be reduced to a "sludge," that can be raised comparatively easily without interruption, telescope pipes being provided which will extend the length of the mains sufficiently to compensate for the advance made in 24 hours. A stoppage would then be made to put in another length of pipe. By this means the shaft would be left comparatively free for the lowering of the materials needed to line the tunnel. At the conversazione the electric light was exhibited, and amongst the models was one of the Forth Bridge, consisting of two spans of 1,700ft., and two of 675ft., the clear headway above high-water being 150ft. The highest part of the bridge above high-water will be 345ft., and 42,000 tons of steel will be used in the construction. A train-boat and an hydraulic hoist, as used on the Aire and Calder navigation also attracted attention, as did a creamer, the invention of Mr. G. De Laval, of Sweden, which is said to be capable of separating the cream from sixty gallons of milk in an hour, leaving only 0·3 per cent. of fat in the skim-milk. Excursions to Bradford and Hull, and visits to many of the works in the neighbourhood of Leeds, finished a well-attended meeting.

IMPROVEMENTS IN SECONDARY BATTERIES.

THE accumulator, or storage-battery, is now recognised as forming an essential portion of many installations of the electric light, especially under conditions where there is a difficulty in keeping the prime mover constantly at work. It is not surprising, therefore, that amongst the numerous applications for patents in connection with electrical matters, "inventions" of secondary batteries should form a large percentage. In one for which Mr. R. Kennedy, of Glasgow, obtained provisional protection a plate of clean lead is coated with a layer of lead dioxide or peroxide, and laid in a bath filled with dilute acid. A sheet of lead being suspended over it, current is sent through, and a deposit of close-grained, spongy lead is formed on the lower plate, which can then be cut up to suitable sizes, and covered with a coat of lead dioxide, obtained by passing chlorine through lead monoxide, and subsequently mixing the product with glycerine. The plates cut from the upper sheets of the preliminary bath are coated with a paint formed of water, glycerine, lead dioxide, and lead sulphate. Messrs. Liardet and Donnithorne have obtained a patent which covers a variety of arrangements, viz., cells packed with lead shot, cells filled with hollow balls of lead, which latter are made by coating with lead soluble substances in the form of spheres, and subsequently dissolving out the cores; cells filled with broken charcoal, coke, asbestos, &c., coated with metallic lead, lead deposited from a salt, such as the acetate, by means of zinc, lead plates attached to compressed cakes of red lead. Other cakes may be employed, obtained by mixing red oxide of lead with plaster of Paris or cement, china clay, powdered glass, &c. Fine divided porous lead, obtained by filling a cell having two compartments divided by a porous wall, with acetate of lead solution, and immersing therein as electrodes two plates of zinc in suitable jackets, and as soon as the zinc is dissolved and replaced by metallic lead, drawing off the solution and replacing it by acidified water. In cases where the cells are started with metallic lead plates peroxides of hydrogen are added to the acid to assist in the formation of peroxide of lead. In this specification it is stated that porous lead may be obtained direct from lead ore by dissolving the latter in acid and precipitating the metal by zinc. Another plan has been patented on behalf of Herr Böttcher, of Leipsic. In this case a solution of pure sulphate of zinc is decomposed by a current, and zinc is deposited on a plate of thin sheet zinc. As an anode thin lead foil is employed, after having been previously prepared by folding it lengthways from top to bottom in order to increase its surface. The lead is dipped into an aqueous paste of pure litharge prepared with the zinc solution, and is coated with a thick layer of the emulsion. The oxygen coming in contact with the lead plate forms on its surface an exceedingly thin layer of peroxide. By closing the circuit the previously-deposited zinc is re-dissolved, and the original sulphate of zinc produced, while the hydrogen reduces into finely-divided lead not only the peroxide, but also a part of the lead plate. By a new regenerative current zinc is again deposited on the zinc plate, while the recently reduced lead is oxidised to peroxide. A few repetitions will, it is said, render the cell ready for use. Yet another invention, which, at least, has some points of novelty, is described in the specification of S. Cohne, of London. In this case the patentee applies to a sheet of lead a layer of mercuric sulphide (HgS) in the form of cinnabar or vermilion. The coated lead sheet is bent into the form of a box or of a spiral, and is used as the positive electrode of the battery. A second sheet is prepared in the same way for the negative electrode. Both sheets are perforated and placed in a cell of dilute sulphuric acid. As soon as the current enters hydrogen is liberated, which reduces the mercuric sulphide, gradually causing a deposition of metallic mercury on the surface of the lead. Immediately the effects of polarisation are manifested, local action disappears, then the amalgam formed, without being destructive to the lead, decomposes the water, and in that way hydrogen is always conserved, and travels backwards and forwards as the cells are charged and discharged, and peroxide of lead is thus formed, the precipitated sulphur acting as a resistance. Sulphate of mercury (Hg_2OSO_3) may be used in place of mercuric sulphide. These are a few of many patents for secondary batteries, the value of which may be safely said to be an unknown quantity.

WINE FROM BEETROOT.

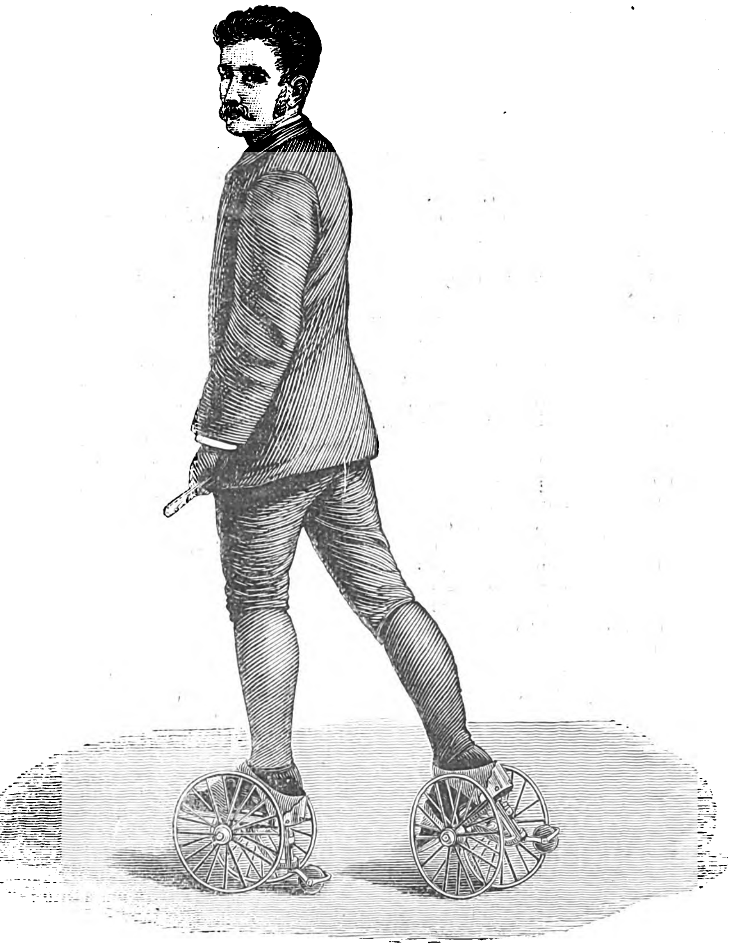
THE phylloxera has caused so great a destruction amongst the vineyards of France, that the wine trade has experienced a serious decline, and many ingenious inventors in that country have been considering how they can best meet the demand. The importation of cheap wines from Italy and Spain, to be "married" in France, is obviously too commonplace a device to satisfy the requirements, and we accordingly find that amongst British patents is one taken out by the Messrs. Brin, of Paris, for the production of red and white wine from beetroot. The inventors, when desirous of producing red wine, use the red beets, preferably cooked, in order to preserve as much as possible of the colouring matter. That beetroot should be chosen which has not the bad taste developed during fermentation; that is, it must be of very good quality and be well washed. The cooking takes place in a boiler, or with more facility, in a digester, or simply by free steam; at this stage it is reduced to pulp by means of suitable pulping apparatus, and the more completely it is pulped, the better the result will be. The pulp may at this stage be put to ferment, but it is preferred to place it in very strong linen cloths or canvas bags and then submit it to powerful pressure, in order to extract from it the greatest amount of juice possible. This juice is immediately put into vessels preferably made of wood, which are specially intended to hold it during the fermentation, carefully avoiding its coming in contact with any metal: these receivers may, however, be made of brick lined inside with a thick layer of Portland cement or other silicate. These receivers or reservoirs are internally provided with serpentine coils for steam or for hot water, or even free steam. By this means the process of fermentation may be regulated at will. The juice of the beetroot, to which may be added, if desired, a certain quantity of water, is immediately put into fermentation, so as to transform the entire mass into juice of a vinous nature; the substances are then added which are necessary to finish the work called fementation: these products are sprouting barley or malt, the yeast of beer or of grains, of slices of apple, or pearl barley. Alcohol may be added in quantity according to the strength of wine desired to be produced. As soon as the work of fermentation is finished, the whole of the liquid mass is strained by means of tannin; then it is allowed to rest one or two nights and filtered, should that be thought necessary, and is allowed to cool. The wine obtained by this process is said to possess all the qualities of grape-wine; the remainder of the treatment is the same as for wine obtained from grape-juice. These wines, owing to their sacchariferous qualities, will much improve wines poor in sweetness and rich in tannin. According to requirement, alcohol may be added and tartaric acid when more power is required to be given to it as well as colour and perfume.

Raw beetroot may be employed; but from the trials already made, it has been found preferable to cook it first, if only to force it to expand by the heat and to yield all its sugar to the mixing waters which are increased as desired. Besides, the cooked beetroot produces wines of better taste and much finer than when the beetroot is used uncooked.

To make white wine, the white beetroot is used either cooked or raw: it is treated like the red beetroot, but, at the moment of fermentation, a little nitric acid is added. Afterwards the whole of the liquid contained in the fermenting receivers is shaken and the juice of sprouting barley, or malted or natural barley roughly ground is added. It is by this process a "natural wine" is said to be produced of very great service in an alimentary point of view. The pure beetroot red wine has such a brilliant colour that it can be employed with great advantage to colour and enrich all natural wines deficient in colour as well as in condition, and for crossing or blending with glucose wines of all kinds.

THE AMERICAN TRICYCLE SKATE.

We give an illustration of the new American Tricycle Skate, said to be the fastest skate ever invented; twenty miles can be done with it. It is reported to act as well upon any ordinary surface, floor, carpet, &c., as any ice skate under the most favourable conditions, and to admit of any figure or evolutions possible in any other skate. The inventor is Mr. J. F. Walter, of 7, Queen's-road, Bayswater, W.



CART AND WHEELMAKING.—XVII.

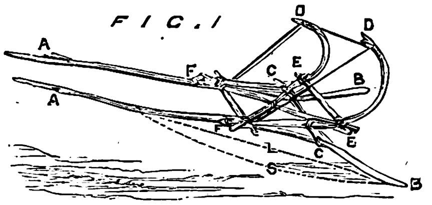
By J. Charles King.

(*Continued from page 254.*)

Having described the processes of painting and varnishing carts, which should always be done as the various parts are completed progressively, to ensure that the woodwork shall have ample coats of colour to preserve it from decay, and the ironwork bearings from rust. I continue the description of the ironwork.

Next to the axle of a cart, the chief pieces of ironwork are the springs; on these depend not only ease to riders, but lessened draught and weight, elegance of design and durability of the whole structure.

As carriage spring-making is a special craft in smiths' work, and somewhat a trade mystery in some of its processes, requiring experience and keen technical application for designing, forging, and tempering steel, to ensure sound and serviceable work. I propose briefly to illustrate and describe the principles upon which all springs of steel, or steel and leather combined, are designed, forged, and tempered, with their adjustment for carts.



The use of steel springs for vehicles does not date back more than three centuries in this country; before their use, the shafts of the vehicles of light weight were made to serve as the yielding medium, the same as the Tartar sledge of tree branches is now made to serve the same purpose.

As it may interest some persons who are making carts, an illustration of a Tartar sledge (Fig. 1) will serve to point out the initial designs of springs of steel in use in the best vehicles of the cart builder.

Here we see branches of trees and thongs of leather are all that are used in making up this sledge.

Although the branches of trees are lashed together so roughly, there is an obvious design in the form and arrangement of the bearing parts to ensure a yielding, springy structure, capable, with the aid of skins or matting, of carrying a family or merchandise, the bent ends of the upper-frame serving to support a rough canopy for shelter.

By comparing the sledge with drawings of the three forms of springs in use in modern vehicles, the resemblance will be obvious.

Fig. B is technically termed an "elbow-spring" or half-spring, such as is used at the back of broughams and on the common hand-barrow; this is seen at B on the sledge.

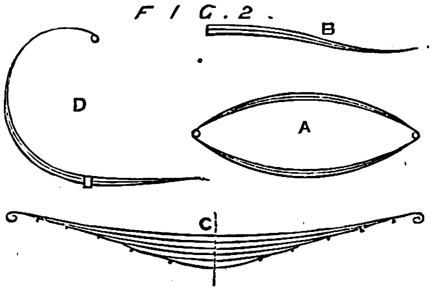


Fig. D is termed a Cee-spring, used on the best and most costly carriages, ensuring the maximum of ease without jarring vibrations; this form is on the sledge, the cross bar E being the fulcrum over which it yields.

Fig. A is an elliptic-spring, to be seen on almost every four-wheeled carriage.

It is formed of two bow-springs coupled at their ends. In the sledge, the form of one-half or the top of the elliptic spring is seen in the long shafts from A to B. In carts, the lower half or bow is used, attached to the shafts by scroll-irons, in form as marked on the illustration, Fig. 1, by the dotted line S.

Perhaps some readers may have seen the antique gig at the South Kensington Museum, about three hundred years old, the workmanship of which would put to shame by comparison many a gig or cart made now, with all our appliances of art and science; there are no springs but the long shafts which have a bow-string support, similar to the line L in the illustration, intended to resist excessive strain.

Bow-springs may be considered the most fitting springs for carts, though elliptic may be used with advantage for light pony traps.

For medium sized dog-carts, bow-springs are made about 4ft. long, 2in. wide, with six "leaves" or "plates," as they are technically termed; each plate is made to graduate in length and thickness, till the shortest plate, which rests for its bearing on the axle, is only 12in. long. Of the six plates, the longest is termed the "back-plate," the next the second plate, and so on, up to the shortest. The steel is specially made for springs, and of thicknesses varying from 3-16th to 5-16th of an inch.

The back-plate and sixth plate are best if of ¼in. thick, the rest, up to the sixth, 1-32nd of an inch less thickness.

The bow of the spring technically termed the "compass" of the spring, is usually about 6in. from a straight line before the springs have the weight of body and carriage on them.

In diagram C, Fig. 2, is shown a bow-string with the plates arranged, each one about ¾in. more span than the next larger plate above it, as far as the third plate, when the span is lessened on each shorter plate till it is only about ¼in more span on the short plate. This extra span is technically termed the force of the plates; the bolt through all the plates, about 1in. from the middle distance from each end, draws the open span-plates to a close fit.

To prevent the plates slipping edgeways beyond each other at the ends, a nib is punched on each plate, about where the dots are on the diagram, and a sunk "slit" is recessed into each other plate to receive the nib opposite to each.

As working steel is different to working iron, especially in spring-making, I propose to detail the methods adopted, and forms of tools used for spring-making, how to "draw" steel, "harden," and "temper" for springs for carts.

PRACTICAL NOTES ON PLUMBING.—XL.*

By P. J. Davies, H.M.A.S.P., &c.

(*Continued from page 537.*)

The New Machine.

All lead-burning machines should be of a cylindrical form, and of a size suitable to the class of work intended. A machine suitable for one job may be found very unsuitable for another. I myself have five sizes, varying from 6in. upwards. The large machines are the most profitable, and work with less attention than the smaller ones. A 6in. machine is very suitable for fixing soil pipes, burning lead on roofs, and general running about on buildings, chemical works, &c. A middle sized machine suitable for cisterns is 11in. in diameter, and a stock machine from 18in. to 24in; such a machine I have now in use for burning up all my soil-pipes. The kind of soil-pipes thus produced are the best to be had, simply because the metal of which they are formed will be of one uniform thickness throughout, and of a far better quality than is generally to be obtained. I also find that there is a considerable saving when it is requisite to bend the pipe. the lead being much softer for dummying. Fig. 228 represents a properly constructed lead-burning machine: this will be found to be light, strong, portable, self cleansing, and lasting; besides this, the material is so arranged that it is put into a stronger and more pleasing shape to meet the eye, and appears what it is, a nice piece of workmanship, a great desideratum with most plumbers, for who would care to carry an ugly square wooden box about with them when they can have a neat and compact small circular instrument quarter the size, not one sixth part of the weight, and capable of doing double the work with half the amount of acid?

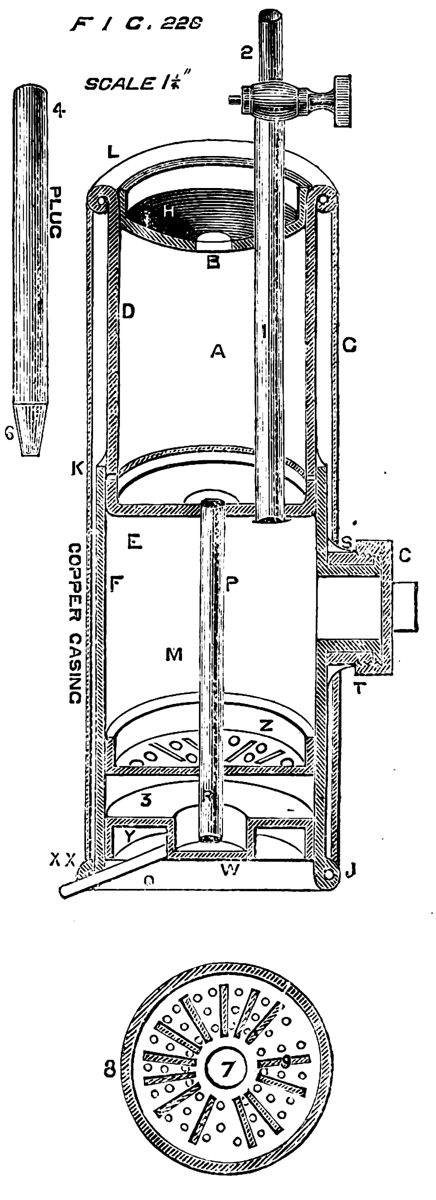
---

* From the *Building News*. All rights reserved.

This machine is constructed as follows: With suitable sized pieces of 4lb. or 5lb. sheet-lead form the sides, or the top and bottom parts. Suppose it to be a 9in. machine these pieces will then be about 3ft. by 1ft. 6in., 3in. being taken up to form the beads JL, Fig. 228, and 2in. for lap at K, leaving the machine to stand 2ft. 7in. high; plane up the edges, and square the top and bottom, next turn the lead upon a mandrel, not necessarily the size of the machine, and get the seam burnt up. Here the first difficulty presents itself, and one that has kept hundreds of men out of the lead-burning branch of the trade.

For a trial machine instead of burning up, solder it with as coarse a solder as you can use, for it is the tin in the solder that the acid eats away, hence the reason for using coarse solder, (this will last you a month or so to practise with until you can burn one up properly); next turn the bottom bead J, and if you do not intend to case the machine, turn the top bead. Having got so far, cut three pieces of 5lb. or 6lb. lead for the bottom, middle, and top, which must be large enough for the turn-up of edge or flange, then burn the pipe P (with the bottom end cut as shown at VU, Fig. 230,) and the pipe I to the middle partition, and fix this partition as shown in the diagram to the top part of the bottom chamber of the machine. Great care should be taken in making the joints perfectly watertight, for you cannot do anything to them after the machine is put together; next shave or clean the inside and outside parts to be burned together, and slip the top chamber into the bottom, say 2in., and let it fit quite tight, then burn it together. Now form the bottom, with the well and grating, to be fixed as shown in the diagram. From the top of the grating to the bottom of the acid pipe should be 5in., the grating to have a quantity of $\frac{3}{8}$in holes. The use of this grating is that the zinc may rest upon it, so that all the acid may drain into the well of the machine, and also to keep the zinc perfectly dry when not generating gas. Care must be taken to fix the grating or strainer in such a manner that the small parts of the zinc cannot get through and into the well, otherwise the zinc would be continually acted upon by the acid, and the machine would constantly generate gas, throwing it up the pipe PR in bubbles at intervals, which of course means a waste of acid and zinc; the same thing will happen should the zinc have very rough surfaces, because the acid hangs to the zinc. If the holes in the strainer be too small, the machine will work irregularly, and cause the gas to jump, by reason of the oxide of zinc closing them up; the same effect will be produced should the oxide get into the well in large quantities to stop up the acid pipe. Now fix the top, H, by cutting a hole for the pipe I, and a 1½in. hole for the pouring in of the acid and water, burn it to the top edge of the machine, as shown. This top, should the machine throw up, prevents the acid from flying about. Next fix a 1½in. or 2in. piece of lead pipe into the side of the well, as shown at Q, this serves to empty the machine, and to drain off the oxide of zinc, &c. A 1½ or 2in. screwed plug will be best, fixed on the end of the emptying pipe for closing. Copper or lead is the best material, but for such plugs, a 2in. boss and an iron plug may be used; but this plug requires renewing about every six months, so that a lead one will be the best. Now fix, as shown at CT, a 4in., 5in., or 6in. cap and screw; the latter size is best, because it admits of large pieces of zinc being put into the machine. This cap and screw may be soldered on, as the acid is not supposed to come into contact with it; then fix a $\frac{3}{8}$ good gas cock on the pipe I as shown, but at least 4in. above the top of the machine, out of the way of the acid. Next get a 1½in. block cut to fit in the bottom to support it. The centre of the middle partition may be partly supported by the acid pipe resting upon the bottom of the well, but care must be taken in cutting this pipe, so that the end be not stopped up by resting on the bottom, otherwise it will hinder the acid water passing from one chamber to another; the bottom of the acid pipe may be cut, as shown at TV, Fig. 230 (hereafter). If the machine is to have a casing K (a thing I recommend), use copper, and keep it well blacked over with Japan black. This casing answers two purposes: it prevents the lead from being damaged, and causes the machine, by keeping the heat in, to work better. The joints or seams of the casing may be soldered up.

FIG. 228



(To be continued.)

PORTABLE engines of 8 horse-power can be obtained in New South Wales for £260, but in Victoria, owing to the duty, they cost £310 each.

BRITISH ASSOCIATION.—PRESIDENT'S ADDRESS.

AT the fifty-second meeting of the British Association for the Advancement of Science, commenced at Southampton on the 23rd of August, Dr. C. W. Siemens, the president, delivered an address as follows:

After alluding to the death of Darwin, and the untimely decease of the hon. secretary, Prof. F. M. Balfour, who recently lost his life in an attempt to ascend the Aiguille Blanche de Penteret, Dr. Siemens proceeded:—Since the days of the first meeting of the Association in York in 1831, great changes have taken place in the means at our disposal for exchanging views, either personally or through the medium of type. The creation of the railway system has enabled congenial minds to attend frequent meetings of those special societies which have sprung into existence since the foundation of the British Association, amongst which I need only name here the Physical, Geographical, Meteorological, Anthropological, and Linnean, cultivating abstract science; and the Institution of Mechanical Engineers, the Institution of Naval Architects, the Iron and Steel Institute, the Society of Telegraph Engineers and Electricians, the Gas Institute, the Sanitary Institute, and the Society of Chemical Industry, representing applied science. If we consider further the extraordinary development of scientific journalism which has taken place, it cannot surprise us when we meet with expressions of opinion to the effect that the British Association has fulfilled its mission, and should now yield its place to those special Societies it has served to call into existence. On the other hand, it may be urged that the brilliant success of last year's Anniversary Meeting, enhanced by the comprehensive address delivered on that occasion by my distinguished predecessor in office, Sir John Lubbock, has proved, at least, that the British Association is not dead in the affections of its members, and it behoves us at this, the first ordinary gathering in the second half-century, to consider what are the strong points to rely upon for the continuance of a career of success and usefulness. If the facilities brought home to our doors of acquiring scientific information have increased, the necessities for scientific inquiry have increased in a greater ratio. The time was when science was cultivated only by the few, who looked upon its application to the arts and manufactures as almost beneath their consideration; this they were content to leave in the hands of others, who, with only commercial aims in view, did not aspire to further the objects of science for its own sake, but thought only of benefiting by its teachings. Progress could not be rapid under this condition of things, because the man of pure science rarely pursued his inquiry beyond the mere enunciation of a physical or chemical principle, whilst the simple practitioner was at a loss how to harmonise the new knowledge with the stock of information which formed his mental capital in trade.

Theoretical and Applied Science.

The advancement of the last fifty years has, I venture to submit, rendered theory and practice so interdependent, that an intimate union between them is a matter of absolute necessity for our future progress. Take, for instance, the art of dyeing, and we find that the discovery of new colouring matters derived from waste products, such as coal-tar, completely changes its practice, and renders an intimate knowledge of the science of chemistry a matter of absolute necessity to the practitioner. In telegraphy and in the new arts of applying electricity to lighting, to the transmission of power, and to metallurgical operations, problems arise at every turn, requiring for their solution not only an intimate acquaintance with, but, a positive advance upon, electrical science, as established by purely theoretical research in the laboratory. In general engineering the mere practical art of constructing a machine so designed and proportioned as to produce mechanically the desired effect, would suffice no longer. Our increased knowledge of the nature of the mutual relations between the different forms of energy makes us see clearly what are the theoretical limits of effect; these, although beyond our absolute reach, may be looked upon as the asymptotes to be approached indefinitely by the hyperbolic course of practical progress, of which we should never lose sight. Cases arise, moreover, where the introduction of new materials of construction, or the call for new effects, renders former rules wholly insufficient. In all these cases practical knowledge has to go hand in hand with advanced science in order to accomplish the desired end. Far be it from me to think lightly of the ardent students of nature, who, in their devotion to research, do not allow their minds to travel into the regions of utilitarianism and of self-interest. These, the high priests of science, command our utmost admiration; but it is not to them that we can look for our current progress in practical science, much less can we look for it to the "rule of thumb" practitioner, who is guided by what comes nearer to instinct than to reason. It is to the man of science, who also gives attention to practical questions, and to the practitioner, who devotes part of his time to the prosecution of strictly scientific investigations, that we owe the rapid progress of the present day, both merging more and more into one class, that of pioneers in the domain of nature. It is such men that Archimedes must have desired when he refused to teach his disciples the art of constructing his powerful ballistic engines, exhorting them to give their attention to the principles involved in their construction, and that Telford, the founder of the Institution of Civil Engineers, must have had in his mind's eye, when he defined civil engineering as "the art of directing the great sources of power in nature."

These considerations may serve to show that although we see the men of both abstract and applied science group themselves in minor bodies for the better prosecution of special objects, the points of contact between the different branches of knowledge are ever multiplying, all tending to form part of a mighty tree—the tree of modern science—under whose ample shadow its cultivators will find it both profitable and pleasant to meet, at least once a year; and considering that this tree is not the growth of one country only, but spreads both its roots and branches far and wide, it appears desirable that at these yearly gatherings other nations should be more fully represented than has hitherto been the case. The subjects discussed at our meetings are without exception of general interest, but many of them bear an international character, such as the systematic collection of magnetic, astronomical, meteorological, and geodetical observations, the formation of a universal code for signalling at sea, and for distinguishing lighthouses, and especially the settlement of scientific nomenclatures and units of measurement, regarding all of which an international accord is a matter of the utmost practical importance.

As regards the measures of length and weight it is to be regretted that this country still stands aloof from the movement initiated in France towards the close of last century; but considering that in scientific work metrical measure is now almost universally adopted, and that its use has been already legalised in this country, I venture to hope that its universal adoption for commercial purposes will soon follow as a matter of course. The practical advantages of such a measure to the trade of this country would, I am convinced, be very great, for English goods, such as machinery or metal rolled to current sections, are now almost excluded from the continental market, owing to the unit measure employed in their production. The principal impediment to the adoption of the metre consists in the strange anomaly that although it is legal to use that measure in commerce, and although a copy of the standard metre is kept in the Standards' Department of the Board of Trade, it is impossible to procure legalised rods representing it, and to use a non-legalised copy of a standard in commerce is deemed fraudulent. Would it not be desirable that the British Association should endeavour to bring about the use in this country of the metre and kilogramme, and, as a preliminary step, petition the Government to be represented on the International Metrical Commission, whose admirable establishment at Sèvres possesses, independently of its practical work, considerable scientific interest, as a well-found laboratory for developing methods of precise measurement?

Electrical Measures.

Next in importance to accurate measures of length, weight, and time, stand, for the purposes of modern science, those of electricity. The remarkably clear lines separating conductors from non-conductors of electricity, and magnetic from non-magnetic substances, enable us to measure electrical quantities and effects with almost mathematical precision; and although the ultimate nature of this, the youngest scientifically investigated form of energy, is yet wrapped in mystery, its laws are the most clearly established, and its measuring instruments (galvanometers, electrometers, and magnetometers) are amongst the most accurate in physical science. Nor could any branch of science or industry be named in which electrical phenomena do not occur to exercise their direct and important influence. If, then, electricity stands foremost amongst the exact sciences, it follows that its unit measures should be determined with the utmost accuracy. Yet, 20 years ago, very little advance had been made towards the adoption of a rational system. Ohm had, it is true, given us the fixed relations existing between electromotive force, resistance, and quantity of current; Joule had established the dynamical equivalent of heat and electricity; and Gauss and Weber had proposed their elaborate system of absolute magnetic measurement. But these invaluable researches appeared only as isolated efforts, when, in 1862, the Electric Unit Committee was appointed by the British Association, at the instance of Sir William Thomson; and it is to the long-continued activity of this committee that the world is indebted for a consistent and practical system of measurement, which, after being modified in details, received universal sanction last year by the International Electrical Congress assembled at Paris. At that Congress, which was attended officially by the leading physicists of all civilised countries, the attempt was successfully made to bring about a union between the statical system of measurement that had been followed in Germany and some other countries, and the magnetic, or dynamical, system developed by the British Association, also, between the geometrical measure of resistance, the (Werner) Siemens unit, that had been generally adopted abroad, and the British Association unit intended as a multiple of Weber's absolute unit, though not entirely fulfilling that condition. The Congress, while adopting the absolute system of the British Association, referred the final determination of the unit measure of resistance to an International Committee, to be appointed by the representatives of the several Governments; they decided to retain the mercury standard for reproduction and comparison, by which means the advantages of both systems are happily combined, and much valuable labour is utilised; only, instead of expressing electrical quantities directly in absolute measure, the Congress has embodied a consistent system, based on the Ohm, in which the units are of a value convenient for practical measurements. In this, which we must hereafter know as the "practical system," as distinguished from the "absolute system," the units are named after leading physicists, the Ohm, Ampère, Volt, Coulomb, and Farad.

I would venture to suggest that two further units might, with advantage, be added to the system decided on by the International Congress at Paris. The first of these is the unit of magnetic quantity or pole. It is of much importance, and few will regard otherwise than with satisfaction the suggestion of Clausius that the unit should be called a "Weber," thus retaining a name most closely connected with electrical measurements, and only omitted by the Congress in order to avoid the risk of confusion in the magnitude of the unit current with which his name had been formerly associated.

The other unit I should suggest adding to the list is that of power. The power conveyed by a current of an Ampère through the difference of potential of a Volt is the unit consistent with the practical system. It might be appropriately called a Watt, in honour of that master-mind in mechanical science, James Watt. He it was who first had a clear physical conception of power, and gave a rational method of measuring it. A Watt, then, expresses the rate of an Ampère multiplied by a Volt, whilst a horse-power is 746 Watts, and a Cheval de Vapeur 735.

The system of electro-magnetic units would then be :—

					C.G.S. Units.
(1)	Weber,	the unit of	magnetic	quantity	$= 10^8$
(2)	Ohm.	,,	,,	resistance	$= 10^9$
(3)	Volt	,,	,,	electromotive force	$= 10^8$
(4)	Ampère	,,	,,	current	$= 10^{-1}$
(5)	Coulomb	,,	,,	quantity	$= 10^{-1}$
(6)	Watt	,,	,,	power	$= 10^7$
(7)	Farad	,,	,,	capacity	$= 10^{-9}$

The word energy was first used by Young in a scientific sense, and represents a conception of recent date, being the outcome of the labours of Carnot, Mayer, Joule, Grove, Clausius, Clerk-Maxwell, Thomson, Stokes, Helmholtz, Macquorn-Rankine, and other labourers, who have accomplished for the science regarding the forces in nature what we owe to Lavoisier, Dalton, Berzelius, Liebig, and others, as regards chemistry. In this short word energy we find all the efforts in nature, including electricity, heat, light, chemical action, and dynamics, equally represented, forming, to use Dr. Tyndall's apt expression, so many "modes of motion." It will readily be conceived that when we have established a fixed numerical relation between these different modes of motion, we know beforehand what is the utmost result we can possibly attain in converting one form of energy into another, and to what extent our apparatus for effecting the conversion falls short of realising it. The difference between ultimate theoretical effect and that actually obtained is commonly called loss; but, considering that energy is indestructible, represents really secondary effect which we obtain without desiring it. Thus friction in the working parts of a machine represents a loss of mechanical effect, but is a gain of heat, and in like manner the loss sustained in transferring electrical energy from one point to another is accounted for by heat generated in the conductor. It sometimes suits our purpose to augment the transformation of electrical into heat energy at certain points of the circuit when the heat rays become visible, and we have the incandescence electric light. In effecting a complete severance of the conductor for a short distance, after the current has been established, a very great local resistance is occasioned, giving rise to the electric arc, the highest development of heat ever attained. Vibration is another form of lost energy in mechanism; but who would call it a loss if it proceeded from the violin of a Joachim or a Norman-Neruda?

The Transmission of Energy.

Electricity is the form of energy best suited for transmitting an effect from one place to another; the electric current passes through certain substances—the metals—with a velocity limited only by the retarding influence caused by electric charge of the surrounding dielectric, but approaching probably under favourable conditions that of radiant heat and light, or 300,000 kilometres per second; it refuses, however, to pass through oxidised substances, glass, gums, or through gases except when in a highly rarefied condition. It is easy therefore to confine the electric current within bounds, and to direct it through narrow channels of extraordinary length. The conducting wire of an Atlantic cable is such a narrow channel; it consists of a copper wire, or strand of wires, 5mm. in diameter, by nearly 5,000 kilometres in length, confined electrically by a coating of guttapercha about 4mm. in thickness. The electricity from a small galvanic battery passing into this channel prefers the long journey to America in the good conductor, and back through the earth, to the shorter journey across the 4mm. in thickness of insulating material. By an improved arrangement the alternating currents employed to work long submarine cables do not actually complete the circuit, but are merged in a condenser at the receiving station after having produced their extremely slight but certain effect on the receiving instrument So perfect is the channel and so precise the action of both the transmitting and receiving instruments employed, that two systems of electric signals may be passed simultaneously through the same cable in opposite directions, producing independent records at either end. By the application of this duplex mode of working to the Direct United States cable under the superintendence of Dr. Muirhead, its transmitting power was increased from 25 to 60 words a minute, being equivalent to about 12 currents or primary impulses per second.

The minute currents here employed are far surpassed as regards delicacy and frequency by those revealed to us by that marvel of the present day, the telephone. The electric currents caused by the vibrations of a diaphragm acted upon by the human voice, naturally vary in frequency and intensity according to the number and degree of those vibrations, and each motor current in exciting the electro-magnet forming part of the receiving instrument, deflects the iron diaphragm occupying the position of an armature to a greater or smaller extent according to its strength. Savart found that the fundamental *la* springs from 440 complete vibrations in a second; but what must be the frequency and modulations of the motor current and of magnetic variations necessary to convey to the ear through the medium of a vibrating armature, such a complex of human voices and of musical instruments as constitutes an opera performance. And yet such performances could be distinctly heard and even enjoyed as an artistic treat by applying to the ears a pair of the double telephonic receivers at the Paris Electrical Exhibition, when connected with a pair of transmitting instruments in front of the footlights of the Grand Opera. In connection with the telephone, and with its equally remarkable adjunct the microphone, the names of Riess, Graham Bell, Edison, and Hughes will ever be remembered.

Regarding the transmission of power to a distance the electrical current has now entered the lists in competition with compressed air, the hydraulic accumulator, and the quick running rope as used at Schaffhausen to utilise the power of the Rhine fall. The transformation of electrical into mechanical energy can be accomplished with no further loss than is due to such incidental causes as friction and the heating of wires; these in a properly designed dynamo-electric machine do not exceed 10 per cent., as shown by Dr. John Hopkinson, and, judging from recent experiments of my own, a still nearer approach to ultimate perfection is attainable. Adhering, however, to Dr. Hopkinson's determination, for safety sake, and assuming the same percentage in reconverting the current into mechanical effect, a total loss of 19 per cent. results; to this loss must be added that through electrical resistance in the connecting line wires, which depends upon their length and conductivity, and that due to heating by friction of the working parts of the machine. Taking these as being equal to the internal losses incurred in the double process of conversion, there remains a useful effect of $100 - 38 = 62$ per cent., attainable at a distance, which agrees with experimental results, although in actual practice it would not be safe at present to expect more than 50 per cent. of ultimate useful effect, to allow for all mechanical losses.

In using compressed air or water for the transmission of power the loss cannot be taken at less than 50 per cent., and as it depends upon fluid resistance it increases with distance more rapidly than in the case of electricity. Taking the loss of effect in all cases as 50 per cent., electric transmission presents the advantage that an insulated wire does the work of a pipe capable of withstanding high internal pressure, which latter must be more costly to put down and to maintain. A second metallic conductor is required, however, to complete the electrical circuit, as the conducting power of the earth alone is found unreliable for passing quantity currents, owing to the effects of polarisation; but as this second conductor need not be insulated, water or gas pipes, railway metals or fencing wire, may be called into requisition for the purpose. The small space occupied by the electromotor, its high working speed, and the absence of waste products, render it specially available for the general distribution of power to cranes and light machinery of every description. A loss of effect of 50 per cent. does not stand in the way of such applications, for it must be remembered that a powerful central engine of best construction produces motive power with a consumption of 2lb. of coal per horse-power per hour, whereas small engines distributed over a district would consume not less than 5lb.; we thus see that there is an advantage in favour of electric transmission as regards fuel, independently of the saving of labour and other collateral benefits.

To agriculture, electric transmission of power seems well adapted for effecting the various operations of the farm and fields from one centre. Having worked such a system myself in combination with electric lighting and horticulture for upwards of two years, I can speak with confidence of its economy, and of the facility with which the work is accomplished in charge of untrained persons.

As regards the effect of the electric light upon vegetation, there is little to add to what was stated in my paper read before section A last year, and ordered to be printed with the report, except that in experimenting upon wheat, barley, oats, and other cereals sown in the open air, there a marked difference between the growth of the plants influenced and those uninfluenced by the electric light. This was not very apparent till towards the end of February, when, with the first appearance of mild weather, the plants, under the influence of an electric lamp of 4,000 candle-power placed about five metres above the surface, developed with extreme rapidity, so that by the end of May they stood about 4ft. high, with the ears in full bloom, when those not under its influence were under 2ft. in height, and showed no sign of the ear.

In the electric railway first constructed by Dr. Werner Siemens, at Berlin, in 1879, electric energy was transmitted to the moving carriage or train of carriages through the two rails upon which it moved, these being sufficiently insulated from each other by being placed upon well creosoted cross sleepers. At the Paris Electrical Exhibition the current was conveyed through two separate conductors making sliding or rolling contact with the carriage, whereas in the electric railway now in course of construction in the north of Ireland (which when completed will have a length of twelve miles) a separate conductor will be provided by the side of the railway, and the return circuit completed through the rails themselves, which in that case need not be insulated; secondary batteries will be used to store the surplus energy created in running downhill, to be restored in ascending steep inclines, and for passing roadways where the separate insulated conductor is not practicable. The electric railway possesses gread advantages over horse or steam-power for towns, in tunnels, and in all cases where natural sources of energy, such as waterfalls, are available; but it would not be reasonable to suppose that it will in its present condition compete with steam propulsion upon ordinary railways.

Electric energy may also be employed for heating purposes, but in this case it would obviously be impossible for it to compete in point of economy with the direct combustion of fuel for the attainment of ordinary degrees of heat. Bunsen and St. Claire De Ville have taught us, however, that combustion becomes extremely sluggish when a temperature of 1,800° C. has been reached, and for effects at temperatures exceeding that limit the electric furnace will probably find advantageous applications. Its specific advantage consists in being apparently unlimited in the degree of heat attainable, thus opening out a new field of investigation to the chemist and metallurgist. Tungsten has been melted in such a furnace, and 8 pounds of platinum have been reduced from the cold to the liquid condition in 20 minutes.

Electric Lighting.

The largest and most extensive application of electric energy at the present time is to lighting, but, considering how much has of late been said and written for and against this new illuminant, I shall here confine myself to a few general remarks. Joule has shown that if an electric current is passed through a conductor the whole of the energy lost by the current is converted into heat; or, if the resistance be localised, into radiant energy comprising heat, light, and actinic rays. Neither the low heat rays nor the ultra-violet of highest refrangibility affect the retina, and may be regarded as lost energy, the effective rays being those between the red and violet of the spectrum, which in their combination produce the effect of white light. Regarding the proportion of luminous to non-luminous rays proceeding from an electric arc or incandescent wire, we have a most valuable investigation by Dr. Tyndall, recorded in his work on "Radiant Heat." Dr. Tyndall shows that the luminous rays from a platinum wire heated to its highest point of incandescence, which may be taken at 1,700° C., formed 1-24th part of the total radiant energy emitted, and 1-10th part in the case of an arc light worked by a battery of 50 Grove's elements. In order to apply these valuable data to the case of electric lighting by means of dynamo-currents, it is necessary in the first place to determine what is the power of 50 Grove's elements of the size used by Dr. Tyndall, expressed in the practical scale of units as now established. From a few experiments lately undertaken for myself, it would appear that 50 such cells have an electro-motive force of 98·5 volts, and an internal resistance of 13·5 ohms, giving a current of 7·3 ampères when the cells are short-circuited. The resistance of a regulator such as Dr. Tyndall used in his experiments may be taken at 10 ohms, the current produced in the arc would be 4 ampères (allowing one ohm for the leads), and the power consumed 160 watts: the light power of such an arc would be about 150 candles, and, comparing this with an arc of 3,308 candles produced by 1,162 watts, we find that 7·3 times the electric energy produce 22 times the amount of light measured horizontally. If, therefore, in Dr. Tyndall's arc 1-10th of the radiant energy emitted was visible as light, it follows that in a powerful arc of 3,300 candles, fully $\frac{1}{3}$ are luminous rays. In the case of the incandescence light (say a Swan light of 20 candle power) we find in practice that 9 times as much power has to be expended as in the case of the arc light; hence, 1-27 part of the power is given out as luminous rays, as against 1-24th in Dr. Tyndall's incandescent platinum—a result sufficiently approximate, considering the wide difference of conditions under which the two are compared.

These results are not only of obvious practical value, but they seem to establish a fixed relation between current, temperature, and light produced, which may serve as a means to determine temperatures exceeding the melting point of platinum with greater accuracy than has hitherto been possible by actinimetric methods in which the thickness of the luminous atmosphere must necessarily exercise a disturbing influence. It is probably owing to this circumstance that the temperature of the electric arc as well as that of the solar photosphere has frequently been greatly over-estimated.

The principal argument in favour of the electric light is furnished by its immunity from products of combustion, which not only heat the lighted apartments, but substitute carbonic acid and deleterious sulphur compounds for the oxygen upon which respiration depends; the electric light is white instead of yellow, and thus enables us to see pictures, furniture, and flowers as by daylight; it supports growing plants instead of poisoning them, and by its means we can carry on photography and many other industries at night as well as during the day. The objection frequently urged against the electric light, that it depends upon the continuous motion of steam or gas-engines, which are liable to accidental stoppage, has been removed by the introduction into practical use of the secondary battery; this, although not embodying a new conception, has lately been greatly improved in power and constancy by Planté, Faure, Volckmar, Sellon, and others, and promises to accomplish for electricity what the gas-holder has done for the supply of gas and the accumulator for hydraulic transmission of power.

It can no longer be a matter of reasonable doubt, therefore, that electric lighting will take its place as a public illuminant, and that even though its cost should be found greater than that of gas, it will be preferred for the lighting of drawing-rooms and dining-rooms, theatres, and concert-rooms, museums, churches, warehouses, show-rooms, printing establishments and factories, and also the cabins and engine-rooms of passenger steamers. In the cheaper and more powerful form of the arc light, it has proved itself superior to any other illuminant for spreading artificial daylight over the large areas of harbours, railway stations, and the sites of public works. When placed within a holophote the electric lamp has already become a powerful auxiliary in effecting military operations both by sea and land.

The electric light may be worked by natural sources of power such as waterfalls, the tidal wave, or the wind, and it is conceivable that these may be utilised at considerable distances by means of metallic conductors. Some five years ago I called attention to the vastness of those sources of energy, and the facility offered by electrical conduction in rendering them available for lighting and power-supply, while Sir William Thomson made this important matter the subject of his admirable address to Section A last year at York, and dealt with it in an exhaustive manner. The advantages of the electric light and of the distribution of power by electricity have lately been recognised by the British Government, who have just passed a Bill through Parliament to facilitate the establishment of electrical conductors in towns, subject to certain regulating clauses to protect the interests of the public and of local authorities. Assuming the cost of electric light to be practically the same as gas, the preference for one or other will in each application be decided upon grounds of relative convenience, but I venture to think that gas-lighting will hold its own as the poor man's friend.

Improvements in the Use of Gas.

Gas is an institution of the utmost value to the artisan; it requires hardly any attention, is supplied upon regulated terms, and gives with what should be a cheerful light a genial warmth, which often saves the lighting of a fire. The time is moreover not far distant, I venture to think, when both rich and poor will largely resort to gas as the most convenient, the cleanest, and the cheapest of heating agents, and when raw coal will be seen only at the colliery or the gasworks. In all cases where the town to be supplied is within say 30 miles of the colliery, the gasworks may with advantage be planted at the mouth, or still better at the bottom of the pit, whereby all haulage of fuel would be avoided, and the gas, in its ascent from the bottom of the colliery, would acquire an onward pressure sufficient probably to impel it to its destination. The possibility of transporting combustible gas through pipes for such a distance has been proved at Pittsburg, where natural gas from the oil district is used in large quantities.

The quasi-monopoly so long enjoyed by gas companies has had the inevitable effect of checking progress. The gas being supplied by meter, it has been seemingly to the advantage of the companies to give merely the prescribed illuminating power, and to discourage the invention of economical burners, in order that the consumption might reach a maximum. The application of gas for heating purposes has not been encouraged, and is still made difficult in consequence of the objectionable practice of reducing the pressure in the mains during daytime to the lowest possible point consistent with prevention of atmospheric indraught. The introduction of the electric light has convinced gas managers and directors that such a policy is no longer tenable, but must give way to one of technical progress; new processes for cheapening the production and increasing the purity and illuminating power of gas are being fully discussed before the Gas Institute; and improved burners, rivalling the electric light in brilliancy, greet our eyes as we pass along our principal thoroughfares.

Previous to the year 1856—that is to say, before Mr. W. H. Perkin had invented his practical process, based chiefly upon the theoretical investigations of Hoffman, regarding the coal-tar bases and the chemical constitution of indigo—the value of coal-tar in London was scarcely a halfpenny a gallon, and in country places gasmakers were glad to give it away. Up to that time the coal-tar industry had consisted chiefly in separating the tar by distillation into naphtha, creosote, oils, and pitch. A few distillers, however, made small quantities of benzene, which had been first shown —by Mansfield, in 1849—to exist in coal-tar naphtha mixed with toluene, cumene, &c. The discovery, in 1856, of the mauve or aniline purple gave a great impetus to the coal-tar trade, inasmuch as it necessitated the separation of large quantities of benzene, or a mixture of benzene and toluene, from the naphtha. The trade was further increased by the discovery of the magenta or rosaniline dye, which required the same products for its preparation. In the mean time, carbolic acid was gradually introduced into commerce, chiefly as a disinfectant, but also for the production of colouring matter.

The colour industry utilises even now practically all the benzene, a large proportion of the solvent naphtha, all the anthracene, and a portion of the naphthaline resulting from the distillation of coal-tar; and the value of the colouring matter thus produced is estimated by Mr. Perkin at £3,350,000. The demand for ammonia may be taken as unlimited, on account of its high agricultural value as a manure; and, considering the failing supply of guano and the growing necessity for stimulating the fertility of our soil, an increased production of ammonia may be regarded as a matter of national importance, for the supply of which we have to look almost exclusively to our gasworks. The present production of 1,000,000 tons of liquor yields 95,000 tons of sulphate of ammonia; which, taken at £20 10s. a ton, represents an annual value of £1,947,000.

The total annual value of the gasworks by-products may be estimated as follows:—

Colouring matter	£3,350,000
Sulphate of ammonia	1,947,600
Pitch (325,000 tons)	365,000
Creosote (25,000,000 gallons) ..	208,000
Crude carbolic acid (1,000,000 gallons)	100,000
Gas coke, 4,000,000 tons (after allowing 2,000,000 tons consumption in working the retorts) at 12s.	2,400,000
Total	£8,370,000

Taking the coal used, 9,000,000 tons, at 12s., equal £5,400,000, it follows that the by-products exceed in value the coal used by very nearly £3,000,000. In using raw coal for heating purposes these valuable products are not only absolutely lost to us, but in their stead we are favoured with those semi-gaseous by-products in the atmosphere too well known to the denizens of London and other large towns as smoke. Professor Roberts has calculated that the soot in the pall hanging over London on a winter's day amounts to fifty tons, and that the carbonic oxide, a poisonous compound, resulting from the imperfect combustion of coal, may be taken as at least five times that amount. Mr. Aitken has shown, moreover, in an interesting paper communicated to the Royal Society of Edinburgh, last year, that the fine dust resulting from the imperfect combustion of coal is mainly instrumental in the formation of fog; each particle of solid matter attracting to itself aqueous vapour; these globules of fog are rendered particularly tenacious and disagreeable by the presence of tar vapour, another result of imperfect combustion of raw fuel, which might be turned to much better account at the dye-works. The hurtful influence of smoke upon public health, the great personal discomfort to which it gives rise, and the vast expense it indirectly causes through the destruction of our monuments, pictures, furniture, and apparel, are now being recognised, as is evinced by the success of recent Smoke Abatement Exhibitions. The most effectual remedy would result from a general recognition of the fact that wherever smoke is produced, fuel is being consumed watefully, and that all our calorific effects, from the largest down to the domestic fire, can be realised as completely and more economically, without allowing any of the fuel employed to reach the atmosphere unburnt. This most desirable result may be effected by the use of gas for all heating purposes with or without the addition of coke or anthracite.

The cheapest form of gas is that obtained through the entire distillation of fuel in such gas producers as are now largely used in working the furnaces of glass, iron, and steel works; but gas of this description would not be available for the supply of towns owing to its bulk, about two-thirds of its volume being nitrogen. The use of water-gas, resulting from the decomposition of steam in passing through a hot chamber filled with coke, has been suggested, but this gas also is objectionable, because it contains, besides hydrogen, the poisonous and inodorous gas carbolic oxide, the introduction of which into dwelling-houses could not be effected without considerable danger. A more satisfactory mode of supplying heating separately from illuminating gas would consist in connecting the retort at different periods of the distillation with two separate systems of mains for the delivery of the respective gases.

The greater efficiency of gas as a fuel results chiefly from the circumstance that a pound of gas yields in combustion, 22,000 heat-units, or exactly double the heat produced in the combustion of a pound of ordinary coal. This extra heating power is due, partly to the freedom of the gas from earthy constituents, but chiefly to the heat imparted to it in effecting its distillation. Recent experiments with gas-burners have shown that in this direction also there is much room for improvement. The amount of light given out by a gas-flame depends upon the temperature to which the particles of solid carbon in the flame are raised, and Dr. Tyndall has shown that of the radient energy set up in such a flame, only the 1·25th part is luminous; the hot products of combustion carry off at least four times as much energy as is radiated, so that not more than one hundredth part of the heat evolved in combustion is converted into light. This proportion could be improved, however, by increasing the temperature of combustion, which may be effected either by intensified air currents or by regenerative action. Supposing that the heat of the products of combustion could be communicated to metallic surfaces, and be transferred by conduction or otherwise to the atmospheric air supporting combustion in the flame, we should be able to increase the temperature accumulatively to any point within the limit of dissociation; this limit may be fixed at about 2,300° C., and cannot be very much below that of the electric arc. At such a temperature the proportion of luminous rays to the total heat produced in combustion would be more than doubled, and the brilliancy of the light would at the same time be greatly increased. Thus improved, gas-lighting may continue its rivalry with electric lighting both as regards economy and brilliancy, and such rivalry must necessarily result in great public advantage.

Utilisation of Gaseous Fuel.

In the production of mechanical effect from heat, gaseous fuel also presents most striking advantages, as will appear from the following consideration. When we have to deal with the question of converting mechanical into electrical effect, or vice versâ, by means of a dynamo-electrical machine, we have only to consider what are the equivalent values of the two forms of energy, and what precautions are necessary to avoid losses by the electrical resistance of conductors and by friction. The transformation of mechanical effect into heat involves no losses except those resulting from imperfect installation, and these may be so completely avoided that Dr. Joule was able, by this method, to determine the equivalent values of the two forms of energy. But in attempting the inverse operation of effecting the conversion of heat into mechanical energy, we find ourselves confronted by the second law of thermo-dynamics, which says that whenever a given amount of heat is converted into mechanical effect, another but variable amount descends from a higher to a lower potential, and is thus rendered unavailable. In the condensing steam-engine this waste heat comprises that communicated to the condensing water, whilst the useful heat, or that converted into mechanical effect, depends upon the difference of temperature between the boiler and condenser. The boiler pressure is limited, however, by considerations of safety and convenience of construction, and the range of working temperature rarely exceeds 120° C. except in the engines constructed by Mr. Perkins, in which a range of 160° C., or an expansive action commencing at 14 atmospheres, has been adopted with considerable promise of success, as appears from an able report on this engine by Sir Frederick Bramwell.

Before many years have elapsed we shall find in our factories and on board our ships engines with a fuel consumption not exceeding 1lb. of coal per effective horse-power per hour, in which the gas producer takes the place of the somewhat complex and dangerous steam-boiler. The advent of such an engine and of the dynamo-machine must mark a new era of material progress at least equal to that produced by the introduction of steam power in the early part of our century. Let us consider what would be the probable effect of such an engine upon that most important interest of this country—the merchant navy.

The Gas-engine for Marine Purposes.

According to returns kindly furnished me by the Board of Trade and "Lloyds' Register of Shipping," the total value of the merchant shipping of the United Kingdom may be estimated at £126,000,000, of which £90,000,000 represent steamers having a net tonnage of 3,003,988 tons; and £36,000,000 sailing vessels, of 3,688,008 tons. The safety of this vast amount of shipping, carrying about five-sevenths of our total imports and exports, or £500,000,000 of goods in the year, and of the more precious lives connected with it, is a question of paramount importance. It involves considerations of the most varied kind: comprising the construction of the vessel itself, and the material employed in building it: its furniture of engines, pumps, sails, tackle, compass, sextant, and sounding apparatus, the preparation of reliable charts for the guidance of the navigator, and the construction of harbours of refuge, lighthouses, beacons, bells, and buoys, for channel navigation. Yet notwithstanding the combined efforts of science, inventive skill, and practical experience—the accumulation of centuries—we are startled with statements to the effect that during last year as many as 1,007 British-owned ships were lost, of which fully two-thirds were wrecked upon our shores, representing a total value of nearly £10,000,000. Of these ships 870 were sailing vessels and 137 steamers, the loss of the latter being in a fourth of the cases attributable to collision. The number of sailing vessels included in these returns being 19,325, and of steamers 5,505, it appears that the steamer is the safer vessel, in the proportion of 4·43 to 3·46; but the steamer makes on an average three voyages for one of the sailing ship taken over the year, which reduces the relative risk of the steamer as compared with the sailing ship per voyage in the proportion of 13·29 to 3·46. Commercially speaking, this factor of safety in favour of steam-shipping is to a great extent counterbalanced by the value of the steamship, which bears to that of the sailing vessel per net carrying ton the proportion of 3 : 1, thus reducing the ratio in savour of steam shipping as 13·29 to 10·38, or in round numbers as 4 : 3.

In considering the question how the advantages thus established in favour of steam-shipping could be further improved, attention should be called in the first place to the material employed in their construction. A new material was introduced for this purpose by the Admiralty in 1876-78, when they constructed at Pembroke dockyard the two steam corvettes, the *Iris* and *Mercury*, of mild steel. The peculiar qualities of this material are such as to have enabled shipbuilders to save 20 per cent. in the weight of the ship's hull, and to increase to that extent its carrying capacity. It combines with a strength 30 per cent. superior to that of iron such extreme toughness, that in the case of collision the side of the vessel has been found to yield or bulge several feet without showing any signs of rupture, a quality affecting the question of sea risk very favourably. When to the use of this material there are added the advantages derived from a double bottom, and from the division of the ship's hold by means of bulkheads of solid construction, it is difficult to conceive how such a vessel could perish by collision either with another vessel or with a sunken rock. The spaces between the two bottoms are not lost, because they form convenient chambers for water ballast, but powerful pumps should in all cases be added to meet emergencies.

If to the improvements already achieved could be added an engine of half the weight of the present steam-engine and boilers, and working with only half the present expenditure of fuel, a further addition of 30 per cent. could be made to the cargo of an Atlantic propeller vessel—no longer to be called a steamer—and the balance of advantages in favour of such vessels would be sufficient to restrict the use of sailing craft chiefly to the regattas of this and neighbouring ports.

Maritime Improvements.

The progressive views perceptible in the construction of the navy are further evidenced in a remarkable degree in the hydrographic department. Captain Sir Frederick Evans, the hydrographer, and vice-president of the British Association, gave us at York last year a very interesting account of the progress made in that department, which, while dealing chiefly with the preparation of charts showing the depth of water, the direction and force of currents, and the rise of tides near our shores, contains also valuable statistical information regarding the more general questions of the physical conditions of the sea, its temperature at various depths, it flora and fauna, as also the rainfall and the nature and force of prevailing winds. In connection with this subject the American Naval Department has taken an important part, under the guidance of Captain Maury and the Agassiz father and son, whilst in this country the persistent labours of Dr. William Carpenter deserve the highest consideration. Our knowledge of tidal action has received a most powerful impulse through the invention of a self-recording gauge and tide-predicter, which will form the subject of one of the discourses to be delivered at our present meeting by its principal originator, Sir William Thomson. The application of iron and steel in naval construction rendered the use of the compass for some time illusory, but in 1839 Sir George Airy showed how the errors of the compass, due to the influence experienced from the iron of the ship, may be perfectly corrected by magnets and soft iron placed in the neighbourhood of the binnacle; but the great size of the needles in the ordinary compasses rendered the correction of the quadrantal errors practically unattainable. In 1876, Sir William Thomson invented a compass with much smaller needles than those previously used, which allows Sir George Airy's principles to be applied completely. Sir William Thomson has also enriched the art of navigation by the invention of two sounding machines; the one being devised for ascertaining great depths very accurately in less than one-quarter the time formerly necessary, and the other for taking depths up to 130 fathoms without stopping the ship in its onward course. In both these instruments steel pianoforte wire is used instead of the hempen and silken lines formerly employed; in the latter machine, the record of depth is obtained, not by the quantity of wire run over its counter and brake-wheel, but through the indications produced upon a simple pressure gauge consisting of an inverted glass tube, whose internal surface is covered beforehand with a preparation of chromate of silver, rendered colourless by the sea-water up to the height to which it penetrates. The value of this instrument for guiding the navigator within what he calls "soundings" can hardly be exaggerated; with the sounding-machine and a good chart he can generally make out his position correctly by a succession of three or four casts in a given direction at given intervals, and thus in foggy weather is made independent of astronomical observations and of the sight of lighthouses or the shore. By the proper use of this apparatus, such accidents as happened to the mail steamer *Mosel* not a fortnight ago would not be possible. As regards the value of the deep-sea instrument, I can speak from personal experience, as on one occasion it enabled those in charge of the Cable s.s. *Faraday* to find the end of an Atlantic cable, which had parted in a gale of wind, with no other indication of the locality than a single sounding, giving a depth of 950 fathoms. To recover the cable a number of soundings in the supposed neighbourhood of the broken end were taken, the 950 fathom contour line was then traced upon a chart, and the vessel thereupon trailed its grapnel two miles to the eastward of this line, when it soon engaged the cable 20 miles away from the point where dead reckoning had placed the ruptured end.

Modern Engineering Enterprises.

The great success, both technically and commercially, of the Suez Canal, has stimulated M. de Lesseps to undertake a similar work of even more gigantic proportions, namely, the piercing of the Isthmus of Panama by a ship canal, 40 miles long, 50 yards wide on the surface, and 20 yards at the bottom, upon a dead level from sea to sea. The estimated cost of this work is £20,000,000, and more than this sum having been subscribed, it appears unlikely that political or climatic difficulties will stop M. de Lesseps in its speedy accomplishment. Through it, China, Japan, and the whole of the Pacific Ocean will be brought to half their present distance, as measured by the length of voyage, and an impulse to navigation and to progress will thus be given which it will be difficult to over-estimate. Side by side with this gigantic work, Captain Eads, the successful improver of the Mississippi navigation, intends to erect his ship-railway to take the largest vessels, fully laden and equipped, from sea to sea, over a gigantic railway across the Isthmus of Tehuantepec, a distance of 95 miles. Mr. Barnaby, the chief constructor of the navy, and Mr. John Fowler, have expressed a favourable opinion regarding this enterprise, and it is to be hoped that both the canal and the ship-railway will be accomplished, as it may be safely anticipated that the traffic will be amply sufficient to support both these undertakings.

Whether or not M. de Lesseps will be successful also in carrying into effect the third great enterprise with which his name has been prominently connected, the flooding of the Tunis-Algerian Chotts, thereby re-establishing the Lake Tritonis of the ancients, with its verdure-clad shores, is a question which could only be decided upon the evidence of accurate surveys; but the beneficial influence of a large sheet of water within the African desert could hardly be matter of doubt.

It is with a feeling not unmixed with regret that I have to record the completion of a new Eddystone lighthouse in substitution for the *chef-d'œuvre* of engineering erected by John Smeaton more than 100 years ago. The condemnation of that structure was not, however, the consequence of any fault of construction, but was caused by inroads of the sea upon the rock supporting it. The new lighthouse, designed and executed by Mr. (now Sir James Douglass), engineer of Trinity House, has been erected in the incredibly short time of less than two years, and bids fair to be worthy of its famed predecessor. Its height above high water is 130ft., as compared with 72ft., the height of Telford's structure, which gives its powerful light a considerably 'increased range. The system originally suggested by Sir William Thomson some years ago, of distinguishing one light from another by flashes following at varied intervals, has been adopted by the Elder Brethren in this as in other recent lights in the modified form introduced by Dr. John Hopkinson, in which the principle is applied to revolving lights, so as to obtain a greater amount of light in the flash.

The geological difficulties which for some time threathened the accomplishment of the St. Gothard Tunnel have been happily overcome, and this second and most important sub-Alpine thoroughfare now connects the Italian railway system with that of Switzerland and the South of Germany, whereby Genoa will be constituted the shipping port for those parts.

Whether we shall be able to connect the English with the French railway system by means of a tunnel below the English Channel is a question that appears dependent at this moment rather upon military and political than technical and financial considerations. The occurrence of a stratum of impervious grey chalk, at a convenient depth below the bed of the Channel, minimises the engineering difficulties in the way, and must influence the financial question involved. The protest lately raised against its accomplishment can hardly be looked upon as a public verdict, but seems to be result of a natural desire to pause pending the institution of careful inquiries. These inquiries have been made by a Royal scientific commission, and will be referred for further consideration to a mixed Parliamentary Committee, upon whose report it must depend whether the natural spirit of commercial enterprise has to yield in this instance to political and military considerations. Whether the Channel Tunnel is constructed or not, the plan proposed some years ago by Mr. John Fowler of connecting England and France by means of a ferry boat capable of taking railway trains would be a desideratum justified by the ever-increasing intercommunication between this and Continental countries.

The public inconvenience arising through the obstruction to traffic by a sheet of water is well illustrated by the circumstance that both the estuaries of the Severn and of the Mersey are being undermined in order to connect the railway systems on the two sides, and that the Frith of Forth is about to be spanned by a bridge exceeding in grandeur anything as yet attempted by the engineer. The roadway of this bridge will stand 150ft. above high-water mark, and its two principal spans will measure a third of a statute mile each. Messrs. Fowler and Baker, the engineers to whom this great work has been entrusted, could hardly have accomplished their task without having recourse to steel for their material of construction, nor need the steel used be of the extra mild quality particularly applicable for naval structures to withstand collision, for, when such extreme toughness is not required, steel of very homogeneous quality can be produced, bearing a tensile strain double that of iron.

Improvements of Explosives.

When the British Association met at Southampton on a former occasion, Schönbein announced to the world his discovery of gun-cotton. This discovery has led the way to many valuable researches on explosives generally, in which Mr. Abel has taken a leading part. Recent investigations by him, in connection with Captain Noble, upon the explosive action of gun-cotton and gunpowder confined in a strong chamber, which have not yet been published, deserve particular attention. They show that while by the method of investigation pursued about twenty years ago by Karolye (of exploding gunpowder in very small charges in shells confined within a large shell partially exhausted of air), the composition of the gaseous products was found to be complicated and liable to variation, the chemical metamorphosis which gun-cotton sustains, when exploded under conditions such as obtain in its practical application, is simple and very uniform. Among other interesting points noticed in this direction was the fact that, as in the case of gunpowder, the proportion of carbonic acid increases, while that of carbonic oxide diminishes with the density of the charge.

Messrs. Noble and Abel are also continuing their researches upon fired gunpowder, being at present occupied with an inquiry into the influence exerted upon the chemical metamorphosis and ballistic effects of fired gunpowder by variation in its composition, their attention being directed especially to the discovery of the cause of the more or less considerable erosion of the interior surface of guns produced by the exploding charge—an effect which, notwithstanding the application of devices in the building up of the charge specially directed to the preservation of the gun's bore, have become so serious that, with the enormous charges now used in our heavy guns, the erosive action on the surface of the bore produced by a single round is distinctly perceptible. As there appeared to be *primâ facie* reasons why the erosive action of powder upon the surface of the bore at the high temperatures developed should be, at any rate, in part due to its one component, sulphur, Noble and Abel have made comparative experiments with powders of usual composition, and with others in which the proportion of sulphur was considerably increased, the extent of erosive action of the products escaping from the explosion vessel under high tension being carefully determined. With small charges, a particular powder containing no sulphur was found to exert very little erosive action as compared with ordinary cannon powder; but another powder containing the maximum proportion of sulphur tried (15 per cent.), was found equal to it under these conditions, and exerted very decidedly less erosive action than it, when larger charges were reached. Other important contributions to our knowledge of the action of fired gunpowder in guns, as well as decided improvements in the gunpowder manufactured for the very heavy ordnance of the present day, may be expected to result from a continuance of these investigations. Professor Carl Himly, of Kiel, having been engaged upon investigations of a similar nature, has lately proposed a gunpowder in which hydrocarbons precipitated from solution in naphtha take the place of the charcoal and sulphur of ordinary powder. This powder has amongst others the peculiar property of completely resisting the action of water, so that the old caution, "Keep your powder dry," may hereafter be unecessary.

The extraordinary difference of condition, before and after its ignition, of such matter as constitutes an explosive agent leads us up to a consideration of the aggregate state of matter under other circumstances. As early as 1776 Alexander Volta observed that the volume of glass was changed under the influence of electrification, by what he termed electrical pressure. Dr. Kerr, Govi, and others have followed up the same inquiry, which is at present continued chiefly by Dr. George Quincke, of Heidelberg, who finds that temperature, as well as chemical constitution of the dielectric under examination, exercises a determining influence upon the amount and character of the change of volume effected by electrification; that the change of volume may under certain circumstances be effected instantaneously as in flint glass, or only slowly as in crown glass, and that the elastic limit of both is diminished by electrification, whereas in the case of mica and of guttapercha an increase of elasticity takes place.

Phenomena of Electrical Discharge.

Still greater strides are being made at the present time towards a clearer perception of the condition of matter when particles are left some liberty to obey individually the forces brought to bear upon them. By the discharge of high tension electricity through tubes containing highly rarefied gases (Geissler's tubes), phenomena of discharge were produced which were at once most striking and suggestive. The Sprengel pump afforded a means of pushing the exhaustion to limits which had formerly been scarcely reached by the imagination. At each step, the condition of attenuated matter revealed varying properties when acted upon by electrical discharge and magnetic force. The radiometer of Crookes imported a new feature into these inquiries, which at the present time occupy the attention of leading physicists in all countries.

The means usually employed to produce electrical discharge in vacuum tubes was Ruhmkorff's coil; but Mr. Gassiot first succeeded in obtaining the phenomena by means of a galvanic battery of 3,000 Leclanché cells. Dr. De La Rue, in conjunction with his friend, Dr. Hugo Müller, has gone far beyond his predecessors in the production of batteries of high potential. At his lecture, "On the Phenomena of Electric Discharge," delivered at the Royal Institution in January, 1881, he employed a battery of his invention, consisting of 14,400 cells (14,832 volts), which gave a current of 0·054 ampère, and produced a discharge at a distance of 0·71in. between the terminals. During last year he increased the number of cells to 15,000 (15,450 volts), and increased the current to 0·4 ampère, or eight times that of the battery he used at the Royal Institution.

The President of the Royal Society has made the phenomena of electrical discharge his study for several years, and resorted in his important experiments to a special source of electric power. In a note addressed to me, Dr. Spottiswoode describes the nature of his investigations much more clearly than I could venture to give them. He says: "It had long been my opinion that the dissymmetry shown in electrical discharges through rarefied gases must be an essential element of every disruptive discharge, and that the phenomena of stratification might be regarded as magnified images of features always present, but concealed under ordinary circumstances. It was with a view to the study of this question that the researches by Moulton and myself were undertaken. The method chiefly used consisted in introducing into the circuit intermittence of a particular kind, whereby one luminous discharge was rendered sensitive to the approach of a conductor outside the tube. The application of this method enabled us to produce artificially a variety of phenomena, including that of stratification. We were thus led to a series of conclusions relating to the mechanism of the discharge, among which the following may be mentioned:—"1. That a stria, with its attendant dark space, forms a physical unit of a striated discharge. 2. That the origin of the luminous column is to be sought for at its negative end; that the luminosity is an expression of a demand for negative electricity. 3. That the time occupied by electricity of either name in traversing a tube is greater than that occupied in traversing an equal length of wire, but less than that occupied by molecular streams (Crooke's radiations) in traversing the tubes. 4. That the brilliancy of the light with so little heat may be due in part to brevity in the duration of the discharge. 5. That striæ are not merely loci in which electrical is converted into luminous energy, but are actual aggregations of matter.

"This last conclusion was based mainly upon experiments made with an induction coil excited in a new way—viz., directly by an alternating machine, without the intervention of a commutator or condenser. This mode of excitement promises to be one of great importance in spectroscopic work, as well as in the study of the discharge in a magnetic field, partly on account of the simplification which it permits in the construction of induction coils, but mainly on account of the very great increase of strength in the secondary currents to which it gives rise."

Solar Physics.

These investigations assume additional importance when we view them in connection with solar—I may even say stellar—physics, for evidence is augmenting in favour of the view that interstellar space is not empty, but is filled with highly attenuated matter of a nature such as may be put into our vacuum tubes. Nor can the matter occupying stellar space be said any longer to be beyond our reach for chemical and physical test. The spectroscope has already thrown a flood of light upon the chemical constitution and physical condition of the sun, the stars, the comets, and the far distant nebulæ, which have yielded spectroscopic photographs under the skilful management of Dr. Huggins, and Dr. Draper of New York. Armed with greatly improved apparatus the physical astronomer has been able to reap a rich harvest of scientific information during the short periods of the last two solar eclipses; that of 1879, visible in America, and that of May last, observed in Egypt by Lockyer, Schuster, and by Continental observers of high standing. The result of this last eclipse expedition has been summed up as follows: "Different temperature levels have been discovered in the solar atmosphere; the constitution of the corona has now the possibility of being determined, and it is proved to shine with its own light. A suspicion has been aroused once more as to the existence of a lunar atmosphere, and the position of an important line has been discovered. Hydrocarbons do not exist close to the sun, but may in space between us and it.

To me personally these reported results possess peculiar interest, for in March last I ventured to bring before the Royal Society a speculation regarding the conservation of solar energy, which was based upon the three following postulates, viz.:—

1. That aqueous vapour and carbon compounds are present in stellar or interplanetary space.

2. That these gaseous compounds are capable of being dissociated by radiant solar energy while in a state of extreme attenuation.

3. That the effect of solar rotation is to draw in dissociated vapours upon the polar surfaces, and to eject them after combustion has taken place back into space equatorially.

It is therefore a matter of peculiar gratification to me that the results of observation here recorded give considerable support to that speculation. The luminous equatorial extensions of the sun which the American observations revealed in such a striking manner (with which I was not acquainted when writing my paper) were absent in Egypt; but the outflowing equatorial streams I suppose to exist could only be rendered visible by reflected sunlight, when mixed with dust produced by exceptional solar disturbances or by electric discharge; and the occasional appearance of such luminous extensions would serve only to disprove the hypothesis entertained by some, that they are divided planetary matter, in which case their appearance should be permanent. Professor Langley, of Pittsburg, has shown, by means of his Bolometer, that the solar actinic rays are absorbed chiefly in the solar instead of in the terrestrial atmosphere, and Captain Abney has found by his new photometric method that absorption due to hydro-carbons takes place somewhere between the solar and terrestrial atmosphere; in order to test this interesting result still further, he has lately taken his apparatus to the top of the Riffel, with a view of diminishing the amount of terrestrial atmospheric air between it and the sun, and intends to bring a paper on this subject before Section A. Stellar space filled with such matter as hydrocarbon and aqueous vapour would establish a material continuity between the sun and his planets, and between the innumerable solar systems of which the universe is composed. If chemical action and reaction can further be admitted, we may be able to trace certain conditions of thermal dependence and maintenance, in which we may recognise principles of high perfection, applicable also to comparatively humble purposes of human life. We shall thus find that in the great workshop of nature there are no lines of demarcation to be drawn between the most exalted speculation and commonplace practice, and that all knowledge must lead up to one great result, that of an intelligent recognition of the Creator through His works.

HOW TO FIND THE MERIDIAN LINE.

THE following method of finding the meridian is described in a paper read recently by Mr. R. W. McFarland before the Association of County Surveyors of Ohio, who has used it for many years and finds that the true meridian can be ascertained within one minute of arc. Nail a slat to the north side of an upper window—the higher the better. Let it be 25ft. from the ground or more. Let it project 3ft. Near the end suspend a plumb-bob, and have it swing in a bucket of water. A lamp set in the window will render the upper part of the string visible. Place a small table or stand about 20ft. south of the plumb-bob, and on its south edge stick the small blade of a pocket knife; place the eye close to the blade, and move the stand so as to bring the blade, string, and polar star into line. Place the table so that the star shall be seen very near the slat in the window. Let this be done half an hour before the greatest elongation of the star. Within four or five minutes after the first alignment the star will have moved to the east or west of the string. Slip the table or the knife a little to one side, and align carefully as before. After a few alignments the star will move along the string—down, if the elongation is west; up, if east. On the first of June the eastern elongation occurs about half-past two in the morning, and as daylight comes on shortly after the observation is completed, I prefer that time of year. The time of meridian passage or of the elongation can be found in almost any work on surveying. Of course the observer should choose a calm night. In the morning the transit can be ranged with the knife blade and string, and the the proper angle turned off to the left, if the elongation is east; to the right, if west. Instead of turning off the angle, as above described, I measure 200 or 300ft. northward, in the direction of the string, and compute the offset in feet and inches, set a stake in the ground, and drive a tack in the usual way. Suppose the distance 250ft. and the angle 1° 40′, then the offset will be 7·271ft. or 7ft. 3¼in. A minute of are at the distance of 250ft. is seven-eighths of an inch; and this is the most accurate way, for the vernier will not mark so small a pace accurately.

The angle of elongation should be computed by the surveyor for each observation. The distance between the star and the pole is continually diminishing, and on January 1, 1882, was 1° 18′ 48″. There is a slight annual variation in the distance. July 1, 1882, it will be 1° 19′ 20″. If from this latter quantity the observer will subtract 16″ for 1883, and the same quantity for each succeeding year for the next four or five years, no error so great as one-quarter of a minute will be made in the position of the meridian as determined in the summer months. If winter observations are made, the distance in January should be used. The formula for computing the angle of elongation is easily made by any one understanding spherical trigonometry, and is this: $\frac{R \times \text{sin. Polar dist.}}{\text{cos. lat.}}$ = sin. of angle of elongation.

As an example, suppose the time is July, 1882, and the latitude 40°. Then the computation being made, the angle will be found to be 1° 43′ 34″. A difference of six minutes in the latitude will make less than 10″ difference in the angle, as one can see by trial. Any good map will give the latitude to within one or two miles—or minutes.

The facts being as here stated, the absurdity of the Ohio law, concering the establishment of county meridians, becomes apparent. The longitude has nothing at all to do with the meridian; and a difference of six miles in latitude makes no appreciable error in the meridian established as here suggested, whereas the statute requires the latitude within one half a second, which is fifty feet. There are some other things, besides the ways of Providence, which may be said to be "past finding out." It is not probable that a surveyor would err so much as three miles in his latitude; but should he do so, then the error in his meridian line, resulting from the mistake, will be five seconds, and a line one mile long, run on a course 5″ out of the way, will vary but an inch and a half from the true position. Surveyors well know that no such accuracy is attainable.

THE FUTURE OF THE BRITISH RACES.

IN an inaugural address at the Welsh National Eisteddfod, on Monday, Dr. Richardson observed that the races of men form the fractional surfaces by which, in natural collision, the knowledge and wisdom which make life worth having struck out. If one race, having the same tastes, desires, hopes, traditions, language, arts, literature, and aptitudes were to become the exclusive inhabitants of the planet, it would become a Babel, and fall, probably, a prey to the lower untamed forms of animal life. The speaker next described in detail the races which occupy this country—the Saxon, the Keltic, the Jewish, and the Gipsy. The vitality of these races formed the second portion of the address. The Saxon was described as the most powerful, physically, but not always so tenacious of life as the Kelt and the Jew. He suffered much from the constitutional disease called struma, or scrofula; from consumption, and from the mechanical shocks and strains incidental to his active physical life. The Kelt was more subject to affections of the emotional and nervous class. The Jew, though very liable to one fatal constitutional disease—cancer, was most of all tenacious of life, suffered less than others from contagious diseases, and from the danger of luxury, was the longest-lived of all, and that under privations and persecutions, which would at first sight seem actually destructive to any people. The Gipsy was formed naturally to live a long life, but in his nomadic state was subject to vicissitudes of climate, privation, and neglect, which often caused his early death. In the third part of his address Dr. Richardson dwelt on the question of the future of these great races, and concluded as follows:—"The three races, Saxon, Keltic, Semitic, in this day strive together, re-act on each other, and, on the whole, beneficially. The Saxon goes to the fringe of some new continent, carrying with him his other self, his lever, his mattock, spade, plough, axe, and other tool or engine. He cuts into the forest, he digs into the earth, he levels the roads, he builds rude houses, warm and comfortable enough for him if he be let alone; he sets up earthworks and forts; he plans docks, builds and mans ships, and does it all often out of what he finds on the spot, taking everything as if it were his own, and fighting the owner if the owner dares to interfere; crushing out all that comes in his way, yet not quarrelsome if he be allowed his own way. When he has made a rough holding he lets the Kelt join him on terms which he keeps the key of, and the Kelt, with light heart and elastic mind, beautifies the place, and makes it more human; builds the temple, the theatre, the mansion; lays out the garden; introduces the picture, the sculpture; improves and lightens the literature; lets in the light, the art, the beauty; in fact, furnishes the place and makes it happy. When Saxon and Kelt have in their ways thus installed the community in comfort and position, in glides the Jew with his money bags, and 'will you buy?' becomes the ring of the street and the market, so commerce completes the whole. The Jew does more than this· he brings music also, enterprise, and, until he feels his way, long-sufferance and stability. In these combinations the three races help each other. Will the partnership survive? The danger underlying the Saxon is physical power. The danger of the Jew is money; heaps of gold are the Goodwood Sands of the Jewish race. The Kelt is safer on these grounds. The Jew may amass wealth, may hold the capital; may dispense and equalise the capital; he is safe at that so long as he does not show his wealth, too feebly hidden, and does not attempt to dominate or put his hand into the works of the mighty Saxon engine. Let him expose his wealth, display himself on it, try to rule by it, and he is under that iron heel of Saxon power again as sure as ever he was before. This is his danger, and, as events elsewhere have shown, it is ever imminent. The danger to the Saxon is with himself of himself. Saxon and Saxon in conflict and other races oppressed by Saxon wrongs, waiting till they can be the dictators and masters of the sullen power, and he, making for himself domains and empires beyond his control, sinking under the burden, and not daring to retract or recede until the resistance is overwhelming. The danger of the Keltic race lies in irritability and sudden action without due forethought, under excitement or impulse. This controlled, the Kelt, under fostering influence of knowledge, is equal to any of his social peers. The hope of all advanced scholars must be that these conflicts may be avoided; that men may learn to know each other socially as well as individually; that they may understand the natural requirements of each race, and let those requirements have legitimate play; that while they do not assume to change the foundations of nature, in which they will most assuredly fail if they try, they learn of her how her courses may be so naturally diverted that they shall progress without injury to anyone; that, as the philosopher who defied not the lightning, nor attempted to stop it by his skill, gleaned from nature herself how to direct it at will, and by a mere line of wire to bring it harmlessly to the earth, its destination, so they, in dealing with vital forces, mental and physical, may let them all have their vent and reach their destinations, directed in their course in such a manner that not a chance of evil shall ensue; that they shall comprehend that the greatness of the world will be best realised when all races shall join to produce the greatness; that for this end all races have some peculiar gifts which will add to the whole; and that, as in the orchestra each one has a part, which, in itself perfectly distinct, combines with the rest to make up the harmonious result, so in the world that is to come, even on this planet, the harmony for which the whole creation yearns can be secured when every social part is brought by its best and wisest, and, according to its own conscience, holiest disposition, into communion and universal concord."

Coal in China.—According to a paper in the *Comptes Rendus* "On the Coal Basins of Tong-King," by M. Fuchs, the workable coal in this district, at not more than 330ft. below the sea level, is estimated to be over five million tons. There are four different species in distinct groups of beds.

SCRAPS of india rubber-coated fabrics have hitherto been useless because the rubber could not be profitably extracted. An American inventor finds that strong hot sulphuric or muriatic acid has no effect on the rubber, but a strong corrosive action on the textile fabrics, and he has taken out patents for a process of recovery in which he eats away the textile fabrics with these acids, preferring hydrochloric.

SCIENTIFIC NEWS.

THE *Eira* relief expedition has accomplished its work, and Mr. Leigh Smith's party are safely home again; but the results of his expedition are practically nil, as everything of value was lost in his yacht. Full details of the expedition have appeared in the daily papers.

A telegram from the Swedish Arctic expedition has been received in Stockholm viâ Tromsö, from which it appears that the party were unable to reach Mossel Bay, Spitzbergen, and had returned to the Norse Islands, where the observatory had been erected, and the party would winter.

At the meeting of the British Association Prof. Sollas, of the University College, Bristol, will describe a scheme for publishing a complete record of the scientific work of the year. Each nation will supply a record of its work, and receive in return a copy of the records of the other nations. The work properly carried out would be of great benefit to science; but there are obvious difficulties which even the British Association may not be able to overcome.

In the expectation of the British Association being invited to visit Canada either in 1883 or at some subsequent period, a private circular has been issued to the members of the General Council, requesting to know whether they could be present, and, if so, what year would suit their convenience most. Last year it was arranged that Oxford should be the place of meeting in 1883, but unforseen circumstances have arisen, which we believe will upset that arrangement, and it is thought that the opportunity will be a good one for visiting Canada, and probably meeting the American Association.

With the object of stimulating the students of King's College, London, to a high standard of proficiency in metallurgical science, Dr. Siemens has founded a medal (value 10 guineas) and a prize of 10 guineas (in books,) open to those who have, as matriculated students, studied in the applied science department for two years, and who, either in their third year, or, if they remain in the department for three years, in the succeeding year, make metallurgy a special study. The first award will be made at the end of June, 1883, and will depend partly on an essay on some particular subject, partly on a written examination on the metallurgical lectures, and partly on actual work done in the laboratory. The subject for the essay for 1883 will be the "Manufacture of Steel suitable for Ship and Boiler Plates." The essays are to be illustrated by free-hand sketches and mechanical drawings to scale, and must be sent in to Prof. Huntington on or before June 30 next year.

The "press" department of the telegraph office in St. Martin's-le-Grand was illuminated on Monday night by the Edison system, the wires being led from Holborn Viaduct to the building—a distance altogether of nearly 2,000ft. There are 59 incandescent-lamps in the department, which occupies the whole upper floor of the building, and gives accommodation to no fewer than 1,200 employés it is said. The gas had previously been alight for a time sufficiently long to render the atmosphere warm, and when the gas was extinguished and the electricity turned on, the effect was marked. A safety link of lead-wire at each lamp is employed to avoid risk of fire, but as it would melt on a given increase of current, the department might suddenly be deprived of light at a very busy time.

A consular report from Sweden gives a description of a new explosive called sebastine, or virite, which, it is said, has competed most favourably with dynamite. Sebastine appears to be an explosive based upon nitro-glycerine, but safer to handle than the ordinary dynamite, while more powerful in effect and cheaper to purchase. The greater safety of sebastine depends on two circumstances—first that the explosive oil is more completely absorbed and bound by a specially prepared kind of charcoal and other ingredients, and secondly that in ordinary cases it requires no percussion cap to explode.

Experiments were made the other day at the Wharncliffe Collieries with the new compressed lime cartridges employed for breaking down coal. The seam is undercut in the usual way, and then, near the roof, holes about three inches in diameter are bored, into which cartridges of highly caustic and compressed lime are inserted. The cartridges have a groove which admits a perforated iron tube through which water is forced; and when properly tamped the steam and the swelling of the lime when water is forced in brings down the coal in about half an hour. In the experiment made at the Parkgate Seam on Monday, about 10 tons of coal were brought down in an almost unbroken mass, while the percentage of small made in the operations was much less than in the more dangerous operation of blasting.

Zorgite, an ore from La Plata, is found to be very rich in selenium; it is a lead selenide containing 30 per cent. of selenium. M. P. Kienlen also states that the deposit found in Wolff's bottles used for the condensation of hydrochloric acid is rich in selenium. There is a considerable demand for that element, and with the increase the price has fallen considerably, many new sources of supply having been discovered.

The Sydney Technological, Industrial, and Sanitary Museum is progressing steadily, the Government of New South Wales being anxious that the colonists should be made acquainted with the improved apparatus and appliances for building and domestic purposes.

A pamphlet describing Binko's electric railway at the Crystal Palace has been issued by the International Electric Railway Company. The pamphlet contains an historical sketch of early roads, tramways, railways, and means of locomotion, by W. Grist.

An exhibition "projected for the purpose of bringing together a display of apparatus and products illustrative of the modes of working and esults attained in the various departments of Science and Industry," is announced to take place in the Public Buildings, Penzance, during the week embracing the 25th to 30th September. This time has been fixed in order that exhibitors at the Cornwall Polytechnic at Falmouth may have opportunity of sending their exhibits on to Penzance. The Falmouth Exhibition opens on the 5th and closes on the 16th September. The arrangements for the Penzance exhibitions are being carried out by an Executive Committee of thirty, including a Chairman and two Hon. Secs; there are also President and Vice-President. The Committee seeks the co-operation of inventors, manufacturers, skilled workers, amateurs, and private individuals, from whom objects for exhibition will be gladly received. "Examples, models, digrams, or descriptions of obsolete or disused machines or processes, possessing historic interest, will be eligible; but the committee more particularly desire a collection of the most approved modern appliances in use at the present time." Exhibits may be for sale if the owners so desire, the secretaries being authorised to receive things for that purpose. The profits, if any, will be devoted to the advancement of Penzance Science Classes. All communications should be addressed to the Hon. Secs., Exhibition Committee, Public Buildings, Penzance.

According to M. D'Arsonval, there is reason to believe that in the telephones with both poles utilised, the really active part of the wire is that between the poles, the rest being mere useless resistance. He has constructed a telephone accordingly; it is formed of a bar-magnet, bent round so as to bring the poles near each other; one polar end is a short cylinder having the coil round it, the other is of ring-shape, and encloses the coil. Both poles are in one plane, and they are brought very near the plate. The instrument, though very small and light, transmits the voice with remarkable distinctness and force. If a trumpet mouthpiece be added, one can hear easily in any part of a room.

There are now several buildings in Paris, in which one may read on all the floors, "Eau, gaz, telephone."

An instructive paper (largely illustrated), on the subject of dynamometers, by M. Richard, has been appearing in *La Lumière Electrique*. We may also note that in *Carl's Repertorium*, Dr. Hammerl deals in a comprehensive manner with the large variety of thermostats that have been constructed.

It has been observed by M. Slouginoff, of St. Petersburg, that just as by action of high temperature in a metal a liquid brought to the metal is repelled, so liquid is repelled from metal when a strong galvanic current passes through; in other words, both heat and electricity may throw a liquid into the spheroidal state; sometimes both act together. The electro-spheroidal state is accompanied by a weak, luminous phenomenon. Besides this electrolytic light-phenomenon, there is luminosity of another sort; and when it occurs at the cathode, particles of platinum are detached from this electrode. In the case of the light-phenomenon in a solution of platina-chloride in hydrochloric acid, and at the cathode, the intensity of the luminous effect depends on the heating of the powdered platina that is detached. (See *Carl's Rep.*)

With reference to a "small illusion," lately indicated by M. Plateau (a system of capillary siphons which, one might think, should give perpetual motion), M. Fougerat has recalled, in *La Nature*, a proposal with the same object made by the famous mathematician, Jean Bernouilli. A U tube with unequal arms has in its shorter arm a mixture of two liquids of different specific gravity, and at the lower part a filter letting only the lighter liquid through to the longer arm, which is filled with the latter, and is a little shorter than for equilibrium of the liquids. A small tube or trough connects the ends of the system, bringing the overflow of the larger arm into the shorter in a continuous manner. It would be interesting, M. Fougerat remarks, if some one were to make the experiment (though it would no doubt fail to give perpetual motion), and communicate the result.

Experiments have been recently made by Dr. Troitzky with a view to ascertain the influence of tobacco-smoking on temperature and pulse. He made some 600 observations on 25 persons grouped in three categories, according to constitution. The main result is, that tobacco-smoking has a stronger influence on the pulse than on the temperature. Taking all the classes of persons together, the mean temperature on smoking, as against non-smoking days, showed an increase in the ratio 1,008 : 1,000; while the ratio for the pulse was 1,180 : 1,000.

While malaria is an old acquaintance among Italian peoples, it appears from old texts that the Agro Romano was at one time comparatively healthy and populous. A professor of Velletri, S. Tucci, believes the cause to have been the system of deep drainage practised by the Romans. One finds in the district numerous conduits known as *cuniculi* (unwalled), having a height of 1·50m., and a mean width of 1·70m. Cuttings for roads have solved the problem of their origin and function. These *cuniculi* have a constant slope, which brings them sometimes 15 metres (50ft.) below the soil. S. Tucci is preparing a memoir in which he means to show (1) that this old system rendered the country very healthy, (2) that the surface-flow now existing is little better than stagnation of the waters, and (3) that the unhealthiness therewith connected is mainly due to the combined action of the water and the atmosphere on the tufa and pozzuolana at the surface of the ground. Encouraging results, it may here be mentioned, have been gained by the Trappist monks of the monastery of Tre Fontane (a short distance out of Rome, on the way to Ostia), in reclamation of marsh land and improvement of a very unhealthy climate by planting of eucalyptus trees, which are known to be efficient agents of sanitation, and by drainage. This work has been engaged in by contingents of the monks that were recently expelled from France.

A dry galvanic element recently patented in Germany by Herr Scrivener consists of three parts: a plate of compressed carbon or graphite, a carefully amalgamated zinc plate, and a depolarising plate applied to the carbon plate, this latter being the essential part, and made from a mass consisting of 10 parts by weight of ammonium-mercury-chloride, 3 of chloride of sodium, and ¼ of chloride of silver. To this mixture is added a weak acid solution of zinc chloride (of 50°) till it forms a consistent paste, with which the previously-paraffined carbon plate is then coated, in a comparatively thick layer. The layer is covered with five or six layers of Swedish filter-paper saturated with a solution of equal parts of chloride of zinc and and sulphide of sodium. By connection of this plate with the zinc plate, a constant element of about 1·3 volt difference of potential is formed. In the case of house telegraphs, the element is placed directly behind the knob to be pressed.

The following (according to *La Nature*) is the way in which those glass plates are prepared, which show an image, or writing, only when breathed upon. The piece of glass should be of the kind used for mirrors, and may be either transparent or silvered, and a little powdered fluor-spar is put in a porcelain capsule and moistened with ordinary sulphuric acid, to an extent which will allow of using it to write with, by means of a quill pen, on the carefully-cleaned glass. The drawing, or writing, is then traced, and allowed to stand five or ten minutes. Then the plate is washed with ordinary water, and dried with a cloth, after which it is ready for use.

Doubts have been raised within recent years, by M. Heckel and others, as to the *rôle* of insects in cross fertilisation of flowers: they have been based especially on the supposed absence, or, at least, great rarity of these auxiliary animals on the flowery summits of high mountains. The results of four years observations at Grenoble, by M. Masset, in a region with all altitudes from 200m. to 3,000m., and amidst an herbaceous flora the richest in the world, are here instructive. He finds (1), that all orders of insects have representatives up to 2,300m.; (2), that beyond 2,300m. lepidoptera, diptera, and certain hymenoptera preponderate in number; (3), that the number of genera, species, and individuals of nectar-loving insects is proportional to that of the flowers, sometimes incalculable; (4), that the hours of sleep and waking of flowers, and those of insects, are synchronous; (5), that the apparent number of nectar-loving insects is in relation with the number of their favourite flowers, and the state of the atmosphere and sky. M. Masset concludes that, as flowers and insects are never simultaneously and mutually wanting, the objection referred to against cross-fertilisation loses weight.

The "Sherwood Forester" Tricycle.—The "Sherwood Forester" made by Messrs. Kirkham and Mallatratt, of the Wellbeck Works, Mansfield, is a rear steering, open fronted tricycle, with the framework of the pattern of the "hay-fork" style. The "Sherwood Forester" is driven by the rotary action, same as a bicycle, and has two equal size driving wheels of 42in. to 50in. diameter, and a 20in. steering wheel. The wheels run on two independent steel axles, and the whole power of the rider is transmitted direct from the cranks to the driving wheels by means of an improved and patented endless chain. A special feature of the "Sherwood Forester" Tricycle is the makers' new patented automatic double driving clutch fixed in the chain wheels on each end of the crank axle. The patent double driving clutch is entirely self-acting, and instantaneous, and no obstacles, irregularities of road, or ground resistance will relieve it, whilst it instantly relieves itself on taking pressure off the treadles, and in turning circles of any size. By the use of this patent double driving clutch the pedals instantly form foot rests by simply ceasing to move the cranks, and allowing the two driving wheels to run on of themselves. It will be thus seen that no power of the rider is wasted; as when the going is easy, the machine may be propelled by intermittent strokes, and the pedals between the strokes form most comfortable foot rests. A new pattern double band brake fitted and applied in the most complete manner entirely removes all objections to brakes acting on the hubs. It can be adjusted perfectly, and by the simple motion of one hand-lever, a powerful brake is applied in the same instant on each driving wheel.

Black Ink.—Peltz in *Pharm. Zeitschr. f. Russl.*, recommends the following for making a good ink:

	Parts.
Extract of logwood	100
Lime-water	800
Carbolic acid	3
Common hydrochloric acid	25
Distilled water	600
Gum arabic	30
Bichromate of potassium	3
Distilled water enough to make	1800

Dissolve the extract in the lime-water, in a porcelain or well-enamelled iron vessel, over a steam-bath, with frequent stirring. Add the carbolic and hydrochloric acids, which change the solution from a red to a brownish yellow colour. After half an hour's heating over the steam-bath, set the mixture aside until cold, then strain or filter. Now add the bichromate of potassium and the gum, each separately dissolved in a considerable quantity of distilled water, and finally add enough water to make 1800 parts. This ink is a fine red colour which quickly turns black. It does not corrode steel pens, and, if it dries up, needs only the addition of water.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

BROMPTON AND THE PATENT OFFICE—RAILWAY SIGNALLING—ACKNOWLEDGMENT OF QUOTATIONS—THE LATE PROFESSOR JEVONS—TELESCOPIC APERTURE AND SEPARATING POWER—TABLES OF SPECTRA—STEINHEIL'S ACHROMATIC EYEPIECES.

[20405.]—Readers of the Parliamentary Reports will have noted how, on the evening of the 10th instant, Mr. Hinde Palmer put a question in the House with reference to the Patent Museum. That the present building is crowded to an extent which renders the examination of any special portion of its contents inconvenient in the highest degree is too notorious to need any insisting on here; and the honourable Member for Lincoln not unnaturally urged that the time had at last arrived for the redemption of a promise made by Sir Austen Layard (when, years ago, as Mr. Layard, he was First Commissioner of Works) that a suitable building should be erected for the reception of a collection of such incalculable value. Mr. Palmer went on to suggest that the large quantity of waste and unused land in the neighbourhood of the Northumberland-avenue might be utilised to provide a most accessible site, and an amply commodious building for this purpose. It would seem, however, that Mr. Chamberlain has been "got at," as well as Mr. Mundella, by the Brompton Ring, for, in his reply to Mr. Palmer, the President of the Board of Trade is reported to have said that "it had been suggested that the exhibition could be best arranged if it were transferred to the Science and Art Department." Of course! To transfer the Patent Museum to the horde of leeches at South Kensington means the creation of Directorships, Curatorships, Registrarships, Keeperships, Cleaner and Deputy-Cleanerships *et id genus omne*, and other devices for adding to the offices of the clique of pluralists there, and further plundering the public in a genteel way. My admiration for Mr. Chamberlain scarcely assumes the form of idolatry; but he has always enjoyed the credit of having a very determined will of his own. Mr. Mundella, unhappily, is a mere tool in the hands of the wire-pullers at Brompton, who manipulate his strings and use him as a mere puppet. I did hope, though, that the President of the Board of Trade was not quite so easily to be imposed upon; albeit his answer on which I am commenting suggests to me the line in Phœdrus (I think it was Phœdrus) which I used to construe as a small boy: "Delusa ne spes ad querelam recidat."

Mr. Stooke (letter 20367, p. 523) must forgive me if I demur to his description of my comment on his system of signalling as "hypercriticism." Reverting to his original letter (20267, p. 427), I find that *Clear* is signified by "Arm-in-arm position between 45° and 85°," and that "From 5° to 45° is to be treated as a 'Doubtful signal,' and worked on as 'Danger.'" Now my contention was—and is—that an angle of 44° (*Danger*) sufficiently resembles one of 46° (*Clear*) as seen from a distance, on a rapidly moving engine, to render discrimination between them, in the last degree doubtful; and I can quite conceive the effect of a driver reading an angle of 44° as 46° or 47°, and so crashing merrily into the rear of a train ahead of him.

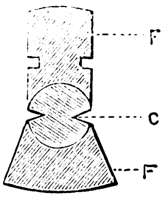
"S. G." (reply 47468, p. 529) repeats, verbatim et literatim, the answer given to the same query on p. 506, with this very important difference: that whereas "J. R. H." (in whose initials I seem to recognise those of a very eminent astronomer) tells us that he quotes from *Nature*, "S. G." leaves it to be inferred that his reply is original. For myself, I regard it as a breach of literary etiquette to extract a whole passage from any work, without the slightest acknowledgment of its origin. Very different indeed is the succeeding reply on the same page, which is so obviously the outcome of personal experience.

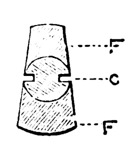
Having, on more than one occasion, expressed a very definite opinion indeed on the monomaniacal craze of the late Professor Jevons concerning sun-spots and commercial panics, I am the more anxious to give utterance to the sincere regret with which I (in common, I imagine, with all scientific men) have learned of the very great loss that English thought has sustained in his lamentable death. Mr. Jevons was, in no legitimate sense, a physicist. As, in the case of his greater predecessor, Bacon, his contributions to the establishment of a sound scientific method were of great and enduring value; although, like those of Lord Verulam, his attempts to apply such method to concrete investigations in physical science were failures. Of this no better illustration could be found than the notorious one of which I have spoken above. As a logician, however, he will leave a gap which it will be very hard to fill. He was an original and independent thinker, and his works on logic and political economy are among the most useful to the student of any extant. I can say sincerely that there are few books in my own library that I have read with more pleasure and profit than those of the great thinker whose loss will be so widely mourned.

If Mr. Gardiner (letter 20382, p. 516) will consult Airy's treatise "On the Undulatory Theory of Optics," he will find it demonstrated that if e be the radius of the aperture of a telescope in inches, the extreme diameter of a star disc in seconds to the first black ring $= 2{\cdot}76$ divided by e. That I may be mistaken in my own estimate of the present distance of the components of ζ Herculis is possible; but that a well determined law of nature suffers an absolute change in four or five hours of longitude certainly does tax my powers of belief very seriously indeed. Perhaps I may add that Dallmeyer's formula gives 1·08″ as the separating limit of a 4in. object-glass, and 0·962″ as that of a 4·5in. objective.

The book that "T. S. H." (query 47710, p. 557) requires is "An Index of Spectra, by W. M. Watts, D.Sc., with preface by Prof. Roscoe, F.R.S., with eight lithographic plates, and a chromo-lithograph, price 7s. 6d.

"Zeta" (query 47420, p. 436), asked for a diagram of the new achromatic eyepieces constructed by Steinheil. "O. V." described them in the next number, but without giving any illustration. I have, therefore, copied the accompanying diagrams from the current number of the *Journal of the Royal Microscopical Society*, in hope that they may supply "Zeta's" want. They represent two of these eyepieces (as constructed for the telescope), of $\frac{3}{4}$in. and $\frac{1}{3}$in. focus respectively. C is the crown-glass convex lens; F and F the flint-glass menisci. The grooves cut in the edges of the lenses are filled in with black cement to form diaphragms, as in the Coddington lens. The definition is stated to be exceptionally sharp and brilliant.





A Fellow of the Royal Astronomical Society.

OBSERVING-WEATHER IN NORTHUMBERLAND—ζ HERCULIS—σ CORONÆ, A. B—λ OPHIUCHI—μ DRACONIS—Σ 2215—μ^2 HERCULIS—τ OPHIUCHI—70 OPHIUCHI—73 OPHIUCHI—ε^1 AND ε^2 LYRÆ.

[20406.]—Since my last letter (Vol. XXXV., No. 900, letter 20181), the weather here for observational purposes has been of the most wretched description, there not having been one night in which the finest work could be done. It seems to me that there is little to choose between the heat of summer and the cold of winter. The atmosphere is nearly always in a state of great disturbance, the stars, when viewed through a telescope, twist and twirl, flutter and jump, wriggle and writhe, as if they had a very particular objection to being measured, and strongly resented the impertinence of terrestrial mortals in prying into their secrets. I hardly ever find them in such good humour that they will stand still to be looked at, and consequently the materials at hand for contributing to your columns information as to the doings of close and difficult binaries are somewhat scanty. However, such as they are, I will give them, hoping still for that "good time" which is always "coming."

ζ Herculis, R.A., 16·36, Mags. 3, 6·5.

My latest measures of this rapid binary are as follows:—

P = 106°·0	D = 1″·2	Ep. 1882·49
P = 101·5	D = 1·32	·55
P = 103·5	D = 1·44	·57

σ Coronæ. R.A. 16·10. Mags. A, 5; B, 6·1.

Chambers tells us that "several computers have investigated the orbit of σ Coronæ, but the results are very discordant. Whilst Jacob found a period of only 195 years, Doberck, in 1875, fixed it at 843 years. The other results are all intermediate between these." The following measures will serve for comparison:—

		°	″	
Herschel$_2$ and South	AB, P =	71·5	D = 1·44	Ep. 1822·83
Smyth	AB, P =	107 6	D = 1·3	,, 1830 76
Dawes	AB, P =	147 8	D = 1·65	,, 1840·57
Mädler	AB, P =	173·0	D = 2·23	,, 1850·70
O Σ	AB, P =	186 8	D = 2·72	,, 1860·74
Dembowski	AB, P =	196·9	D = 3·09	,, 1870 43
Perry	AB, P =	206·8	D = 3·5	,, 1882·54

λ Ophiuchi. R.A. 16·25. Mags. 4, 6·1.

Smyth says that this object is very beautiful and close, and that the measures are attended with great difficulty, except when, as H_1 expresses it, "the star will be quiet." Chambers remarks that "Mädler found the period to be 88 years, and Hind made it 95 years; but Doberck has arrived at a much higher value—viz., 233 years, and there can be no doubt that this is much nearer the mark." H_1 says that it "requires a most excellent telescope to see it well."

The following are some of the measures:—

Σ W.	P = 331°·8	D = 0″·84	Ep. 1825 51
Smyth	P = 351·2	D = 1·0	,, 1834·48
Dawes	P = 358·3	D = 1·07	,, 1840·54
Mädler	P = 12 9	D = 1·05	,, 1850·58
Σ O	P = 18·6	D = 1·35	,, 1861·63
Dembowski	P = 28·6	D = 1·51	,, 1870·45
Doberck	P = 33·5	D = 1·59	,, 1878·47
β	P = 37·7	D = 1·45	,, 1880·46
Perry	P = 37·6	D = 1·34	,, 1882 52

μ Draconis. R.A. 17·2. Mags. 5, 5·1.

A slowly moving binary, with a period said to be about 600 years, and considered by Herschel$_2$ to be a miniature of Castor.

Herschel$_1$	P = 232°·4	D = 4″·35	Ep. 1781·73
Σ	P = 205·1	D = 3·23	,, 1832·22
O Σ	P = 191·1	D = 2·82	,, 1851·74
Doberck	P = 171·0	D = 2·49	,, 1877·64
Perry	P = 165·0	D = 2·20	,, 1882·53

Σ 2215. R.A. 17·40. Mags. 5·9, 7·9.

Gledhill says that the change in angle is uncertain.

	°	″	
Σ	P = 310·6	D = 0·74	Ep. 1831·53
Dembowski	P = 304·6	D = 0·67	,, 1855·92
Spörer	P = 300·7	D = 0·70	,, 1875 54
Perry	P = 294·0	D = 0·93	,, 1882·57

μ^2 Herculis. R.A. 17·41. Mags. 9·5, 10·5.

This very rapid and interesting binary was discovered in 1856 by Alvan Clark. "In 1860," says O Σ, quoted by Gledhill, "the measures of this star presented no difficulty; but in 1873 its separation could not be effected on any but the finest nights." "Doberck," says Chambers, "finds a period of 54·2 years." The following are some of the measures:—

	°	″	
Dawes	P = 59·2	D = 1·81	Ep. 1857·50
O Σ	P = 93·7	D = 0·88	,, 1868·50
O Σ	P = 185·5	D = 0·63	,, 1873·50
β	P = 245·9	D = 0·96	,, 1880 47
Perry	P = 259·1	D = 0 79	,, 1882 58

τ Ophiuchi. R.A. 17·56. Mags. 5, 5·7.

H_1 April 28th, 1783, found it to be "the closest of all his double stars." In 1825 and 1827 Σ could not see the companion. In 1835, however, with a power of 1000, and in moments of best definition, he saw the stars separated. Hind finds the period about 120 years, and Doberck about 217 years. I find this star an easy object now.

O Σ	P = 223°·1	D = 0″·94	Ep. 1840 51
Secchi	P = 245·8	D = 1·30	,, 1860·77
Dembowski	P = 247·8	D = 1·42	,, 1870 50
Jedrzejewicz	P = 252·2	D = 1·89	,, 1880·67
Perry	P = 252·2	D = 1·34	,, 1882·52

70 *Ophiuchi*. R.A. 17·59. Mags. 4·1, 6·1

Dawes says that this is, "One of the most interesting and beautiful of the binary systems;" and there is a very fair agreement amongst computers as to its period, which seems to be somewhere between 73 and 88 years. Sir John Herschel noted that the rings round the telescopic image of this star "seem to have something peculiar about them; they are thin, and extend further than in general."

We have the following measures:—

Σ	P = 168°·4	D = 4″ 66	Ep. 1819·63
Dawes	P = 124·8	D = 6·62	,, 1840·59
Auwers	P = 107 9	D = 6·49	,, 1860·74
Doberck	P = 75·4	D = 3 03	,, 1878·54
Jedrzejewicz	P = 62 8	D = 2·74	,, 1880·65
Perry	P = 51·3	D = 2·58	,, 1882·56

73 *Ophiuchi*, R.A., 18 3. Mag. 5·7, 7·2.

The binary character of this close double star seems to be not yet fully determined, although, as Chambers points out, there is evidently a diminution in both angle and distance, as the following measures will show:—

Σ	P = 259°·7	D = 1″·54	Ep. 1831·05
Mädler	P = 252 8	D = 1·17	,, 1861·89
Doberck	P = 250 0	D = 1·03	,, 1876 61
Perry	P = 247 0	D = 1·03	,, 1882·61

ε^1 Lyræ. R.A. 18·40. Mags. 4·6, 6·3.

This, with the following pair, form the celebrated "double-double," the separation of which with the naked eye, is a remarkable and somewhat unusual feat. Webb, in his charming and most useful "Celestial Objects," says there is "little doubt of the rotation of each pair; ε^1 perhaps in about 2,000 years, ε^2 in half that time; and possibly both pairs round their common centre of gravity is something less than a million years." We have the following measures:—

Herschel$_1$	P = 33°·9	D = 3″·44	Ep. 1779·83
O Σ	P = 22·5	D = 3·52	,, 1840·74
Doberck	P = 16·3	D = 3·04	,, 1878·56
Perry	P = 17 0	D = 3·62	,, 1882·60

ε^2 Lyræ. R.A. 18·40. Mags. 4·9, 5·2.

Herschel$_1$	P = 173°·5	D = 3″·50	Ep. 1779·83
O Σ	P = 151·1	D = 2·73	,, 1840 83
Doberck	P = 139·1	D = 2·24	,, 1878·56
Perry	P = 131·5	D = 2·69	,, 1882·60

I shall be very happy to look up the stars mentioned by your valued correspondent, Mr. Herbert Sadler, when an opportunity occurs of dealing with them successfully.

The above measures were made with the 18¼in. Calver reflector.

Jevon J. Muschamp Perry.

St. Paul's Vicarage Observatory, Alnwick.

MARKINGS ON JUPITER.

[20407.]—Another observation of the red spot on Jupiter was obtained on August 19th, the *p.* end being on the C. M. at 16h. 20m., and the centre at 16h. 47m. The spot was very well defined, with power 186 on my 5¼in. Calver, and but little fainter than last year. A delicate streak extended from the *p.* end for some distance south preceding; but otherwise it appeared perfectly regular. In letter 20380, p. 546, Mr. W. F. Denning both delineates and refers to the narrow streak seen following the red spot last year as being continuous now with the south equatorial belt; but on August 19th, it was just possible, though with very great difficulty, to separate this streak. It has, however, increased immensely in size and prominence. On the same night, a spot was seen similar to the new one, figured on p. 546, in the northern hemisphere, and in the same position. It was much shorter than this spot, not being much more than half as long as the red spot. It was noted on the centre at 13h. 55m.

The south equatorial dark belt is now in an extremely interesting condition, numerous dark patches and spots being visible. One of these, of unusual size and darkness, and very well defined, was observed on the C. M. as under:—

August 19th	....	14h. 28m., *p.* end.
,,	....	14h. 43m., centre.
,,	....	14h. 58·5m., *f.* end.

A fainter spot of the same kind was visible a little *p.* the *p.* end of the red spot. It projected a little way south of the belt, and formed, with the dark streak following, a shallow bay, which conformed to the curve of the north edge of the red spot. This patch was noted central at 15h. 55m.

A. Stanley Williams.

Brighton, August 19.

P.S.—In letter 20360, p. 520, I stated that the white equatorial spot was on the centre on August 5th at 15h. 35m. This observation, however, really refers to another spot, very similar in appearance, a little following.—A. S. W.

ζ HERCULIS—4·56in. / APERTURE.

[20408.]—In justice to myself allow me to say that I did not supply the eyepieces Mr. Gardiner, of Newburgh, N.Y., refers to in letter 20382. Had I been allowed to do so, my own eyepieces would have done every justice to a really fine object-glass.

W. Wray.

Laurel House, North-hill, Highgate, Aug. 18.

HOW TO MAKE A FLAT FOR A NEWTONIAN REFLECTOR.

[20409.]—As by some mistake on my part or the printer's, the sketches did not appear in letter 20370, I have sent others. I also wish to correct another error of my own or the printer's, occuring in the 12th line from top, of letter 20370. This should read, "For if the discs are slipped (or slid) together, there is a chance of scratching." The dotted lines in Fig. 1. show the sections of major axis when edged. As this will conclude my letters on this subject, I will here say that I shall be glad to answer any questions concerning the matter that may crop up.

FIG. 1.

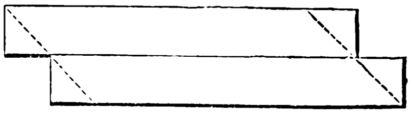


FIG. 2.

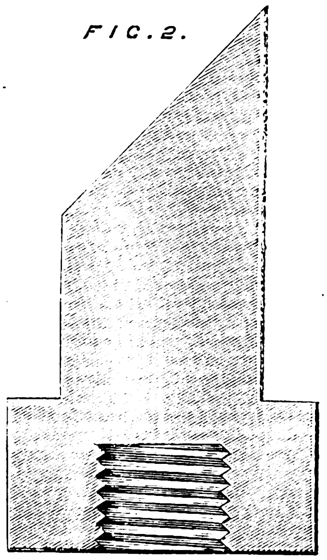

Prismatique.

FOCAL IMAGES, CASSEGRAIN TELESCOPES, &c.—TO "F.R.A.S.," "ORDERIC VITAL," "W. G. P."

[20410.]—May I ask "F.R.A.S." to kindly turn to his letter of May 19th last, in which he gave me what I had not before seen—a rule for the diameter of star disc, and supplement the rule by informing me what is the lowest power per inch of object-glass that is necessary to raise a disc on a star. "Old Kitchener" refers to the point, but his remarks are not very accordant *inter se*. The answer which "F.R.A.S." favoured me with was not really a reply to my original query (addressed to "Orderic Vital," and by him referred to "F.R.A.S."), and as, so far, no reply has appeared, I venture to re-state the question, or rather questions.

The first is this: With a given lens of known focus (and aperture?) what will be the diameter of the light-spot as received on a card at the focus of such lens. As regards the insertion of "aperture" in the query, a letter of mine on p. 156, April 21st, will explain why I do so.

The other question refers to the effect on the rays of light of the length of focus in a lens or mirror.

Let there be two lenses of the same diameter, but one of them having twice the focal length of the other, and let them be so placed that their foci are on the two sides of a photometer screen, what will be the proportionate illumination of one to the other when thus measured? For the Cassegrain telescope, I will (in order to save engraving a fresh block), ask your correspondents above referred to to insert in the diagram on page 217, May 12th, a small x between E and F, and a large X behind the concave mirror to the left of D, both letters referring to points on the axial line D H. Then let the bent line, D C E, turn about the point C till C E passes through x, then we may assume that C D produced will pass through X. This gives a geometrical method of finding what alteration in the focus of the small mirror will throw back the point D at vertex of large mirror to any given point X behind it, since x and X will be the conjugate foci of the new mirror, just as E and D are the conjugate foci of the original one, and F x will be the required focus. In this case the distance apart of the mirrors remains unaltered, but I do not quite see how to throw back D to X by any rule which allows the distance apart to be varied, but retains the same focus for the mirrors. Can a *rule* be given for this, which is the *practical* state of the case, the point D being always in reality considerably behind the vertex of the large mirror. Also for the Gregorian. Lens.

TESTING MIRRORS, &c.

[20411.] It appears from our private correspondence that the method of zone-testing occurred independently to both Mr. Wassell and myself, and I need hardly therefore say that I have been reading up the back numbers since my return with special interest in Mr. W.'s articles. I would now like to explain that I fancy some such method was used by Short, and for this reason. I have an old Gregorian made by him, in which the sliding block, which carries the small mirror, is graduated to serve as the vernier of a fixed scale attached to the body-tube, the graduation being such as to read to 1-200 (one two-hundredth) of an inch. It is the only instance which I have seen, or heard of, in which such an attachment occurs. Unfortunately, the mirror has been rendered practically useless by amateur attempts at refiguring it, or it would have been interesting to subject it to careful testing. There is one point in connection with this question, zone-testing, which I hope Mr. Wassall will not omit to notice, as I think it is not an uncommon difficulty in obtaining a good figure. In all the descriptions or sketches of the "rings" and "mounts," these are shown as symmetrical and concentric, but in certain cases a kind of "lop-sidedness" (if I may use such a term) seems to occur; in fact, the axis of the mirror is not at its centre, and is also out of square with the chord of the curve. If such a curve were accurate and producible at pleasure, I presume it would be exactly suitable for a Herschelian telescope; but as it is practically neither one thing nor the other it can only be looked on as a very bad Newtonian mirror.

In running over the different letters I see some correspondence has taken place about eyepieces, but I have not noticed any reference to the fact (?) that the Huyghenian is in one respect less fitted for reflectors. There is in this form of eyepiece, with the lenses proportioned as usual, a power of correcting to a certain degree, the spherical and chromatic aberrations of an object-glass or microscope objective, but since with the reflector the image is colourless, what is in other respects an advantage must become a defect. What says our friend, "O. V."?

A. S. L.

FAURE'S ACCUMULATORS.

[20412.]—If "Caloric" (p. 549) had looked on the opposite page to that from which he quotes the statement about 24 Swan lamps being worked by 24 Faure accumulators, he would have found a wise Frenchman saying, "I would have everyone write what he knows, and as much as he knows, and no more," and a further perusal might have induced him to cross out that passage from his letter in which he says, "It is a pity that people write about what they know little about, causing such absurd and misleading statements to be made." That is a dreadfully stale platitude, but it looks simply awful in "Caloric's" letter, which is as beautiful a specimen of the genus mare's-nest as has been recently seen. "Caloric" has actually been to the office of the Faure Accumulator Company, and learnt from the obliging attendant that one Swan lamp requires four accumulators, and thereupon he jumps to the conclusion that your correspondent "E.," who has contributed some really valuable notes on dynamos, "knows nothing about it." Go to, "Caloric"; return to the obliging attendant, and ask him what sort of a Swan lamp he meant that requires only four accumulators to work it. Then let him refer to Mr. Swan's Royal Institution lecture, and read, "When I pass through the filament one unit of current, light equal to two candles is produced. If now I increase the current by one-half, making it one unit and a half, the limit is increased to thirty candles." Having digested that, "Caloric" may multiply 24 accumulators by two volts, and he will find the E.M.F. comes out as 48 volts, and as the E.M.F. required for a Swan lamp is 45 volts, he will find that the French watchmaker knows just as much and no more than the correspondent "Caloric" has criticised, without knowing anything about it. Presumably, "Caloric" is the same gentleman who, on p. 556, has carefully examined the "Lampe Soleil," and has arrived at the conclusion that "it is not approached by any other form of arc light." Verily "It is a pity that people write about what they know [nothing] about." What amount of energy is expended over that solitary Lampe-Soleil, which has produced so valuable a testimonial from so high an authority? Does "Caloric" know, and has he ever seen more than one Lampe-Soleil in his life? Finally, why does he not study his English Mechanic, and learn what E.M.F. really means? **Calorimeter.**

[20413.]—"Caloric" (letter 20394) gives three statements, gathered from different sources, which appear to him contradictory. As a matter of fact all three are true. A 16-candle Swan lamp has a resistance of about 40 ohms! and since we require over 1 ampère current, the minimum number of Faure cells is about 24 or 26. If this number of cells be obtained, provided they are large and thus do not offer any great resistance, we may light 24 or even more lamps with the same number. As to the statement of the Faure Co. attendant, he no doubt referred to a small 2 or 5-candle lamp. The small 2-candle Swan can be worked with 2 or 3 Faure cells, so that 4 would do it well.

"Caloric" would do well to inquire more closely into facts before stating that "E." "knows nothing about it." **Ll.B.A.**

[20414.]—With reference to my remarks on the above in "Notes on Dynamo-Machines," "Caloric" has ventured to express an opinion that I am ignorant of the subject, and his conclusion is based on two facts. 1st. A watchmaker in Paris lights his shop with 24 Swan lamps worked with 24 accumulators. 2nd. On page 523, I write: "The E.M.F. of a Faure accumulator is 2 volts, and the E.M.F. required for a Swan lamp is 45 volts." I have observed sundry good-natured criticisms of my Notes from time to time, and have taken no notice; but there is a limit to human endurance, and that limit is reached when one sees a man strutting through the columns of a scientific journal evidently under the impression that he is writing jokes for a weekly comic. I say emphatically that a Swan lamp of the ordinary construction will not give 20 candles with an E.M.F. of 45 volts. I have also to remark that I did not fit up the lamp in the watchmaker's shop at Paris; it is consequently not my business if he does not work his lamps up to their full power. It is easy to calculate the E.M.F. at the terminals of his lamps. E.M.F. of each accumulator 2 volts; resistance ·01ohm; number of accumulators 24. Resistance of each lamp 33·6 ohms; number of lamps, 24. If V = E.M.F. at terminals of lamps, then

$$\frac{2 \times 24}{V} = \frac{\frac{33{\cdot}6}{24} + {\cdot}01 \times 24}{\frac{33{\cdot}6}{24}}$$

$$1{\cdot}4\,V + {\cdot}24\,V = 67{\cdot}2$$

$$1{\cdot}64\,V = 67{\cdot}2$$

$$V = \frac{67{\cdot}2}{1{\cdot}64} = 41 \text{ volts nearly.}$$

Does "Caloric" suppose that reducing the E.M.F. at the terminals of the lamp causes it to strike on the spot and refuse to give a light, or is he aware that decreased E.M.F. simply means diminished light? The obliging attendant to whom "Caloric" refers certainly did not mean a Swan lamp, as understood in the ordinary sense by electrical engineers. The Swan lamp is a well-known standard lamp employed to give an illuminating power of 16 to 20 candles, and if "Caloric" will read over the paragraph of mine with which he finds fault, he will see that I specially mention lamps lately constructed of small candle-power to light with six volts—i.e., three accumulators. The attendant evidently had one of these in his mind. I have no intention to be hard on a critic whose knowledge is of schoolboy order. It is really very kind of "Caloric" to furbish up a newspaper report, and interview the attendant at Faure's for the purpose of administering an antidote to readers of the "E.M." who may have been unfortunate enough to come under the baneful influence of my pernicious writing; but attendants are not *generally* considered scientific authorities, and newspaper reports are not *wholly* reliable. It may be true that four accumulators will light a small Swan lamp, although not the ordinary Swan lamp; it may be a truthful report about the Paris watchmaker; it is certainly a fact that a 20-candle Swan lamp requires at the least 45 volts, while it is abundantly manifest and beyond the shadow of a doubt that "Caloric" is profoundly ignorant of the very foundation of the subject, and glad to pin his faith to Faure's attendant or anything else. Had "Caloric" asked civilly for the explanation of a seeming paradox, one might have been disposed to clear away the mists for him; but that *he*, knowing nothing whatever of the matter—as shown by his letter—should step to the front with all the dignity of a savant, and tell another correspondent that he knows nothing of what he is writing, only shows that his ignorance is equalled by his unapproachable presumption. Alas! fools rush in where angels fear to tread. **E.**

SMALL DYNAMOS.

[20415.]—Will you permit me to join with Mr. Lancaster in warning amateurs and others from laying out money in small dynamos, persuaded by the extremely low price charged? There is no commercially valid reason why a maker of a really good machine should be satisfied with the cost of the materials used, and charge nothing for designing, mounting, &c. A few years ago a series of articles appeared in these columns, written with great authority, giving amateurs advice and instructions how to build small dynamos. I do not know whether any were ever built; but the writer simultaneously advertised that he made dynamos for industrial purposes. I was foolish enough to order and pay for one—£25 was the cost; but in repairs, fares for sending to and from Scotland, telegrams, &c., it stands in between £30 and £40. It never did any work, is a monster in ugliness, and a paragon of bad finish. It will not realise £5, if I was going to sell it. Such was my experience of cheap dynamos; let others take warning.

I built a machine myself, partly according to the instructions published, partly after own observations. It never did so much work as any other dynamo with the same weight of iron and copper wire. But it did afford me great instruction, and as a commercial concern has earned its cost ten times over, and will turn out many hundred pounds' worth of good work. For general work I have bought one of Elmore's splendid machines, which is all any man can desire.

As I have built a dynamo which does, and has done, useful work for more than nine months, I think I am right in saying that small laboratory machines can be made—in fact, both Weston and Elmore make such—but I should think magneto machines would be the handiest where power is not available. A machine for supplying one small arc or a few incandescent lamps need not be either large or expensive, and with the excellent opportunity we had in the Crystal Palace of examining machines, combined with the articles in *Engineering* and elsewhere, I think that any amateur with some knowledge of electricity might construct a machine that will suit him. Any one who does not knows the laws of electricity I would strongly advise to master these first before building a dynamo. **Anglo-Dane.**

[20416.]—To show that I believe I can satisfy all as to the strict veracity of my statements, I will notice a few of Mr. Lancaster's otherwise welcome criticisms on my letter. First, then, he is informed that the speed (in my note) for four to six ten-candle lamps was 2,000 revolutions per minute, not 1,700, and this was done by *one* man for a little over that space of time. It is not to be supposed that a man could exert all his strength like this for many minutes, but he could certainly do so for this short time. But what is the question at issue? What I spoke of was a small dynamo, and not by any means limiting it to the power of one man: especially when trying, as I did, to get the best possible results out of the machine. I think if it took half-horse power to work it, the results obtained are very favourable. The quarter-horse that I judged was put into the machine was when it was going at the rate of 4,000 revolutions per minute. The engine I worked it by was very powerful, and it was extremely hard to tell the exact amount of power used. However, I have nearly got a half-horse power engine finished, and I expect this will drive my machine very easily.

I cannot understand how a quarter horse-power is four times that of a man, for I have always been under the impression that one horse-power was equal to eight men. This is what some gas-engine makers take, and what I intended our readers to understand. Then the case stands thus:—One man (for short time) five ten-candle power lights at 2,000 revs., $\frac{1}{4}$ horse-power (two men) four five-candle power, two ten-candle power, and six twenty-candle power (half-lighted) at 4,000 revs.

I need scarcely add that it was straining the machine to run it at 4,000 revolutions, but I did so to *get all I could out of it*. For continuous running, of course, these results would be lessened 30 or 40 per cent., but for short experiments all I have said could be got out of the machine.

I think it would have been far better for me to have waited until I could give in proper language the power of the machine; but I really could not let such an attack on my veracity go by unnoticed.

To show that I feel certain my results are as near as possible correct, I make the offer to Mr. Lancaster, as I have already to another gentleman, to give him every facility in my power for testing the machine, and I shall be glad for him to report on it himself.

I must add, before closing, the best results when driving by hand-power were obtained by separately exciting the field-magnets with a bichromate cell, but when using steam I did not use that.

I must add, too, that I am in no way connected with the makers of this machine; but I am with a company supplying largely Swan lamps, so that I know their power when I see it.

I am sorry I cannot give my own name, but solely on business grounds I must again subscribe myself **Tried.**

SMALL DYNAMOS.

[20417.]—As Mr. Lancaster (20403) has taken upon himself to say that "Tried" (29394) states "what must be absolutely false," I feel it my duty to corroborate "Tried's" statements. I presume that the machine "Tried" referred to is Mr. Patrick's; if so, I may state that I also went to his shop and asked to see the capabilities of his machine; but, as it happened, he only had four 10-candle incandescent lamps in the shop, and it was found that when the machine was driven from the foot-lathe there was not sufficient resistance in the lamps for them to give their full light; but after introducing a piece of thin iron wire, about 1ft. long, between the terminals of the machine, which I imagine would be equal to about two lamps (making up the six) it was found that with a little of my assistance with the treadle of the lathe, they gave, as "Tried" states, as much light as they should. **Fred. W. Ball.**

Queen's-road, Battersea.

[20418.]—I was very much pleased to see the letter of "Tried" in the "E.M." of Aug. 4, clearing up a lot of doubts concerning small dynamos, upon which so much cold water has been thrown.

Amateurs desiring to construct small dynamos have not known what to do in the matter, as one person in one number of the "E.M." would say it was useless to make such a machine, and in perhaps the very next number another person would say the contrary.

I think "Tried" would oblige others besides myself if he would state what kind of armature the machine has, and if Siemens', whether the cylindrical or H girder.

I have an idea that I could drive a small dynamo by means of a small water-motor, No. 3 Empress for instance, which runs 1,500 revolutions per minute, as we have here a pressure of 90lb. per square inch. If in this idea I am mistaken, I shall be very glad to be told so. **W. L.**

VOSS' ELECTRICAL MACHINE.

[20419.]—In damp and rainy weather it is often found that this machine requires a small initial charge of electricity to start it into action. This may be supplied, I find, in the following simple manner:—Take a small camel-hair brush, costing a penny; hold it lightly against the revolving plate; the slight friction thus produced will almost instantly give the needful charge. The sparks, too, may be increased both in length and frequency by another simple device. Take a piece of wire, say No. 20, and 6in. long; sharpen one end and bend the other into a hook; insert the pointed end into a cork, previously fastened on the top of the vertical comb; bend the wire forward till the hooked end projects over the two knobs of the conductors. From this hook suspend a worsted thread, or one of thick cotton, long enough to reach to the base board nearly. Now, on turning the crank-handle and withdrawing the knobs of the conductors the sparks will be found to come faster and grow longer through the influence of this simple thread which wriggles about in a curious and life-like manner. Another device I have adopted is this: To the base-board, near the front edge, I have fixed two binding posts—one near to and in connection with one condenser, and the other near to and in connection with the other condenser. To these posts may be attached two chains, one to each. On laying the chains on the table in two heaps—say, an inch apart—and then separating the two conductor-knobs to the same distance, two bright sparks will be produced simultaneously—one between the knobs, and the other between the chains. Vacuum tubes, laid on the table between the chains, will be bautifully lit up, and shocks can be taken from the chains in various ways. If one chain be laid, say, over one shoulder, and the other chain over the other, the shocks will be felt smartly through the clothes; the strength of which can be regulated to the greatest nicety by increasing or decreasing the distance between the knobs of the conductors.

I consider the machine a most interesting and beautiful invention; for by its means, Static Electricity may be produced at any time, in large or small quantities, for charging Leyden batteries, lighting up vacuum tubes, giving shocks, &c., &c. It is always ready—no amalgam or other preparation being required; the mere turning of a small crank handle, which may be done by a child three years old, is all the power required to develop copious streams of electricity. I am surprised so little has appeared in your valuable paper on this *the best* of electrical machines.

August 21. **John C. Frank.**

STRAIGHTENING CROOKED CASTINGS.

[20420.]—Thomas D. West, whose article you have reproduced from the *American Machinist*, is incorrect in many things, according to my judgment. He says truly, that the foreman of a foundry is puzzled to tell how a casting will go, when looking at a complicated pattern for the first time; and in order to keep it straight the great question is, how so to manage that all parts will cool equally. T. D. W. says "There are two reasons for castings warping. The first is ill-proportioned thickness, the second the allowing of some parts to cool before the others." This is very misleading; for what he states as the first reason is only the cause of the second, and so there is only one reason—viz., *one part cooling before the others*. Again, he says, "When the thickness of metal in a column is not equal, the thin side will cool first, and draw the thick side towards it, thereby making the thin side of the column concave and the thick side convex." The very opposite of this is the result of an unequal column; the *concave side* is the *thick side*, the cause being that the thin side in cooling becomes rigid, while the thick side being still plastic, and subject to compression, is, therefore, not liable to bend by the contraction of the thin side; and after *that* contraction is passed, the thick side has *its* shrinkage to undergo, and that force acting like a bow-string, draws the ends of the casting nearer to each other on that side, and *it* therefore becomes *concave*.

T. D. W. seems to me to be more of a practical man than a theorist. He says: "*Cool the thick parts and keep the thin parts hot* is about all that can be said as regards keeping ill-proportioned castings straight." This is correct. He further says: "Try to keep all parts of the same temperature, so that their contraction will be equal." He should have added *as to time*, as contraction in all parts of a casting (thick and thin) is alike in amount, not as T. D. W. has it, *i.e.*, "a thin body of iron will contract more in cooling than a thick body."

Again, he says, "Often moulders will . . . shovel the sand from the top in the middle of a casting, in order to keep the ends of it from coming up. This is wrong; for by cooling the middle on the top side this part is contracted quicker than the under side, which will naturally cause the ends to come up." I say this will not be the case if cooling is done early enough—all along the top side—for the under side being still plastic will compress by the action of the cooling side, therefore will not be affected from the straight, and, when the under side comes to contract, *it* will act like a bowstring and draw the *ends down*—just the reverse of what T. D. W. states. Again, "The part that cools first will generally keep the casting in the shape it was bent when hot." No, it won't; the part that is cold is rigid, while the part that is warm has still to shrink a bit, and will either cause bending or break *itself* in cooling down.

At the close of his article, T. D. W. gives an instance of gates and runners drawing a casting crooked, "The casting of a small toothed rack was run from a runner parallel with it, by a series of sprues entering the rack mould from the runner at equal distances all along, and when the casting was taken from the sand, it was bent sideways, *concave side next runners*. This," he says, "was caused by the runner being lighter than the casting, and in cooling and contracting quickest it drew the casting crooked. To remedy this runners were made on both sides, &c." This is another instance of T. D. W.'s practice being correct, but of his theory being fallacious; having a runner on both sides was right, but the cause he assigns for the casting being crooked the first time—with the runner on one side—is most certainly wrong. The side of the casting next the runner being concave shows that the runner must have been plastic while the casting was cooling, and the runner having its shrinkage to undergo afterwards, acted as a bow-string along that side of the casting and drew the ends towards it. **Patternmaker.**

Bonnybridge, August 16th, 1882.

BREAD.

[20421.]—Some time ago, I inquired through your columns why English bread was so wretchedly underbaked. I elicited no satisfactory reply. I have now found out the reason. A baker frankly avowed to me to-day that it would *not pay* to bake bread thoroughly, on account of the attendant loss of weight. It appears, therefore, that the less you bake the bread the better for the baker,—but the worse for the stomach, I fancy. For my part, I would rather pay more and get bread that can be assimilated. **Disgusted Foreigner.**

SCREW PROPELLERS.

[20422.]—The arrangement described by "C. T. E." on p. 551, letter 20402, does not appear to me to possess any theoretical advantage as a mode of propulsion over the paddle or screw methods. If the plate be supposed to be parallel to the vessel's side when first put in motion, a considerable part of the stroke, and that also being the part where the plate offers the greatest resistance to motion, will be comparatively ineffective to drive the vessel forwards, the greatest effect being only attained towards the end of the stroke, one of the great advantages possessed by the screw being, I conceive, that it keeps up a continuous as well as a uniform thrust forward. It would be fatal to the speed of any vessel to have four rods sufficiently strong enough to work such a pair of "fins," projecting from the sides at right angles to the line of motion; then there would be the complication of stuffing boxes, as well as several additional joints necessary to connect the fin to the two rods, which I presume are to slide in and out parallel to each other.

Moral.—This plan is much more complicated in its arrangements than a screw propeller; possesses no advantage in theory over that means of propulsion, and won't do. **J. J. A. (Liverpool).**

STONEHENGE AND SUN-WORSHIP.

[20423.]—If "Neo" can come across a book entitled "The Druidical Temples of the County of Wilts," by the Rev. E. Duke, M.A., &c., 1846, he will find some interesting chapters on Stonehenge and other stone circles.

A Would-be Piper.

RAILWAY SIGNALS.

[20424.]—My patent automatic apparatus is a mechanical contrivance placed at, or near, the signal itself, being capable of various modifications. A straight or segmental bar of novel construction, slotted at one end, is actuated from the signal-box by means of the usual interlocking lever, and a latch passing along the bar by means of the slot, is in connection with the signal. When this latch is in position, with the shoulder on the bar, the signal can be taken off by the signalman, or kept on, as per requirement; but should the signal be off, the train on passing the mechanism releases the latch from its point of detention, and the weighted arm in connection with the signal places it in the danger position. Electrical contact apparatus may be applied in various ways, and it is not unfrequently that the distant signal is taken off after the train has run within it, in consequence of the same not being seen from the signal-box.

I desire to retain the signal at danger until the train has cleared the section; but I do not interfere with any systems now in use.

Hackney. **J. Harrison.**

[20425.]—I ought to be much obliged to those correspondents who have kindly noticed my suggestion *re* railway signals; but owing, I suppose, to the heat or the holiday season, they have scarcely paid me the compliment of understanding what I meant. Perhaps, however, I did not make matters clear. One gentleman (p. 523) does not see "any advantages," and thinks a semaphore much better than a disc, by which I learn for the first time that I have suggested a disc instead of a semaphore. Another (p. 548) says the suggested alteration is a "mechanical disadvantage"—which is extraordinary, too, considering that the alteration is only in the meaning to be attributed to a signal, let that signal be what it may. This gentleman, having set up the skittle, proceeds to knock it down in a variety of ways until at last he is satisfied that it is really down. Probably twenty years' hence the mechanical disadvantages of the present signalling arrangements will be generally recognised as out of place in these times, but until then I can agree with "Tittesworth," that "both for the sake of uniformity and clearness an angle of 45° for a 'go-ahead' signal would be the best to adopt universally." The chairman of the London and North-Western (p. 548), commenting on my assertion that by the present system a driver proceeds unless obstructed, says "so he would if the system was changed as proposed." On the contrary, I put it the other way, and say the driver would be perpetually "obstructed" except when he had a positive signal to come on. Mr. Moon says the "all-right is a positive order to come on," and Mr. Stooke says "we *do* give a positive signal to come on," both statements being positive enough. But if it really is so, permit me to ask what was Mr. Stooke's original question, accompanied by a beautiful little engraving (p. 427)? It seemed to me, so far from being a positive signal, that "when we come to examine the arms at different places, we find many different angles are shown for what is intended to be the same signal"—and drivers are occasionally in doubt as to whether the signal is "off" or "on." Mr. Stooke is the only correspondent who has really begun a reply to my letter, and he gives no argument, but simply says "we want a conspicuous signal for danger, and to obtain such we must keep the arm in a horizontal position." Allow me to ask why? Why should any signal at all be wanted to block the line? I grant that circumstances may arise when a danger signal is necessary, but that should be of so special a character that no mistake could possibly be made, like the fearful blunder at Canonbury. But for all ordinary purposes, the *absence* of the signal "line clear," should, could, and would indicate "danger," which should be considered the normal condition of any railway. What is done at present? A driver starts by a signal which gives him permission to go, and he runs on, passing the signals one by one until he finds one against him; then he pulls up if he can. If it should have been put on suddenly, the margin of safety is, as Sir H. Tyler put it, the "thickness of a signal-post." What is the objection to taking a bare pole as a stop signal? or, to put it the other way, what is the objection to making a rule that an engine should be in motion only when the signal in front ordered the driver to come on? If the present arrangements of semaphores and posts are retained, there will be no questions of angles, for when the line is not clear the semaphores will be within the post, and the signal to come on will be given by putting the semaphore at whatever angle may be found most convenient. There will, certainly, be no necessity to make it 90°. The drivers will thus, technically, be perpetually "obstructed," and will proceed only when a signal is given to do so. I should like to hear what objections the drivers have to the suggestion. I think they will see that there is nothing very puzzling in the change. **Nun. Dor.**

[20426.]—Mr. Stooke, 20367, p. 523, says, "There is not likely to be any confusion or misunderstanding of any kind whatever, if a rule of strict uniformity is established, never mind what the angles determined on may be." This sentence requires a modification, and certain conditions must be fulfilled before it is said to be true. In the first place it implies that the driver is capable of estimating the angle made between the signal and the post to the utmost *nicety* (which, by the way, is a qualification Mr. Stooke does not expect), or he will cause great confusion. According to Mr Stooke's arrangement, 20267, the angles from 45° to 85° are allowed as clear; but immediately the arm falls to 86° it must be treated as danger. I am inclined to think that there are very few drivers who are capable of distinguishing in this case between the clear signal and the one for danger. In fact, we may venture to state that there is not one driver in a dozen who, at a hundred yards' distance, could estimate such a nicety, let alone when he is on the engine and travelling at the rate of 40 to 50 miles an hour. The same objection applies to the doubtful signal, because from 5° to 45° has to be treated as danger; but should the arm indicate 46°, then, according to the rule, it is strictly clear. Secondly, the angles determined upon must be such that one cannot be taken for another.

Although Mr. Stooke cannot agree to the angles suggested in letter 20296, we do not see but what they can be made to fulfil the conditions which he requires. For instance, suppose, as suggested in letter 20296, the danger signal be from zero to 30°, and the first fall of the arm be to 15°, then there is a margin of 15° to allow for wear and tear of axles and axle bearings, and also expansion before it reaches the clear signal. The same principle applies all through; but, of course, if the suggestion is barren, let it pass as such. It was tendered in response to the following sentence: 20267, "If anyone disapproves of these angles will he be so good as to say so, as by doing this assistance will be rendered in settling a somewhat important question?"

A. Manock.

WAGGON COUPLINGS AND RAILWAY ACCIDENTS.

[20427.]—A large number of the needless casualties which occur to railway servants are directly due to the use of chain or link couplings now universally used on railway trucks and waggons. The operation of "coupling" and "uncoupling" with the present appliances necessitates that the operator should place himself in a position of personal risk, and it will readily be seen that the risk should, if possible, be obviated. In the five years ending 1880, no fewer than 206 railway servants were killed outright, and 1,614 others lost limbs, were crushed, or otherwise injured, whilst engaged in coupling or uncoupling trucks and waggons. I estimate that from 12,000 to 14,000 men represent the total of those whose regular duty it is to marshal and distribute trains; and it is amongst this number that the foregoing casualties occurred. After making every allowance for incautiousness on the part of workmen, the list of killed and wounded deserves serious consideration from those responsible for the continued use of an appliance in great part the cause of so much human destruction.

In consequence of a communication from the Amalgamated Society of Railway Servants, the Board of Trade, in February last, addressed a circular to the railway companies calling their serious attention to the matter, and asking for suggestions calculated to obviate the constant risk now incurred under the present system of coupling waggons. I do not know what effect the circular has had, but there are no apparent signs of improvement.

A great many improved waggon couplings have been invented, and not a few have, by practical tests, proved efficient. All those I have seen or read of, provided, 1st, against personal risks to the operator, by enabling him to manipulate them without going between the waggons; and 2nd, for greater despatch in forming and distributing the component parts of a train. In a word, they aim at greater safety and economy in time. Hitherto, however, no company has adopted an improved coupling. The objections urged are the cost involved and the desirability of maintaining uniformity for the convenience of through traffic. The objections prevail, and the work of death and mutilation goes on at its usual average.

In the hope of assisting in promoting the adoption of improved appliances by the spread of information, the Amalgamated Society of Railway Servants respectfully invite the proprietors of improved waggon couplings to send working models of their appliances to an exhibition to be held at the Mechanics' Institute, Darlington, on October 3rd and four following days. Arrangements will be made to explain to visitors the merits of the several exhibits, and to contrast them with the dangerous and time-wasting appliance now used on all railways. Any communication that may be addressed to me will receive prompt attention.

In the interest of my fellow workers I beg the insertion of this letter.

Fred W. Evans.
Gen. Sec. Amalgamated Society
of Railway Servants.

306, City-road, London, August 14th.

VEGETARIANISM AND SLEEPLESSNESS.

[20428.]—Having read with much interest Dr. James Edmunds' letter in your issue of the 11th inst., may I—as a vegetarian of eight years' standing—be allowed to say, with regard to the remark about vegetarians suffering from sleeplessness, that such was my experience when I first left off eating meat. I did not, however, think it necessary to abandon vegetarianism on that account, although strongly urged to do so. I attributed the sleeplessness to my brains having felt so clear and vigorous on the new diet, that I greatly overtaxed their powers at the outset.

I am working hard now, and find that dropping all study at nine, and then taking a light supper of cooked onions or celery, with a cup of cocoa, and getting, if possible, a little "turn" in the open air afterwards, are pretty sure to secure me a good night's sleep. **Spes.**

Chislehurst, 16th August.

STRING VIBRATIONS.

[20429.]—"Nur ein Geiger" says:—"I have been given to understand that a string vibrates in sections $\frac{1}{2}$, $\frac{1}{3}$, &c., of the whole length, and that this secondary vibration goes on at the same time that the string moves as a whole." Yes, this is the old formula—easy to say, difficult to prove. But let anyone take a strained string (a piece of thread will do) and they will see it does not vibrate in parts; but as a whole, forming a bow-shape, the widest part being in the middle of the string. Of course the whole string moves, but not in sections, and pulls each end in the same plane as the directions of the vibrations. This must be sufficient without any further explanation. "N." says: "A solid body touching a vibrating string produces a point of no vibration—i.e., a node." I answer that the contact, if close enough, will produce another fundamental or full tone, but if lightly applied will produce an harmonic node only at certain parts of the string, and not at any other part; in fact, there it will have no node at all, but simply a blurr. I wonder what kind of harmonic node is formed between a violin-bridge and post, and what tone it represents? Please permit an illustration, showing the directions and formation of vibrations. Take a wineglass filled with tea or dark liquor that will reflect the light, and vibrate the edge with a well-rosined violin bow. You will see a pattern formed on the surface of liquor much the same as that shown on the back of a lever watch. The circles begin at the edge furthest from the bow, and are reduplicated till they cross each other almost infinitely. Now, the edge of the glass is the centre of these vibrations, and the furthest away from the bow is the primary circle; therefore, where the sound commences is where the harmonics are produced all together; hence the harmonics are inclosed in the diameter of the vibration, and not in the length of the string, as is generally supposed. Then you say, Why are harmonics formed *on* the length of the string? Because, by lightly interfering with the vibrations, you reduce their diameter or size as springing from the middle of the string, and thus only produce a *part* of the fundamental or open tone. Why can't we form harmonics on a length of free reed? Because there is not sufficient control or weight at the free end to allow a reaction; but fix two free reeds together, *à la* violin string, and harmonics can be obtained. Sound is always produced from a centre, like light; and only in its centre can it be analysed. The sound of a string begins in its middle or centre, and from thence arise the phenomena of nodes forming part of the whole. The node of an harmonic does vibrate, as any one can feel when playing the violin, because it depends on the middle of the string. Now, granting, what is true that the soundboard and string sound together, I fail to see why a node, and so small a node, formed between bridge and soundpost, can affect the tone. Besides, such a node would be formed in so small relation to any tone or tones, that its effect would not exceed the addition of a slight harmonic. Drums can be tuned to pitch, and are, therefore, musical—side kettle-drums in some of Handel's choruses. I don't mind "N.'s" closing remarks about adding soundposts; but he can do it if he likes to his Klotz and piano or banjo; the result will be the same—very bad, indeed. I acknowledge that the new violin is in the process of perfection, and, like all other sublunary things, not perfection itself.

"N. E. G." desires less gas; so now for the daylight. He says, "I agree with 'Fiddler' in thinking the post unnecessary, if the soundboard be moved the right way." Now this is professional blarney; because it is well known that no violin other than my own has been made without a soundpost, to be any way efficient, and I tell "N. E. G." that if he tries for twenty years, on his so-called scientific and universally accepted plan, he will not succeed in making a violin without a post, worth the hearing. Take the finest Strad, remove the post, and it is worth nothing; its wood "may be cut in such a way as to give ascendency to the favoured harmony," or any other high-art style, and the effect will be *nil*. If, then, I can produce a new violin in two or three days without hurry, and without a post, for a nominal sum in shillings, that shall far surpass any other violin without a post, that cost the same in pounds, I consider the victory mine. I shall not paste old labels on my violins, or daub them with dirt, or play any other professional games; but in the daylight, and in the open, my work shall tell its own tale—please or displease whom it may. But to follow "N. E. G.'s" reasoning, where he says:—"To sum up, the soundpost acts by transmitting a certain number of vibrations to the back; an action of slight importance." Then why have any back at all? Let the transverse vibrations of the strings act on the soundboard across the grain; go the hardest way to work, and let the violin remain in its present mysterious condition another 700 years. There may be half a dozen *bonâ fide* makers of violins in England—perhaps not so many; and the reason there are so few is because of the difficulty in making a good instrument, and the high price consequent thereon. At the same time, we have it on record in these pages that a fiddle thrown together in a hurry by one of our mechanics, sounded louder than a violin made the ordinary way. **Fiddler.**

SCIENCE AT SOUTH KENSINGTON.

[20430.]—I begin to feel quite interested in Mr. Jackson's friends; so much so, that I should like to know what it is they really do. In his first letter (p. 498), he mentions four who would have been in the workshop, &c., and as he specially noted that one was a "teacher of science," and another a "science master," the conclusion seemed obvious that the other two were not science teachers. It appears now that they are all engaged in science teaching, and we will hope that the results of their labours are more gratifying than those mentioned in your article, Sir. I observe that Mr. Jackson carefully avoids the question as to the responsibility for the ignorance displayed by the candidates, which is, after all, of rather more importance than a question as to whether or not he and his friends still "teach." His example of the "medulla oblongata" question does not touch it, however absurd the answer may have appeared to him. The fact is, as your article plainly intimated, that many of the so-called teachers have crammed themselves to pass, and now, to earn the grants, cram candidates in turn; for, take the answers given on p. 463, and it is obvious that those who gave them were crassly ignorant, not to say stupid, and could only have been sent by "teachers" who hoped the papers would contain just such questions as their "students" had been coached to answer. If the teachers are not responsible, once again it may be asked, who is? It does not at all follow that, because a man enters at South Kensington, passes the examinations, and gets sent out by the department as a "teacher," that he is really qualified to teach, which is an art *sui generis*, and is not to be acquired. Given a class of fairly intelligent pupils, anyone who has passed the examinations can insure the passing of a good percentage; but to really educate the masses, born teachers are required, and it is clear that those who sent the candidate who believes that the "increase of civilisation of the British Island is rectified by the many indentations in the coast," &c., must have lost whatever faculty for teaching he once possessed. Science teachers there are, I know, who work honestly and laboriously for small pay, having a love for the labour, and an earnest desire to do their duty; but such as these never send crammed candidates to be examined, on the chance that they may pass and obtain a "science certificate."

Nun. Dor.

LEGAL REPLIES.

[20431.]—BANKRUPTCY (47686). In this extraordinary case it seems as if the bankrupt's estate had in the end realised more than the debts owing. If this be so, then the bankrupt or his personal representatives would be legally entitled to the surplus. If the querist knows who was the trustee in the matter, or if it was in the hands of the official assignee, he would certainly consult a solicitor with a view to recovering this surplus. I have known of cases where money has been obtained in much the same way after a long lapse of time.

WILL (47687).—There is no doubt whatever that a devise of houses which are mortgaged, only passes the property to the devisee, subject to the mortgage debt. In this case, therefore, and, as I presume, the will does not expressly provide for paying off the mortgage out of the personal estate; the executors are quite right. The querist takes the house and must arrange with the mortgagee, notwithstanding the curious disposition of the testator's personal property.

WINDOW LIGHT (47695).—I am afraid I cannot understand this question, which I would gladly answer upon having the facts more fully and clearly stated. But I may say that twenty years'-user is required to establish a right to a window light, under the Prescription Act; and I may add that one man has a perfect right to open windows overlooking the land of his neighbour; but, on the other hand, that neighbour has a perfect right to block them up, if he can do so, by building upon his own land, unless the right to their enjoyment has been acquired by twenty years' enjoyment or given by deed of grant.

VOID LEASE (47736).—In this case the writing being without seal or stamp is void as a lease for seven years, and it could not so be used in any Court. But as the tenant has entered and paid rent under it, he has become a yearly tenant at the rent thereby reserved. The landlord can, therefore, sue for the rent in arrear as use and occupation, and he can also give six months' notice to quit, expiring at the quarter-day at which the tenancy commenced, while he might, perhaps, bring an action for ejectment. He can, however, have no right to put a lock upon the gate, or in any other way take the law into his own hands. But I could advise much more fully if I saw the writing, which though void as a lease, may in some respects regulate the position of the parties.

TENANTS' LIABILITIES (47742).—If a landlord lets his house at a yearly rent, without any agreement whatever as to the time of payment, I think, unless there is some clear custom of the country that it should be paid half-yearly, he can only claim the rent at the end of the year. Of course, if the tenant had paid, even once, at the quarter or half-year, this would become part of the contract, and he must so continue. A yearly tenant is only bound to leave the house in the same state as it was when he commenced, fair wear and tear excepted. **Fred Wetherfield.**

COLOUR.

[20432.]—IN reply to "X. N. X." (20372), I must ask him to kindly tell me what oxide of copper is used for staining glass blue, and also if he has tried the experiment? I ask this because I have taken great pains to study what colours can be obtained in glass with the various metallic oxides. I have been to one of the first assayers in London, whose business it is to prepare these oxides, but they do not know of the one in question. I should be glad to know where I can obtain a specimen of *blue* glass, guaranteed to be coloured with oxide of copper only. (If there is any modern work, treating specially and practically upon the oxides available for staining glass, I should be glad to know of it).

"X. N. X." writes: "The light transmitted by cobalt glass, though very far indeed from pure blue, does not contain sufficient green for our purpose." This statement is very misleading, the fact being that cobalt glass is unsuitable for making green, *on account* of its impurity, it being a rich blue purple; that is to say, it contains a considerable percentage of red.

I note "X. N. X.'s" experiment with sodium carbonate "in the dark." If he wishes to have a green effect, he should first have sufficient light to be able to distinctly recognise the blue, and then illuminate with his sodium. In fact the blue should have as much light upon its surface as the strength of the yellow light.

I am not at all suprised at "X. N. X." failing to see the green in this, or in any of the other experiments he mentions, even if he were entirely without bias upon the subject. Under such misleading conditions, it is probable I should not be able to form a fair opinion, although I have had so much practice with colour.

"X. N. X." writes: "The light seen on blue and yellow being added together is brighter than the yellow light alone, and not darker, as Mr Caltón supposes." "X. N. X." appears to misunderstand me. I stated that a yellow light thrown upon the screen would show a stronger light than if it were only thrown upon the screen alternately with a blue light. Of course two lights added together will be brighter than either individual light, but lights flashed alternately upon the same spot are not added together. Would "X. N. X." call it adding to a man's account at his bankers if he drew out £100 and paid in £80, or even £90, directly afterwards? (I am here taking it for granted that the blue light is less powerful than the yellow, as this is pretty certain to be the case.) A banking account that varies between £80 and £100 can hardly be said to exceed the latter amount.

As for the so-called blue glass that transmits a considerable quantity of green, it is strangely miscalled.

"X. N. X.'s" prediction that pure blue and yellow pigments would produce black, is a great advance upon the philosopher's-white theory, as the green produced would certainly be much nearer black than white; but he goes from one extreme to the other: his prediction is entirely contrary to practice, for it is an invariable rule that the purer the blue and yellow, the more intense the green.

"X. N. X." endeavours to discredit my experiment of throwing a yellow shadow upon a blue surface by saying "the blue paper is able to reflect green, although it absorbs yellow and red, and therefore the light reflected from the paper is green."

Here, I contend, he is mistaken, and maintain that a blue surface does not absorb either red or yellow. If a red light be thrown upon a blue surface, the combined light reflected to the eye is purple, and with a yellow light the combined effect is green. Neither the red nor yellow is absorbed, but are, in each case, reflected back to the eye, combined with the original colour of the surface. In fact, a blue surface reflects any hue that is thrown upon it, and has no special partiality for green.

I really must protest against the self-assurance of people who calmly designate all their own ideas as "science." "Sigma" writes (20324), "From a purely scientific point of view, the discussion about which colours are primary, and which secondary, is quite meaningless." If he had said, from his own (limited) point of view, it would have been more modest. I consider the latter part of his statement entirely erroneous, and, therefore, unscientific. It strongly reminds me of a remark made during last year's discussion—viz., "What we (the scientists) state with regard to colour is as demonstrable to a colour-blind man as to one who is not." I should say that, to a colour-blind scientist, the whole of this discussion may be "quite meaningless." "Sigma" continues: "The whole question has two aspects—the scientific and the artistic, which have no point in union." While the scientists' view of the question is kept forcibly apart from the artistic, it is likely to remain in its present unsatisfactory condition.

I was much struck with "Sigma's" remark about "the production of music from a violin." Do his theories differ as widely from practice in sound as in colour?

Again, he writes, "a so-called blue glass transmits blue and green, and a yellow glass yellow and green; the resulting hue should be white, *with an excess of green.*"

Here, I maintain, he is at fault. It might as reasonably be argued that, upon combining blue and red, the blue glass transmits blue and purple, and the red glass red and purple, and the resulting hue should be white, with an excess of purple; or, on combining red and yellow, the red might be said to transmit red and orange, and the yellow yellow and orange, and the resulting hue should be white, with an excess of orange; so that we find that blue glass, when it is combined with yellow, transmits blue and green, but when it is combined with red, transmits blue and purple, while yellow glass transmits yellow and green, or yellow and orange, according as it is combined with blue or red; and yet these people would claim the monopoly of science.

What astonishes me the most is that anyone (not colour-blind) can look at a vivid green and not be able to see the blue and yellow in it. A good illustration of the effect of combining blue and yellow is seen in a piece of shot silk, in which the green effect is produced by separate threads of blue and yellow. Last year I suggested the experiment of ruling parallel lines of blue and yellow, ⅛in. wide by 6in. long. If they are made two or three times as long the effect is plainer; but I find the green is easier seen in a room if yellow and pale blue lines are ruled with a pen, about forty to an inch, over a surface of about 6in. or 8in. square. In these two experiments we get a good green without the blue and yellow being in any sense lost to the eye, and they cannot, therefore, be said to absorb one another's colours.

Take Tyndall's statement as quoted by Mr. Smith, viz., "that with a mixture of blue and yellow powders, white light plunges into the powders to a certain depth, and is discharged by external reflection, minus its yellow and blue (he omits to mention anything about the red), the green alone remains." Now I should like to know where the line is drawn at which "green alone remains" without blue and yellow being visible, for we can have green that is nearly all yellow, or green that is nearly all blue, with endless varieties between. Surely, even a scientist would not say that in either of these two extreme cases the reflection was green "minus its yellow and its blue;" therefore, they must draw a line somewhere. I can inform Mr. Tyndall that there is no necessity for the blue and yellow to overlap to produce green. The powders can be carefully arranged so that the colours are simply alongside one another, and yet the effect is green, and this reflected colour is certainly not "minus its blue and yellow."

If we take a saucer and rub some gamboge and water in it, and then add a small percentage of (say, Prussian) blue, it immediately shows green exactly to the extent of the blue added. To this pale yellow green we add more and more blue, and observe the effect. We see it changes from yellow green gradually to a deep blue-green. Now what right have we to say that the blue and yellow have neutralised one another, and are lost? We find in every combination of these two colours the same effect is invariably produced, and I maintain that it is their joint visible presence that we recognise as green, exactly the same as we call the joint effect of red and blue purple. What do the scientists understand by blue-green and yellow-green? Surely, it can only mean that these two colours predominate!

Most of "X. N. X.'s" remarks are met by my letter, to which his is a reply. It simply rests to prove who is mistaken, as one of us most certainly is. I would call his attention to "Sigma's" letter. That gentleman is coming much nearer to my views than any other opponent, as he candidly admits "an excess of green" on combining blue and yellow lights. What is the difference between "an excess of green" and "a pale green"? His term is very singular, he might as well say that in mixing black and white an excess of grey was obtained, or that a mixture of copper and zinc gave a vacuum, with an excess of brass. Then "X. N. X." admits that the white produced by his experiment has "perhaps a yellow tinge." I predicted the result would be a very pale yellow green. So we are not so very far apart, after all, and if "X. N. X." will kindly compare his "yellow tinge" with a strong white light, perhaps he may admit a greenish-yellow tinge.

Upon careful examination it is satisfactory to find how nearly we agree; and yet how much we differ in explaining the same result; but I think it is a considerable advance to have it acknowledged by anyone who calls himself a scientist, or at least defends their cause, that a combination of blue and yellow lights produces a green effect, even though it is called "an excess."

"E. H." in his letter, 20329, mentions some apparently extraordinary effects, seen upon looking through various coloured mediums at other colours. I have observed something the same effects, and if I had not prepared the glasses myself should probably have been at a loss to account for them.

I was preparing some green glasses with aniline dyes and gelatine (to show that any colour may be rendered visible upon superimposing various red and green glasses, and that yellow is only visible when that colour is in excess) as I found the only green glass I could purchase was of a very yellow hue, being, in fact, nearly all yellow. I, therefore, made some green by mixing various yellows and a blue, which latter was strongly tinted with red. On looking through some of these greens, in which both component colours contained red, at the apparently white flame of a paraffin lamp, which is nearer white than a gas-flame, I was greatly suprised to see the flame appear deep orange (this colour many would call deep red) while the rest of the glass appeared green. At first glance this appeared rather extraordinary, and some friends I showed it to were equally struck with the result; but upon thinking the matter over I find it admits of a very simple explanation, In the first place, the flame upon being compared to a white cloud, in daylight, is evidently of a strong orange hue, and the blue and yellow dyes, of which the green was composed, each contained a quantity of red, so that it was quite evident that the colour seen was simply from the red and yellow being strongest under the circumstances, and giving an excess of orange. One very important fact to remember in using aniline dyes is that the red is not only much the most intense, but appears to pervade many of the other colours.

I sent to a wholesale scientific depot for some aniline blue, red, yellow, and green. The red was the only satisfactory colour; the blue when dissolved in a four-ounce bottle showed such a strong tinge of red that I was afraid it would not be of any use, but found the red was not so perceptible when the dye was only in a thin layer. I had three dyes sent me as yellow, which happened to be orange; they contained so much red as to be quite useless for my purpose, and the green dye, as was the case with the stained glass, was nearly all yellow.

I write this to warn "tyros in optics" that when using colours, aniline especially, red may be present even when only its complement—viz., green, is apparent by ordinary light, and I suggest the following as an explanation of "E. H.'s" statement that grass appeared scarlet when looked at through a purple glass.

Grass is a very yellow green, there being a very slight quantity of blue in it. The red in the purple and the yellow in the grass overpower the blue and give a more or less scarlet effect (which many would accept as red, while it is really orange); in fact, it is only a combination of the three primitive colours, red, blue, and yellow, and whichever are in excess will be visible, although the result may appear perplexing at first glance, especially to those whose whole knowledge has been acquired from books.

In aniline colours the red appears to be so much the most intense that it will frequently assert itself where least expected. May not this be owing to its being in a much finer state of division? The blue I used appeared when dissolved to be in comparatively coarse grains, even to the naked eye, and upon superimposing red and blue glasses of the same depth, the latter was almost annihilated.

I think the scientists, in their disregard of artistic reasoning, have sometimes lost themselves in profound sophistry, when a very simple explanation would have kept them right.

I do not altogether agree with "E. H.'s" conclusions in his fifth paragraph, 20339. "E. H." should know that there are many reasons (which are quite beside the subject in question) why different artists do not paint the same object alike. It is impossible, even when desirable, to make an exact copy, and artists have different theories of what to aim at and also of how to get the desired effect; some will be afraid of erring in one direction and some in another. The æsthetic school, for instance, goes in for what they call breadth (but what others call dirt or philosopher's white) at the sacrifice of other qualities. The leaders of this school are, I believe, strongly colour-blind, and only go in for these semi-neutral tones because they cannot trust themselves with purer colours. I do not suppose any artist considers his picture an exact counterpart of nature in colour. When I am painting a landscape I am sometimes painfully aware of this discrepancy, and it would be a great error to take my sketch as an example of how nature appears to me. In fact, this power of copying what we see constitutes the difference between a good artist and a duffer.

If "E. H." will go to any school of art, preferably to one where professional artists study from the figure, and just walk round and note how differently the same figure is rendered by each, one will have drawn the man very tall and slim, with small head, hands, and feet; a second will have depicted him as short and dwarfish, with very large head, &c.; while as to colour, amongst a couple of dozen studies you will find every variety, from a pale pink to a dusky brown figure. But this is not a proof that the various artists saw the man as they painted him; and I do not see that we have any right to assume that these studies give a more correct representation of their views of the figure in colour than form.

I would here point out that I am not claiming infallibility for artists. Perhaps some will say these are not fair samples, while others may smile at these admitted failings in our profession. An artist's work is always on view for criticism, and everyone considers he has a right, if indeed it is not his duty, to criticise a picture, no matter how slight his own knowledge of the subject may be; but it must not be supposed that the members of any other profession are any more immaculate. No other profession offers so great an opportunity for public criticism; but even in this comparatively trifling discussion, I note that some of my critics flatly contradict one another's statements, although they probably imagine they are defending the same view, and think they know all about it. If we could have an *exhibition* of the scientists' views upon colour—not mere quotation, but each man writing a treatise out of his own head, I think we should find the most extraordinary discrepancies amongst people who at present imagine they agree, simply because they have read the same book.

"E. H.'s" proposed test for colour-blindness would, I am afraid, be much too severe a test for most scientific men. The power of mixing pigments to copy any given hue, is not near so simple as might be imagined; and I should consider it quite sufficient if they could match a number of pairs of coloured articles. I agree with "E. H." that the complementary colour of blue is orange, and should like to know why he objects to "any theory of the three primaries." Amongst his other statements with which I agree, I would state that I also have found that a very small quantity of white light on a disc will overpower the colour; and as I have previously stated, any hue, however strong, black included, may be so brilliantly illuminated as to appear white if seen by itself.

Mr. Geo. Smith (20373), in his last paragraph, describes a disc which gives a very simple and true illustration of which are complementary colours. **S. Calton.**

[20433.]—Some of the correspondents who have recently favoured you with remarks upon the subject of colour, appear to be arguing at cross purposes, for pieces of coloured glass, and, above all, pigments, are sure to confuse a student who is examining that branch of light which is denominated Colour. So far as we can tell, there is no such thing as colour in the abstract, but it is certain that the normal human eye is capable of distinguishing very many shades of colour, and of recognising at least seven distinct colours. The modern theory of light holds that these are due to a difference in wave-length combined with a difference in the velocity of undulation which may be roughly represented as 7 to 4 for violet and red respectively. Although the normal human eye sees seven distinct colours in the spectrum, it is obvious that if the undulatory theory is true, the spectrum must be made up of an infinite number of colours, or at least of all wave-lengths between the 434 billion undulations of red to the 758 billion of violet. The exact way in which these waves act upon the eye to produce the sensation of colour is still a matter of pure supposition, and although we know that some animals are capable of appreciating differences in colour, we do not know that they see the same colours as we do. We do know, however, that all human eyes are not alike; that with some, through a disease or defect, the phenomena of what is known as colour-blindness are experienced, and that with certain drugs the action of the optical mechanism can be so disordered that a healthy eye sees objects in their wrong colours.

According to the Young-Helmholtz theory, the retina possesses three distinct kinds of nerve fibrils, each of which is capable of distinguishing one of three colours. Of these sets of fibres one is sensible to red alone, another to green, and the third to violet or perhaps to blue. The entire chromatic scale is made up of combinations of these three so-called primary colours. Every sensation is due to the excitation of the fibres of the retina by these colours, or more properly by the waves of the luminiferous ether, each set of fibres being strongly stimulated by its own special excitant, and feebly stimulated by the others. In the case of red, for example, the terminal apparatus of the fibres adapted for conducting red are powerfully stimulated by the large waves of the less refrangible extremity of the spectrum, whilst the terminal apparatus of the nerves adapted for green and violet are very feebly stimulated, and the sensation of red is the result. In like manner, when the sensation of green is perceived, the terminal apparatus of the nerves adapted for conducting the impression of green are stimulated by the waves of moderate amplitude in the middle of the spectrum, whilst the red and violet fibres respond but slightly to such waves, and the sensation of green results. And so, too, the fibres adapted for conducting violet respond to the short and rapid waves of the more refrangible rays which have only moderate action on the green and still less on the red conducting fibres. The intermediate colours, such as orange, are due to the simultaneous stimulation of the several sets of fibres to a greater or less extent, and when all these sets are equally excited, the impression of white light results.

M. J. Soury, in the *Revue des Cours Scientifiques*, says that lately a new theory—that of Hering—has been advanced. According to this physicist there are six simple sensations of vision, and the various colours seen result from their different association and blending. These elementary sensations are disposed in couples or antagonistic pairs: black and white, green and red, yellow and blue. On this theory violet is a compound colour formed by the blending of blue and red, and in an ordinary perception of colour four primary sensations are excited: black and white and two colours; but the blue and the yellow are never simultaneously excited, nor are the red and the green. Black and white are capable of mingling, and produce all the shades of grey, but red and green or blue and yellow have no disposition to blend, but rather behave like the poles of an electric battery, and in this sense the school of Hering, of which Happe is the chief exponent, speak of the polarity of colours. The organic substratum of colour sensation, according to Hering, is not the terminal apparatus of the nerve fibre itself, but certain hypothetical substances, such as the visual purple, which undergo chemical change. On looking at "white" light, the visual purple, by a photo-chemical process, is constantly undergoing decomposition and destruction, and is as rapidly restored. Red light decomposes the visual purple slowly, violet light decomposes it more rapidly. Further, on Hering's theory, processes both of disassimilation and of assimilation are supposed to take place, so that when exposure to red light has exhausted or partially destroyed the visual purple, or its mother substance, purpurogene, green light aids in the reparation of this material, and fits the eye again for perceiving red light. Black does the same office for a retina exhausted with white light, and blue for yellow. This theory affords a good explanation of the phenomena of contrast, and of complementary colours. A red wafer placed on a sheet of white paper gives the sensation of a vivid red disc. As long as it is looked at it causes disassimilation of the retinal purple, which is as constantly renewed; but if the eyes be closed, the sensation of red vanishes, and is replaced by green, because assimilation is then taking place in excess of disassimilation. When one of these states is equal to the other two, the two antagonistic sensations are reciprocally destructive. Hence red and green do not blend to form white. Another theory, originally suggested by Draper, and more recently developed by Preyer and by Charpentier, refers the colour sensations we perceive to modifications of temperature. Charpentier, who has just completed a series of researches with Landolt, finds that the statements recently made to the effect that certain zones of the retina are specially adapted for the perception of certain colours have been founded on imperfect observations, and that even the most peripheral portions of the retina can differentiate colours providing they are sufficiently intense. Charpentier differentiates in every normal eye a sensibility for light, a sensibility for colour, and a visual sensibility or sensibility for form. In every chromatic impression made on the peripheric regions of the retina he further distinguishes three phases: a simple impression of light, a vague indeterminate impression of colour, and a distinct impression of the true colour. The first phase he thinks clearly proves that the luminous sensation is distinct from that of colour, that it is the result of a simple excitation of the optic nerve; but in the second phase the cerebral centres for colour are excited, and the reason that a quicker and surer recognition of colour is made by the macula and central parts of the retina is only because they are more used. The sense of colour and of light being a general function of the retina, he regards neither the rods nor the cones as the retinal elements which are stimulated by chromatic stimuli. He looks rather to the layer of ganglionic cells which lie on the anterior part of the retina as the functionally active elements.

Although it is abundantly obvious that there is ample room for several investigators in this field of research—the mechanism of the sensation of colour—I imagine there is no room to doubt the facts of Helmholtz, Clerk-Maxwell, Tyndall, and others. I am afraid there is no help for a paradoxer who says "it is really quite time for the old dogma of white being composed of colour to be exchanged for a more rational theory," and who also thinks that "green is composed of blue and yellow, exactly as much as brass is composed of copper and zinc." Some of the experiments of your correspondents—though they have really nothing to do with the subject of light and the sensation of colour—are very interesting, but they would be more valuable if one knew what was meant by the terms red, green, blue, &c. Some people call vermilion, for instance, red, while others class it as orange, and so on. It would be well if the approximate position of the colour in the spectrum could be always indicated.

Calorimeter.

Electricity and Flame.—A contribution to the subject of the electricity of flame has been lately made by Herren Elster and Geitel (*Wied. Ann.*, No. 6). The discrepancies in previous results are attributed largely to the behaviour of the air layer immediately outside of the flame having been left out of account. The authors used a Thomson quadrant electrometer for measurement. They find the supposed longitudinal polarisation of flame merely apparent, and due to unequal insertion of the wires used as electrodes. On the other hand, flame is strongly polarised in cross section; an electrode in the air about the flame is always positive to one in the flame. The theory the authors adopt is this.—By the process of combustion *per se* free electricity is not produced in the flame; but the flame-gases and the air-envelope have the property of exciting, like an electrolyte, metals or liquids in contact with them. To this electrolytic excitation is added a thermo-electric, due to the incandescent state of the electrodes. The amount and nature of the electric excitation is independent of the size of the flame, and dependent on the nature, surface-condition, and glow of the electrodes, and on the nature of the burning gases. *Inter alia*, it is remarked that flames may be combined in series like galvanic elements, and so as to form a "flame-battery." An article giving a full account of the experiments appears in *Nature*, for August 3, over the initials "S. P. T."

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[47144.]—**Bending Wood.**—Will "Collodion" kindly say whether the steam should be under pressure, and, if so, what pressure; and with regard to safety-valve.—No Name.

[47206.]—**Dry Plate Developer.**—I send the following, which I always use now, and which gives me the greatest satisfaction. Weigh out as much pyro. as you want, say 144gr. Then weigh out just 4 times as much soda sulphite (*neutral*), i.e. 576gr., dissolve this in about 4oz. of distilled water, and neutralise with citric acid, as the soda sulphite is sure to be a little alkaline. Then add the pyro., make up the solution to 6oz. with distilled water, filter, and keep for use. These proportions will give 3gr. pyro. per drachm; but it is most convenient to mix it, so that each drachm will contain just the right amount of pyro. for 1oz. of developer, according to the formula sent out with the plates. Pyro. solution made up by this formula will keep almost indefinitely, and, unlike any other pyro. solution, will not turn seriously brown, even if used with twice the usual amount of ammonia and kept on the plate for a lengthened period. With correctly exposed plates, therefore, the same solution can be used for several consecutive plates, and will give negatives with *perfectly clear glass* in the shadows, and *entirely* free from stains, even without using alum and citric acid or any other clearing solution.—Patent Plate.

[47228.]—**Telephone.**—I believe in the present Bell's Telephone the wire is divided into three lengths, and wound on the bobbin together, each set of three ends, being then connected to a binding-screw. It is said to act better.—Amido.

[47261.] — **Arsenic in Wall-Paper.** — The method which I have found easiest and simplest, is to boil the wall-paper with strong pure hydrochloric acid for some time, the neck of the retort passing into a flask, kept cold, and having just enough water in to cover the end of the neck. Chloride of arsenic is formed, which forms a yellow precipitate, by adding sulphuretted hydrogen solution and a few drops of HCl.—Amido.

[47321.] — **Electro - Deposition of Carbon (U.Q.)**—Some experiments which I have been trying under this head have proved very unsatisfactory. I am afraid carbon cannot be satisfactorily deposited, and it is an open question as to whether the particles would adhere.—H. Stooke.

[47346.] — **Boomerang.** — Perhaps "Bushranger" may find what he wants in the following account of this weapon, which I have taken from Beeton's "Encyclopædia." Thinking the description given may be interesting to other readers of the "E. M.," I have copied the whole of the article;—Boomerang, a missile instrument used by the Aborigines of Australia, in war, sport, and the chase. It consists of a piece of hard wood of a bent form, with the curve of a parabola, is about 2ft. long, 2½in. broad, ⅜in. thick, and is rounded at the extremities. One side is flat, the other convex, and it is brought to a bluntish edge. It is discharged by the hand by one end, the convex edge being forward and the flat side upward; and it is thrown as if to hit an object in advance; instead, however, of going forward, it ascends into the air with a rapid rotatory motion, until it reaches a considerable height, when it begins to retrograde, and finally passes over the head of the projector and falls to the ground behind him. This singular motion is produced by the air impinging on the bulged side of the instrument. The boomerang, the invention of which would have done honour to the most celebrated man of science, has long been a common weapon among almost the lowest races of savages upon the earth, and was first made known in this country by Professor M'Cullagh in 1837.—H.

[47396.]—**Simple Rotary Engine.**—You had better make an ordinary reciprocating engine, and not trouble yourself with rotaries, especially as the pressure is only 30lb. If you must have a rotary, I would suggest taking one from Reuleaux's "Kinematics," for he illustrates several; but you will have to make the working drawing yourself.—T. P.

[47402.]—**Summer House.**—You must make sketches and measure off the work; and as to sizes of timber, it depends on how you want the house —strong or light. Posts 1½in. square would be strong enough; but some would prefer 2in. square. You don't say whether you want it close-boarded or trellis; but matched boarding ¾in. thick will do for sides and roof. The latter you can make splendidly waterproof by coating with coal tar applied hot; then lay down flat sheets of good brown paper, and give two more coats of tar, sprinkling sand on the last.—E. G. M.

[47408.]—**Fish Glue.**—I believe this is made in Europe in both Russia and Norway. The process is the same as the other in the main; that is, any parts capable of yielding gelatine are boiled, and, when dissolved, the liquor is drawn off, the first portions forming the best quality of glue.—T. P.

[47411].—**Throwing the Hammer.**—There is no help for it, except to practise the throw in such a manner that the head lands dead, as it were. If it lands so that the shaft is thrown over, and brought on to the ground with the force due to the momentum, the best ash and hickory will break at times.—Blacky.

[47417.]—**Varnishes.**—I do not know of any really good work on the subject. The best "papers" were read before the Society of Arts some years ago, and if you searched the back volumes of this paper you would find much valuable information. The art of varnish-making depends so much upon personal skill, that it is impossible to write very much about it. Copal is valuable for making varnish, because it is difficultly soluble, and is very hard and tough. There are, however, several qualities of the gum. I don't know the "prepared painter's copal."—J. T. M.

[47418.]—**Refrigerator.**—You could make an air-compressing pump, and use the air to do some work, when, escaping, it would absorb heat, and cool the surrounding atmosphere. But you certainly would not do much in the way of refrigeration with a pump worked by hand only; and I fancy you would get more coolness out of one of Pictet's small ice machines.—Essar.

[47426.]—**Regnard Incandescant Light.**—You certainly will not get an incandescent light with the arrangement depicted—not even if you use gasoline. You want something much larger than a bottle with a small tube dipping under the liquid. Try a case in which the air is made to pass amongst cotton wicks kept saturated with benzoline—(you will have a difficulty in getting gasoline; and as to petroleum, I don't think that is sold here, for, of course, it is the crude petroleum that is meant) —like Fletcher's gasoline furnace.—Essar.

[47463.]—**Change-Wheels.**—I see that your printer has made me say that the wheels to cut 31 threads per inch are 20 and 55 driven, and 85 and 100 driven. Of course it is evident that this is a mistake, and it should be 20 and 55 drivers, and 85 and 100 driven. I hope you will correct this in your next impression. When compound wheels are used the drivers should be multiplied together as well as the driven wheels.—T. F. Gell.

[47463.]—**Change-Wheels for Screw Cutting.**—I appear to have a difficulty in making my wants properly understood. Mr. T. F. Gell and "J. K. P." give me combinations, found by trial, for cutting nearly 31 to the inch, Mr. Gell saying his is the nearest to be found. But this is not what I asked for. I can find the combinations by trial; but what I want is, if possible, to calculate directly to the nearest combination, without spending hours seeking for a nearer one. I give below seven combinations, which I have found by a method of trial similar to that recommended by these two gentlemen. They are all nearer than those they gave—one particularly near; but I know that I have not exhausted, by a tenth part, the combinations which might be considered near enough for use, and still I am not sure I have the nearest. Those I have found are—

$$\frac{4 \times 75 \times 125}{22 \times 55} = 30\frac{120}{121} \text{ (very near)}$$

$$\frac{4 \times 95 \times 110}{30 \times 45} = 30\frac{26}{27}$$

$$\frac{4 \times 95 \times 120}{21 \times 70} = 31\frac{1}{49}$$

$$\frac{4 \times 65 \times 125}{30 \times 35} = 30\frac{20}{21}$$

$$\frac{4 \times 85 \times 105}{23 \times 50} = 31\frac{1}{23}$$

$$\frac{4 \times 85 \times 115}{21 \times 60} = 31\frac{2}{63}$$

I hope that my query is now plain enough. To go through, perhaps, a thousand combinations is rather a task, and yet having the change-wheels to use, why not use that particular combination which is nearest truth? It is a method of arriving directly at this one combination for any particular thread that I am asking for. Does such a method exist? —Try Again.

[47473.]—**Gas for Laboratory.** — A few volumes back, a very good illustrated article appeared, entitled, "Gas from Gasoline," by F. H., Godstone, which will give you all the information you want. It tells how to produce a pressure of air direct, by means of a trompe (a kind of simple injector, easily made), which is far simpler than any Root's blower, and less expensive by far. You can use the apparatus there described, or you could use one of Fletcher's gas-generators equally well for saturating the spirit. I followed the latter plan, making the lot myself. I would tell you the date when the article appeared, but am not now in a position to consult back vols.—J. Hezmalhalch, Jun.

[47486.]—**Euclid's Axioms.**—In attempting to show how Euclid's axiom 3 can be deduced from axiom 2, Mr. Romanes says: "A + C = B + D; from this we can deduce A − D = B − C, &c." Surely this is a petitio principii with a vengeance. —A. J. Smith.

[47491.]—**Magic-Lantern Slides.**—I quite agree with "M.I.C.E." that it is possible for a person that is slightly acquainted with painting to colour lantern-slides. I should be obliged to him if he will give full descriptions of his method of transferring prints to glass, as from the reading of the answer I suppose he does, and if specially printed pictures are required.—Grapho.

[47540.] — **Measuring Flow of Water.**— "Ditton," in answering this query, has made a serious omission—viz., the coefficient for contraction; he has omitted the quantity "c," out of the formula, which is, $5{\cdot}35\,c \,.\, b \,.\, h.^{\frac{3}{2}}$; for practical purposes, call $c = \frac{5}{8}$ of the total. The correct quantity is ·22 cubic feet per second, and not ·33 cubic feet. John S. B. Bell, C.E., Newcastle.

[47553.] — **Problem in Dynamics.** — Mr. Romanes says: "Suppose the monkey to ascend to a height v above E, the point at which they are in equilibrium. The action of gravity will cause it to descend." How so, seeing that the monkey and the ball are supposed of equal weight?—A. J. Smith.

[47553.]—**Problem in Dynamics.**—I look upon the problem in this light, which I offer for the consideration of "Tam O'Shanter." It is the ball which descends, and not the monkey, and this I conclude from what follows. Let g = force of gravity, m = the mass of each body, and d = distance from the earth when they are in equilibrium. We know that $g = m / d^2$. When the monkey has climbed through s feet, this becomes $g = m / (d + s)^2$, and since $m / d^2 > m / (d + s)^2$ the ball must acquire a velocity. Now, for every increment in the monkey's ascent, the ball will fall through a corresponding increment; but this will draw the monkey through an additional equal increment, so the monkey, for every s feet in the descent of the ball, will always traverse $2s$ feet. Suppose the monkey to have a velocity v, then it follows the ball will acquire a velocity = $\frac{1}{2}\,v$.— C. H. Romanes.

[47573.]—**Model Locomotive Boiler.**—I should advise "Shakespear," if his boiler is not too far advanced, to adopt a more simple method of construction, unless he is making an exact model of some particular engine; the bend between firebox and boiler and riveting the plates which form the barrel of boiler would not be necessary, and a stronger boiler would be obtained. One way is to cut out a sheet of metal of the shape shown in Fig. 1, which, when bent round, would form the barrel of boiler sides and top of outside firebox in one piece; another method is to obtain a piece of brass tube of the required diameter and thickness—this will form the barrel of boiler; at one end of this, and fitting outside, is riveted the outside firebox shell. However, if I had to make a boiler as shown by sketch (on page 508), I should make the rings in one plate, and the bend at A would be most easily made by cutting out a curved strip of copper long enough to take about ⅔rds of circumference of boiler when bent to shape (see Fig. 2); then each edge must be worked out parallel, the large end to fit inside of outside firebox-top, and the small end to fit outside the two-thirds of diameter of barrel and then riveted (see Fig. 3). This strip will be like a continuation of the front plate of outside firebox, and they must lap each side; the top of this plate must be flanged forward to fit underside of barrel, and the sides flanged back to fit between sides of outside firebox, see Fig. 3. Tubes 5-16in. diameter are much too small—they ought to be at least ⅜in. diameter; about 20 could be put into this boiler. The dome should be screwed to boiler, and the joint

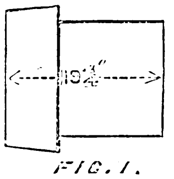

FIG. 1.

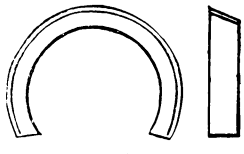

FIG. 2

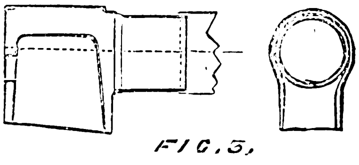

FIG. 3.

made steam-tight with red-lead (see my reply to query 47432, p. 482). In "Shakespear's" sketch the inside firebox is shown too high. There would not be sufficient room for steam and water space; it should not be more than 1in. from centre line of boiler.—E. L. P.

[47578.]—**Egg-end Template.**—I should be glad to give "B. M" the information he requires, but I am afraid it will take up too much space to fully describe and then sketch. I should advise "B. M." to get one of the workshop handbooks on boiler-making, one in particular containing a vast amount of information on templates of all kinds. If he will advertise his address I will give the name and merits of several handbooks and advise which will be the most useful.—Boswell.

[47586.]—**Pure Silver.**—Pure silver may be obtained in the following manner. Dissolve your metal in nitric acid; evaporate to dryness, and fuse the residue as long as red fumes come off. Now dissolve in water and filter, dilute with 30 parts of water and add pure HCl, when you will get a white curdy precipitate of AgCl, which must be well washed, first with dil. HCl, and then with pure water. Dry the precipitate and powder finely in a mortar. Digest several times with aqua-regia, and afterwards wash, until all traces of acid have disappeared. Now reduce the AgCl to the metallic state by boiling with dil. pure KHO solution, to which milk-sugar is added. The reduced silver is washed with dil. H_2SO_4, and then with water, and fused. A solution of the metal thus purified, in HNO_3, should give no blue colour on treatment with NH_3 solution; and if HCl is added to the solution, the precipitate so obtained should be *completely soluble* on adding NH_3.—Caius.

[47590.]—**Honours Chemistry.**—(1) Reduce the volume of air to normal pressure and temperature.

$$\text{Vol. at } 0^\circ \text{ C and 760mm.} = \frac{851{\cdot}4 \times 273 \times 537{\cdot}4}{(273 + 4) \times 760}$$

(2) Find the contraction in the volume after explosion, and this gives the volume of H and O, which have combined to form H_2O; one third of this decrease, therefore, is due to the O.

$$\begin{array}{rl} 657{\cdot}06 & \text{air + hydrogen} \\ 374{\cdot}73 & \text{air + excess of H} \\ \hline 3\,)\,282{\cdot}33 & \text{vol. of H and O which have combined} \\ \hline 94{\cdot}11 & \text{vol. of O.} \end{array}$$

(3) The next thing is to find the percentage of O; and having done that the percentage of N is found by subtracting this from 100.

$$\text{Percentage of O} = \frac{94{\cdot}11 \times 100}{\text{Vol. obtained in (1)}}$$

$$\text{Percentage of N} = 100 - \text{Percentage of O.}$$

—Caius.

[47622.]—**Bisulphide of Carbon Prism.**—You can make one of tin, but composition metal is better. You can get some thin, flatted crown-glass, which answers perfectly. It can be cemented by means of glue. I have not found the bisulphide to act on it. One prism in the form of an equilateral triangle will show double D line, that is with 1in. object-glass telescope.—Amido.

[47623.] —**Electro-Motor.** —Has "Conrad" tried his motor as a dynamo? If not, would it be asking too much to ask him to do so, and give results?—F. W. Ball.

[47636.]—**Gas-Engine.**—"Dun Browne" has not been "done so brown" as some other readers, as he has at least got an engine, and I expect with very little outlay it can be made to work. I expect it is the supply or admission of gas arrangement that is at fault; if so, and he will explain all fully, I shall do my utmost to get it put in order. Has the engine ever run well? As, if so, it should do it again if the obstacle is removed.—Argudante.

[47639.]—**Legal.**—Mr. Wetherfield, in his reply to this query (letter 20404), appears to base his statement that "a license is not necessary for the purpose of killing birds destroying fruit in a garden," on the fact that the occupier of any land using a gun for the purpose of killing vermin on such land is exempt from duty, rather than on the general ground of use within the curtilage of a dwelling-house. I would warn the querist that the Board of Inland Revenue and Mr. Wetherfield are at variance in this matter, the Board holding that the term "scaring" does not include the killing of any bird whatever, and consequently that the term "vermin" does not include birds of any kind under any circumstances, for if "scaring" excludes, the term "vermin" cannot include the killing of the same object. Further, I know of cases in which convictions have been obtained for killing birds which were engaged in destroying fruit, in one case in an orchard not more than a stone's throw from the dwelling-house of the occupier. Of course, I do not include the fact that a gun license is not required in any case of use within a dwelling-house or its curtilage.—Excisum.

[47642.]—**Silicate of Soda.**—In the "E.M." of June 16, in reply to 46495, you will find the method of applying it. I suppose by outside walls you mean the outside walls of a house? If so, I may say that silicate of soda by itself will prevent rain from beating in, but not dampness arising from the foundation. Silicate of soda has been applied as a preservative to Cleopatra's Needle and the Houses of Parliament. There is one good property about silicate of soda which the silicate paints have not—viz., it does not alter the colour of stone.—W. L.

[47647.]—**Boiler.**—The following answer will, I think, meet "J. R. G.'s" requirements. The boiler A is of copper, about 1-16in. thick, brazed or riveted together, brazing being sufficiently strong for a model. The fire-tube B is 2½in. diameter, and is continued the whole length of the boiler. The flue C is carried through the dome D, thus thoroughly drying the steam before use. The water-filter being placed at E, it is impossible to overfill the boiler, for even if the water overflows at E there is ample steam room in the dome. The lamp that should be used is as follows:—A tank for spirit is placed at a certain position in the boat, so as to be above the fire-tube B. A brass tube about ¼in. diameter is carried from the bottom of this tank along inside the fire-tube, as shown. In the holes in the tube, F F F, are inserted bundles of fine brass wire, and the supply of spirit is regulated by a tap in the brass tube just where it leaves the tank. The boiler is 10in. long, 5in. wide, and 5in. deep; the fire-tube 2½in. diameter, dome 2½in. high, 4in. diameter; flue 1in. diameter, and is carried up the height required to make chimney look in proportion to the boiler.—Grapho.

END VIEW

[47648.]—**A Cabbage Broccoli.**—[Mr. R. Gilbert writes that if "W. T. B." will send him his address to Burghley-gardens, Stamford, a circular and full particulars of the cabbage-broccoli, or chou de Burghley, will be forwarded.—Ed.]

[47651.]—**Examination of Malt (Estimation of the Grape Sugar and Dextrine.)**—Preparation of the copper solution:—Dissolve 34·632grm. of pure re-crystallised sulphate of copper in 200cc. of distilled water; dissolve in another vessel 173grm. of perfectly pure tartrate of potassium and sodium (Rochelle salt) in 480cc. of pure solution of soda, specific gravity 1·14. Add the first solution gradually to the second, and dilute the deep-blue fluid exactly to 1 litre; 10cc. of this solution equals ·045grm. of starch or dextrine, or the same amount of the solution equals ·050grm. of grape-sugar. The dextrine will require to be converted into grape-sugar before it can be estimated; this is most conveniently done as follows:—Two or three strong flasks are taken, and into each is placed from ·5 to 1grm. of the substance to be examined, with 50 or 60cc. of decinormal sulphuric acid; the flasks are stoppered with caoutchouc corks, tied down with strong string, and capped with a piece of linen, and the whole suspended in a water-bath, and heated for from 6 to 8 hours. At the end of 4 hours one of the flasks may be taken out, cooled, opened, and titrated, and at the end of 6, the second. If there is no marked increase in the amount of sugar between the first and the second, the operation is finished; but in any other case the third flask should be heated for another 4 hours before being examined. As the dextrine is now converted into grape-sugar the two are estimated in exactly the same manner. Make the solution for examination up to exactly 50cc. Pour 10cc. of the copper solution into a porcelain dish, add 40cc. of water, heat to gentle ebullition and allow the prepared solution containing the grape-sugar to drop slowly into the fluid from an accurately graduated burette. After the addition of the first few drops the fluid shows a greenish-brown tint, owing to the hydrated suboxide of copper suspended in the blue solution; continue the addition of the solution, and when the liquid assumes a deep red colour remove the lamp, allow the precipitate to subside, and give the dish an inclined position, which will enable you to readily detect the least greenish-blue tint—to make quite sure, however, pour a small portion of the clear supernatant fluid into a test-tube, add a drop of the sugar solution, and apply heat. If there remains the least trace of copper salt undecomposed a yellowish red precipitate will form, in which case continue adding the sugar solution till the reaction is complete; read off the amount used—this equals ·050grm. of grape-sugar, or ·045 of starch or dextrine. When the operation has terminated, ascertain whether it has fully succeeded by filtering the solution while still hot, adding to the filtrate (which should be colourless) a drop of the copper solution and heating; this will show if the sugar solution has been added in excess. Acidify two other portions, and test one with potassium ferrocyanide, and the other with H_2S. Neither of these tests should produce the slightest alteration; if, however, a precipitate is produced, the experiment must, accordingly, be repeated. The results are satisfactory and constant. Bear in mind that the copper solution must always remain strongly alkaline. Should the sugar be acid a dilute solution of soda should be added in place of the 40cc. of water. Keep in a cool, dark place when not in use; but it is best prepared for such analysis. Calculation: Before we can find the amount of grape-sugar or dextrine, we must calculate how much malt the quantity of the solution used equals. Supposing we took 1grm., 50cc. would = 1grm. Suppose you used 25·7. If 50cc. equals 1grm. of malt, what does 25·7cc. = ·514. We have now found that the quantity of the solution used equals ·514grm. of malt, and as 10cc. corresponds to ·050 grape-sugar, ·514grm. of malt must, consequently, contain ·050grm. of grape-sugar. We then find the percentage thus: If ·514grm. of malt contains 0·50grm. of grape-sugar, what does 100?—J. C. Belcher.

[47663.] — **Railway Crossing.** — There are many patents in existence relating to "improvements in points and crossings," but the inventions have not come into general use. The best of these systems is considered to be the one designed by Mr. Williams, which is now receiving much attention. The diagram shows the Williams crossing. M represents the main-line rail, B the branch-line rails, and L the moving piece which provides the bearing surface for the wheels of branch trains when crossing the main line. Fig. 1 shows the crossing-piece L placed in position for a branch train, and Fig. 2 shows the piece L withdrawn, leaving a continuous and unbroken main-line rail. It is claimed for the system that it affords a perfect bearing surface throughout the crossing, and that as the piece L is moved over the main-line rail any desired degree of super-elevation can be given to the outer rails on curves. The movable piece L is attached by a rod R and crank to the ordinary point-rod, therefore the points and crossings are worked together. It may be mentioned that this system has been tried in

FIG. 1

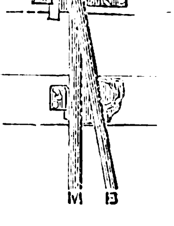

FIG. 2.

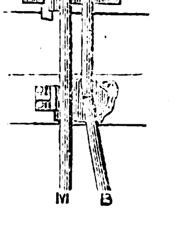

Scotland, and after a year's working it is officially stated to have fulfilled all that was promised regarding it, and that its use is attracting much interest in railway circles.—Clement E. Stretton, Saxe Coburg-street, Leicester.

[47673.]—**Electric Lighting.**—It is a pity "Caloric" should have such a warming towards the "Lampe Soleil" in preference to any other form of arc light, and after having carefully examined it be able to testify to "its simplicity, steadiness, whiteness of colour, and general perfection." I might as well inform "Caloric" that I have carefully examined, and had special experience with the Lampe Soleil, and have formed a very different opinion. In the first place, there is the building up of the box with six separate blocks of stone, which have to be filed to fit, and which takes up more time than changing the carbons in any ordinary lamp; also the marble, after the lamp has been lighted, calcines very shortly, absorbs moisture from the atmosphere, and falls to powder (lime). This necessitates building up another box. So much for its simplicity. I must admit its steadiness; but as to its whiteness of colour, I must say that a person who pronounces it a white light must be colour-blind, as it is a reddish, warm-looking light—hence its name. I even made the remark to the patentee himself as to its tinge, and he said, "Ah! you know it is de light of the sun; that (referring to another system) the light of de moon." As to its general perfection, it sometimes leaves an assembly in darkness, and will not relight without switching on another set of lamps (there are two lamps in each globe, in case one should extinguish itself). If the second set of lamps go out, you are altogether done. As to the h.-p. and other details, "John Bull" has explained them very fully and correctly. If "D." wishes the information as to how I have acquired my experience with the Sun lamp, if he will advertise his address in the "E. M." I will be most happy to supply it.—Practicus.

[47694.]—**Taking Top off Violin.**—You really must not do so, and in the case of the Berliner violin it is really not required; but it will not be long before our readers will be able to judge for themselves, and I hope to report progress myself. I forgot all about the soundpost when I recommended a fastening for the resonator through the *f* holes. Of course, it would be too close, and would absorb the return action of the vibrations. I think the adjustment of these patent vibrators will be very simple, as the needful appliances will no doubt be supplied.—Fiddler.

[47705.]—**Incandescent Lamps.**—The Leclanché battery is utterly unsuited for operating incandescent lamps, its work being confined to electric bells, &c., for which it proves eminently satisfactory. The Bunsen battery is certainly the best adapted for this kind of work. In order that you may have some idea of the number of quart Bunsens required, I may say that an incandescent lamp of the "Lane-Fox" type, and of 20-candle power, requires 26 of these—that is to say, 1¼ battery per candle-power. It is rather difficult to say with truth which is the best incandescent lamp extant; but I think it may be safely stated that the "Lane-Fox," if not the best, is, at all events, an excellent lamp.—John Bull.

[47705.]—**Incandescent Lamps.**—You cannot use Leclanché batteries for electric lighting—they fail after a few hours' continuous use, and weaken very much in a few minutes; they are only fit for purposes where the current is not wanted continuously, with long rests in between. Better by half use Bunsens. Swan's incandescent lamps may be had 5, 10, and 20-candle power, 6s. 6d. each. If "Medicus" will advertise his address, I will write him as to price of batteries.—Fred. W. Ball.

[47705.]—**Incandescent Lamps.**—Leclanché batteries are not constant enough. They give good current for short time. If you wish to fail, use them; but if not, try a more constant cell. I was experimenting a few weeks since with about 40 cells, and two carbon points, and after about half an hour power diminished very much, and the spark was not much to speak of at first.—H. Stooke.

[47706.]—**Plumbing.**—Refer to "Practical Notes on Plumbing," Chapter IX., English Mechanic, August, 1881. Nothing can be better for "Anxious" to know.—Plumber.

[47711.]—**Electrical Measurement.**—The formulæ quoted by "Student" are all correct, where C is measured in ampères, E in volts, R in ohms. In speaking of candles per h.-p., it is generally understood per h.-p. expended in the lamp, though some persons refer to the h.-p. expended on the machine. The former is of course correct. Since the ampère is merely another name for the old weber-per-second, a volt-ampère is the same as a volt-weber (per second).—Ll. B. A.

[47712.]—**Largest Dynamo and Coil.**—The largest dynamo ever constructed is Mr. Edison's installed on the Holborn-viaduct; it has four field-magnets placed horizontally. The armature consists of a steel shaft 6in. diameter, on which is mounted a wooden cylinder 12½in. The core of the armature consists of 53 thin iron discs, insulated from each other by tissue-paper; the total diameter of the core is over 45in.; in place of the usual wire 106 copper rods of nearly square section are used, and placed lengthwise; these average 52in. in length, are wrapped by machinery with special insulating paper, and covered by a special insulating material; they are also kept apart by vulcanised rubber encased in mica and placed about every 12in. to admit air. The whole armature is wound with steel wire, with double mica insulation beneath, to counteract centrifugal action. The resistance of this armature is as low as ·0049 ohm. Field magnets are wound with No 10 wire Brown's gauge; resistance, when connected, 6·11 ohms. The pole pieces weigh several tons. The armature is driven by a Porter-Allen engine, fastened on the same base and driving direct by main shaft, making 350 revolutions per minute, and of 125 indicated H.P. The E.M.F. of machines is 125 volts, and current 1,000 ampères, working 1,000 lamps of 16 candle-power. The entire weight of dynamo and engine, installed at 57 Holborn-viaduct, is 22 tons, and for comparison I may state that the 40-light "Brush" machine weighs but two tons. Largest coil was made by Apps, special pattern; length of spark 57in., constructed in 1868 for Royal Polytechnic, and sold this spring for about £16. Dr. Spottiswoode, F.R.S., has coil by Apps, spark 42in. Description in "Engineering," for April 20th, 1877.—Storey, Chemist, Parade, Canterbury.

[47712.]—**Largest Dynamo and Coil.**—I cannot inform "Electrician" who has the largest dynamo. The Brush Company had some fine ones at the Crystal Palace; but, probably, Edison, at Menlo Park, has larger. The largest coil is, I believe, one made by Apps, of the Strand, for Mr. Spottiswoode, of Sevenoaks. Its spark is 42in. long. The Polytechnic coil was the next, I fancy, as it used to give a 29in. spark till it broke down.—B. H.

[47717.]—**Problem.**—By writing $1/y$ for $x + 1$ the equation may be transformed into $5(y^2 - y)^2 + 5(y^2 - y) = a - 1$, when it is easily solved.—C. W. B.

[47720.]—**Oilstone.**—I don't know anything about softening an oilstone, nor do I see why it ought to be softened; but I do know that paraffin oil will quickly remove all clogged matter from its surface, which I conclude is all that is required.—J. J. A., Liverpool.

[47721.]—**Studying for Medical Profession.**—Means a preliminary examination for general education; for this many certificates are accepted in lieu, both English and foreign universities. If "Delta" has not such a certificate, the examination consists of the following: Writing from dictation; English grammar; English composition; arithmetic; geography of Europe, and especially British isles; English history; mathematics, Euclid, books 1 and 2; algebra, to simple equations; translation from "De Bello Gallico," and one of the following optional subjects: Greek, German and French grammar, and translation; mechanics; chemistry; botany and zoology. This enables the person to register as medical student, and it is not until after four years of professional study and registration as student that the "final" can be passed. Compulsory attendance at hospital about two and a half years. Scotch diplomas easiest and cheapest. More privately on addressing—Story, 1, Parade, Canterbury.

[47728.]—**Electrical.**—Could not say how many necessary. That is a matter for experiment. Siemens' alternating current-machine reverses 40 times per second or so.—E.

[47731.]—**Killing-Bottle.**—It is cheaper and better to buy; with care and a good cork always kept tightly in the bottle, it will last a season. They are made by alternate layers of cyanide and blotting paper or gypsum; mine kill in about half a minute. I generally leave the insects in all night, and when about half-dozen are in put a piece of blotting-paper over them to prevent damage.—John Alex. Ollard, F.R.M.S., Enfield.

[47733.]—**Switch for Telephones.**—If "F. C. M." will advertise his private address in next week's number of the "E. M.," I will send him drawings and a full description of a switch I made for myself, which is simple and answers the purpose well.—R. H. R.

[47733.]—**Switch for Telephones.**—There is no switch required. Connect up the set of instruments at Station C as you have done at A and B. Put on earth at the earth terminal of the C set, bring C's line wire into B's office, disconnect B's earth, and place C's line wire on the terminal that you have disconnected from earth. Your "circuit" should now be complete, A to C through B.—Science.

[47734.—**Microscopic.**—(1) Any you may fancy; (2) a binocular is not necessary; (3) one that will move in any direction freely without rack and pinion adjustment; (4) ½in. and ¼in. aperture—I don't know; (5) the eyepiece only enlarges what the objective defines. By using a more powerful eyepiece you get a large image, a less field, and less light. Powell and Lealand, 170, Euston-road, No. 3, £11 11s.; I do not know what accessories it has. Civil Service Stores, from £2 10s.; object-glasses, ½in. 40s., ¼in. 40s., ⅛in. collar adjustment, £6 10s. Shall be pleased to give any further information personally.—John Alex. Ollard, F.R.M.S., Enfield.

[47734.]—**Microscopic.**—To "O. O."—I would recommend a binocular, with removable prism, thus converting it into a "mono." The price named should secure a good instrument, and often a reliable one may be obtained second-hand. A good mechanical stage, with several motions, should be obtained—one which has also concentric rotation. Stand should have quick and slow motions, be free from vibration in all positions, and thoroughly well fitted. Spot lens is very useful in investigation on the animalcule. A 2 – 3 or 1 – 2 is the shortest focus that can be used with "bin"; and to possess a ¼ obj. and deep eyepiece all ordinary investigations may be carried on. If you will write me personally, stating your requirements, I will assist you.—Story, Chemist, Parade, Canterbury.

[47735.]—**Cataract.**—*Don't eat salt.* Notes would be too long for "E.M."—John Alex Ollard, F.R.M.S., Enfield.

[47735.]—**Cataract.**—"Architectus" should not trouble himself about his eyes as long as he can read comfortably in spectacles, and while his distant vision is good. He should be careful to have the right sight in the spectacles.—A. Howes.

[47735.]—**Cataract.**—Cataract is undoubtedly hereditary in some families, but you need not disquiet yourself prematurely. It is highly probable that you may escape altogether. The symptoms you describe are not those of cataract at all. It first interferes with distant vision. You should at your age always wear glasses for reading, especially by artificial light. Proper glasses, such as would enable you to read the small print in the English Mechanic at a distance of 10 or 12in. from the eye will not weaken your sight, but rather tend to preserve it. There is no remedy against the formation of cataract. Keep yourself in good health, mind and body, and you have the best chance of escaping. Laborious occupations, which cause profuse perspiration, undoubtedly tend to produce cataract; hence its greater frequency in the country than in the town.—Charles Ed. Glascott, M.D., Manchester.

[47735.]—**Cataract.**—May I be allowed to call attention to Dr. J. Compton Burnett's "Supersalinity of the Blood; an accelerator of Senility and a cause of Cataract"? I have not seen the work, but only a review in the *Dietetic Reformer* for August, wherein appears the following quotation, amongst others: "If salt can cause cataract in the lower animals, it may be fairly inferred that it possesses a like power over the human body."—Spes.

[47737.]—**Black Shellac Varnish.**—I find the best way to make and use sealing-wax varnish is as follows:—First make a solution of shellac in methylated spirit; also keep separate in a small box some kind of black pigment in fine powder (such as ivory black), dip the brush into the varnish, and then into the powder, and lay it on as thick or as thin as you like. You can use, instead of black, vermilion or ultramarine, if those colours are desired. This is the only method by which I have been able to obtain a perfectly opaque coating.—Os.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last H. Stooke has replied to 47721.

QUERIES.

[47743.]—**Discharge of Egg-shaped Sewers.**—In a translation of "Molesworth," the following formula is given for calculating the discharge in egg-shaped sewers $\frac{2}{3}$ full :—

$$Q = 19{\cdot}320 \sqrt{d^5 \frac{f}{l}}$$

Q being discharge in litres per second.
d = diam. (I presume, diam. of large end ?).
f = fall.
l = distance.

I fail to see any connection between diam. raised to 5th power and the discharge, and should feel obliged to any mathematical reader of the "E. M." who could enlighten me on this formula, or give a more comprehensible one ? In "Abstracts of Papers in Foreign Transactions and Periodicals," Vol. LXVII, p. 25, Session 1881-2, Part II., published by the Institution of Civil Engineers, in a report of various sewage works in Europe, the discharge in egg-shaped sewers in cubic metres per second, is calculated by the following formula :—

$$\text{Log. } D = 2{\cdot}0803 + \frac{5 \log. r + \log. s}{2}$$

D = discharge in cubic metres per second.
r = mean radius (whatever that may mean).
s = sine of slopes, the form being egg-shaped, and width $\frac{2}{3}$ of height, and $\frac{2}{3}$ full.

This formula appears to me to be just as unsatisfactory as the former. By sine of slope, I presume is intended fall per metre. How is the total area of an egg-shaped sewer calculated ? The proper proportions should be, I think, diam. large end = $\frac{2}{3}$ height; diam. small end = $\frac{1}{3}$ height.—Etna.

[47744.]—**Trigonometry.**—I shall be glad if any one will solve the following :—

$$\text{Tan} \frac{a + B}{2} + \tan \frac{a - B}{2} = \frac{2 \sin a}{\cos a + \cos B}$$

—Constant Reader.

[47745.]—**Palpitation of the Heart.**—Will any medical friend tell me of a cure for palpitation of the heart ? Is it heart disease or not ?—A Subscriber.

[47746.]—**Terra-Cotta Paintings.**—Can any reader inform me the cheapest and best preparation for preventing terra-cotta paintings from being spoilt when washed ?—A. C. S.

[47747.]—**Legal.**—I filed my petition in 1877, and the first meeting of creditors broke up without passing any resolution, and no further proceedings of any kind were taken under the petition, nor by any individual creditor. If I am sued for any of the debts contracted prior to the date of the said petition after May 1883, can I successfully plead the Statute of Limitations ?—W. A. B.

[47748.]—**Pickles.**—Some ten or twelve years ago I saw amongst the answers to queries in the Mechanic a recipe for making pickles, signed "Sweedlepipe Cottage." My wife made a large quantity at the time, and they turned out superior to any we had ever met with. Somehow or other, she has lost the recipe. Could any reader furnish me with it ? I have searched through my old Mechanics, but cannot come across it.—Amateur Gardener.

[47749.]—**Polarised Relay.**—Will Mr. Lancaster, or some other able correspondent, kindly explain the make of a polarised relay ? Also, should steel prepared for magnetisation be made dead hard, or have its temper drawn at all ?—G. R. E.

[47750.]—**Polishing Wardrobe.**—I have made a wardrobe of spruce, and not being a practical hand, there are a few places I have had to fill up with putty, and I find that after I come to polish, I can see the marks of the stopping after the polish is applied, but not before. Can anyone tell of a remedy to avoid this ? I don't care if it covers the grain, if it is something I can polish or varnish on ; but I don't want to paint. Any plain instructions would greatly assist.—Amateur.

[47751.]—**Declination Circle.**—My circle has two verniers, and when I am reading the declination of an unknown star, how am I to know whether it is N. or S. ? The two verniers give me the same declination, whichever I read from ; but one will be N. and the other S., and how am I, therefore, to know which I ought to read from ?—Brickwall.

[47752.]—**The Flux of Soap.**—Will Mr. Allen kindly inform me what is meant by the so-called "flux" of soap ? Lately, I have come across the word in the *Chemical News* and other papers, but cannot find out its meaning.—Inquisition.

[47753.]—**Polishing Piano-Keys.** — To Mr. Davies.—I want to scrape and polish my piano-keys. Would it be be best to scrape and polish each key separately, or keep them on the key-frame and do them altogether (of course, removing the black-keys), as you direct for a new set ? Also, should I use putty or pumice powder ?—J. Jones.

[47754.]—**Tin.**—I have about 100 tins that have been imported with castor-oil in them. Is there any means of disposing of them, or have they all to be thrown away ? If some kind reader of ours can suggest a means of making something out of them, he will oblige many, I dare say, besides—Soap-Boiler.

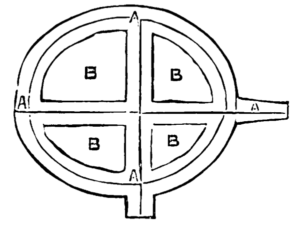
[47755.]—**Heating Henhouse.**—Will somebody kindly tell me the best way to heat a henhouse ? Would a pipe with hot air, heated with a lamp running the whole length of the floor, and back again, be sufficient ?—Jingle.

[47756.]—**Electro-Plating.**—Will Mr. Lancaster, or other kind reader, inform me of the best instrument in use for measuring the intensity of the electric current from the batteries used for electro-plating ? Also, please give instructions how to make, or say if it would be better to purchase the instrument ?—Galvanometer.

[47757.]—**Manganese.**—Will Mr. Allen, or other of our chemical readers, say what the impurities are in commercial manganese ores, and give particulars how to analyse them ?—Chlorine.

[47758.]—**Carbolic Acid.**—Will Mr. Allen, or other of our chemical readers, inform me how to analyse carbolic acid quantitatively, and to estimate the quantities of the impurities usually found in the commercial article ?—Disinfectant.

[47759.] — **Archæological.** — Will some of our antiquarian friends kindly tell me what the inclosed is,



which I came across when walking in the South of Scotland, about three years ago ? I may mention that the neighbourhood abounds in cairns, camps, &c The parts marked A are raised about 18in., and are half-circle in shape, the insides B being the level of the outside ground.—A Would-be Piper.

[47760.]—**Tinning and Galvanising Iron.**—I shall be obliged if any reader can give me information about the tinning and also the galvanising of iron by the electro process ; whether, since the introduction of the dynamo-electric machine, there is a likelihood of the electro process superseding the ordinary dipping process ? Also, which process is the more economical in regard to price, and which produces the best article ? I think I have seen an objection stated somewhere that the coating was more porous—and not so homogeneous—by the electro process than by the ordinary process.—Tin-Plate.

[47761.]—**Steam-launch.**—Will some kind reader help me with the following information ?—I want to build an iron sea-going steam-launch, strong enough to stand *any gale*. What size angle-iron, what thickness sheet-iron—steel or iron, which ? Should the iron be put on in narrow strips or broad pieces ? What power engine to steam 20 miles an hour without strain in smooth water ? Would a boat 45ft. long, 8ft. beam, 7ft. deep l.w.l., and 3ft. freeboard carry enough coal for eight days ? What would be about cost of engine, boiler, propeller, &c., complete ? Living in the jungle, I would like to build above in spare hours. Have built two wooden boats : no experience in working with iron.—Indigo Planter.

[47762.]—**Insects in Fernery.**—Can any of ours tell me of a simple means of destroying insects without injuring the ferns, in a small fernery ? It is about 4ft. by 1ft. 3in. by 3ft. high, fitted in the window outside ? It is nearly airtight, and all appear to thrive fairly well, except Adiantums : these do not get along as I should like. I get very little sun, often none. Is it advisable to water them so long as the soil is moist ? If so how often ?—Boswell.

[47763.]—**Osier-growing and Basket Making.**—Will any reader kindly give information or say if there is a work published on osier-growing and basket-making ?—Dolomite.

[47764.]—**Greenhouse.**—To Mr. Wetherfield.—I have built a greenhouse in garden, the back supported on a 4½in. wall that abuts against the garden wall. I am leaving the house at Christmas, and intend giving notice to my landlord at Michaelmas. I am told that if I take it down before I give notice to quit, I can do so with impunity. Is this legal ?—Douglas.

[47765.]—**Preserving Eggs.**—Can any one tell whether silicate of soda is of much use in preserving eggs ? I have heard that if eggs are coated with a solution of this substance they keep a very long time. If any one can give me their experience in this matter, I shall be much obliged.—A. M. R.

[47766.]—**H.M.S. Ajax.**—Can any reader kindly give me a short description of the engines of this ironclad, which is at present in Chatham dockyard ?—H. W.

[47767.]—**American Loco.**—Can any one tell me what that American loco. that ran from Manchester to Leeds on the 15th, and from Leeds to Doncaster on the 16th of last March, has been doing since those dates ?—H. W.

[47768.]—**G.N.R. Engines.**—I should like to know how many 8ft. single engines there are on the G.N.R., and where they are all stationed ?—H. W.

[47769.]—**Wire for Induction Coils—Incandescent Lamps.**—Would any subscriber kindly tell me whether No. 36 cotton-covered wire will do for induction coils, as I have a quantity, and should like to make use of it in that way ? Also, the filament for incandescent lamps. What is principally used—platinum wire or carbon filaments ?—Amateur Electrician.

[47770.]—**Preventing Rust.**—I have in a glass case a quantity of cutlery and other steel goods which, from exposure, have become covered with rust. I should, therefore, be glad to learn of some method of preventing the rust. The case is against an outside wall, but is well lined with board. I have been told that by keeping a small but constant supply of heat in the case by means of a small lamp or a jet of gas, and making the case as airtight as possible, the corrosion would be prevented. Would this be effectual, or would the gas, as I have heard, increase the evil ?—W. P. M.

[47771.]—**Dead Black for Brass.**—Will some obliging fellow-reader tell me the best method of doing this ? I am told that it is done with nitrate of silver and sulphate of copper, or with dilute acid and heat, or with chloride of platinum. What I want is the "modus operandi." I can get nothing approaching a black with chloride of platinum. What I have seen on instruments is dead black, with no lacquer on it, and evidently produced by chemically acting on the metal.—One in a Fix.

[47772.]—**Henley's Discharge.**—Will any reader give me full directions how to make an "Henley's Discharger" (for a coil) ? About medium size will do.—A. Chapman.

[47773.]—**Voyages in Small Craft.**—Will any of your numerous readers inform me where I can procure books or accounts of voyages in small craft ? I have been much interested in reading the "Log of the Little Western," and should like works of a similar nature. Accounts of cruising round the British coast would also prove interesting. Probably, many of your readers have themselves made similar voyages. Should this be the case, and they would give detailed accounts of the cruise, it would doubtless be interesting to others as well as—Aconite.

[47774.]—**Cutters for Use in Lathe.**—Would any mechanic well up in wood-cutting machinery give design of cutters that would round the ends of brushes to any template, and put the hollow usually seen in the edge of brushes, cutters to run in lathe, and to do the work speedily ? I have cutters on the same principle as circular moulding machine, made to run in common lathe, but find great difficulty in holding the brush to the cutters, as they tug it out of my hand ; but running the cutters horizontal in lathe has the advantage of right and left cutting, and running them vertically you have the advantage of the table to rest and steady the brush, but can only cut one way, and would cause extra expense to have two spindles with cutters. By giving a hint how these brushes are finished by machinery, will greatly oblige.—J. C.

[47775.]—**Staining Sycamore.**—Would any friend give directions how to stain sycamore to resemble American birch ? Water-stains do not suit. Sycamore to be stained are veneers glued on to ground-work.—J. C.

[47776.]—**Reading the Morse Code.**—As this, I believe, consists wholly of dots and dashes, will some one explain how, in reading, the termination of one letter or word is distinguished from the commencement of the next—thus : A being a dot and a dash, and N a dash and a dot, how can AN be distinguished from WE, which would be dot dash dash dot ?—M. E.

[47777.]—**Cloud Negatives.** — Will any reader kindly give instructions for printing clouds into the skies of landscapes so that no join is visible ? Are both the landscape and cloud printed simultaneously ?—Glen.

[47778.]—**Whitewashing.**—Can any of "ours" tell me the cause of ceilings or brickwork drying with yellow stains in it after being carefully washed off and whited (two coats) ? Is it because the work was not dry enough before whiting, or is it due to any chemical present either in plaster or brick, or does the ultramarine blue I put in the whitewash have any effect ? I have done many a ceiling and staircase, but am seldom troubled by these stains. Can any of "ours" tell me the cause and how to remedy it ? I am now doing some brickwork which persistently turns up a brownish yellow half-hour afterwards.—A. Hunt, Lambeth.

[47779.]—**Soda - Water Siphon.**—Can any of "ours" give me the method of filling soda or potash water siphons ? Is the gas forced in by means of a pump or generated in the bottle itself ?—Phenol.

[47780.]—**F.C.S.**—I should be glad if some of "ours" would give me the qualifications required to become a "Fellow of the Chemical Society," and also a "Fellow of the Institute of Chemistry."—Phenol.

[47781.]—**Gold-Dust.**—Is there not some liquid for mixing with gold-dust for painting besides that sold with the gold dust ?—Artist.

[47782.]—**Confectioners' Oven.**—What is the best kind of oven for a confectioner's use (that is an iron oven), not a very large size ?—R. Barraclough.

[47783.]—**Legal.**—To Mr. Wetherfield.—A. (father) transfers certain property in trust of B. and C. (gentleman and unmarried lady) for his daughter, D., about to be married. Marriage takes place ; A. dies ; trustees act jointly in interest of D. Somewhat later B. (the gentleman trustee) also dies, leaving C only (unmarried lady) as acting and sole trustee. Eventually, C purposes marriage.—What becomes of the trusteeship ? Can C., when married, continue legally to act as trustee for D., or does the husband of C. obtain any controlling rights over the trust property, or does the trusteeship altogether cease, and in that case how is the trust property to be dealt with ? Can D. claim its being paid to her ? Kind advice in this difficulty will oblige:—Marienberg.

[47784.]—**Cistern.**—A cistern holding 1,200 gallons is filled by three pipes, A, B, C, together in 24 minutes ; the pipe A requires 30 minutes more than C to fill the cistern, and 10 gallons less run through C per minute than run through A and B together. Find the time in which each pipe alone would fill the cistern.—Sheffield.

[47785.]—**Bisulphite of Lime in Beer.**—Will Mr. Allen give a test for this ?—R. G.

[47786.]—**Bisulphite of Lime in Beer.**—To Dr. Edmunds.—It is no secret that this is used extensively to preserve beers. I am drinking the bottled beer of a leading firm of Burton brewers, and can smell it when I draw a cork. What will be the effect on the system if taken for a long time, say a year ?—R. G.

[47787.]—**Marine Engineering at Woolwich Arsenal.**—Will any reader kindly inform me whether it is likely employment can be obtained as marine engineer at Woolwich Arsenal, and to whom should application be made ?—S. H. F.

[47788.]—**Lending Money on Title Deeds.**—If a person lends money to a building club, and the trustees of the club find and hand over the deeds of property belonging to the members of the said club as security to cover the amount lent, would the lender be fully secured by the above transaction in case of the club coming to grief ?—Thos. Brown.

[47789.]—**Tent.**—I have a canvas tent erected for preaching, and find when it rains the water drops through, to the great inconvenience of the congregation. Can anything be done for it to make it watertight, and still be as pliable as at present, and by no means the light inside to be interfered with? It is often put up and taken down and transferred to another place.—James Wharton.

[47790.]—**Mechanical Lantern-Slides.**—I should be very much obliged if some reader would give a description of some of the various mechanical slides that are sold, some of which are: rippling water, the chameleon, the choreutoscope or lantern actor, the wheel of life, &c.—Grapho.

[47791.]—**Loan.**—Would Mr. F. Wetherfield be good enough to inform me on the following question?—I obtained a loan about a month since for £40, for which I gave a bill of sale on all my goods and furniture. I paid up with the amount all my liabilities but two, one for amount of £2, the other £15. Can either of these individuals sue me through the County Court, and distrain any of my property under the circumstances if I am not in a position to pay, or what course can they take in the matter? I may say the amount for £2 is the balance of an account for which plaintiff obtained judgment in the Court, but I have been unable to keep up instalments. The summons was issued previous to my giving a bill of sale.—Timid One.

[47792.]—**Staining Glass Green.**—What is the best means of staining ordinary window-glass green. Can it be done by a chemical solution? If so, what are the ingredients?—An Old Contributor.

[47793.]—**Electro-Plating.**—Seeing in a work on electro-metallurgy that a silver-plating bath should be made "by dissolving one oz. of nitrate of silver in distilled water, and adding cyanide of potassium in just sufficient quantity to precipitate all the silver as cyanide of silver," I got the cyanide of silver easily by these directions, being a white ppt. when first thrown down, but it soon became brown—by the action of sunlight, I presume. It is the second part of the process that has gone quite contrary to my expectations, as the directions say, "to the cyanide of silver thus produced add 3 oz. of cyanide of potassium, when the cyanide of silver (which has previously been covered with a gal. of water) will be immediately dissolved. Stirring expedites the dissolving." Now I added 6 oz. of cyanide of potassium (commercial) to the cyanide of silver, and only succeeded in 24 hours in dissolving half of the ppt., the other half remaining as a brown mass at the bottom of my electro-plating bath. Will some of ours kindly say where I have gone wrong, and say whether the solution is now useless, or can I repair it in any way?—A Beginner.

[47794.]—**Legal.**—Having been made a bankrupt a year or two ago, and the trustee and committee of inspection had given their unanimous consent to my order of discharge, which, I was given to understand, is to be had for the asking, would Mr. Wetherfield kindly inform me if I can obtain it by myself, and if so, what fee, if any, I should have to pay to the Court official? And if I do not trouble about getting it at all, what effect this would have on any future earnings or property that might come to me?—W. A.

[47795.]—**Riveting China.**—To "Alfojoe."—Kindly say how the brass or copper wire used for rivets is tempered, and, also, how to give the rivets a little spring so as to catch under the holes on the inner side?—A Young Amateur.

[47796.]—**Electrical.**—I have had my field-magnet cast in best iron, also the armature. I have wound the E.M. with 30lb. of No. 10 wire, and properly insulated the whole. I am now waiting to see if I can obtain any guide how to wind the armature for quantity, as I want the machine for electrotyping. Also, the size of the wire? A small sketch of the connections would be of great assistance to me. I have no doubt that many of our readers are stuck fast in the same place as myself. What is required is for some one to give answers to the following questions:—How much wire should there be on E.M., and the size B.W.G.? How much on the armature, and the best form of ditto? How to wind the machine for quantity and intensity? How many revolutions per minute, and a small sketch to show connections?—W. T. W.

[47797.]—**Legal.**—A person who owed me eight guineas has recently (in April last) filed his petition, and a dividend of 2s. 4d. in the £ was declared. As the bankrupt did not schedule my debt, I did not know of the liquidation till a week ago, and am informed there is no dividend reserved for me. The liquidator is now living with and on his mother-in-law. How can I obtain any of my money, and is the bankrupt criminally liable for not scheduling my debt?—Ramchullunder.

[47798.]—**Heating by Steam.**—In manufacture certain articles have to be subjected to a temperature of 212° Fahr., either boiling water or steam, as the case may be; but would the same effect be produced when using that process at an elevation of 4,000ft. above sea-level, at which elevation water boils at a considerably lower temperature—viz., 204°, and where, I presume, the steam would likewise be of the same diminished temperature? In this latter case, would it, or would it not be necessary to subject the articles to steam under pressure, in order to have the temperature of the steam to be used raised to 212° Fahr.?—No Name.

[47799.]—**Small Battery.**—I should be obliged if Mr. Lancaster or some other of your kind correspondents would tell me if it is possible to make a small electric battery to inclose in a small vessel about quarter the size of an ordinary tumbler-glass that would not be in action excepting when the elements were brought in contact by the pressure of a spring or screw, and if such a battery could be constructed, could it be made to produce about 70° Fahr. of heat in another vessel of similar size?—Highfield.

[47800.]—**Deodorising Oil.**—I have bought at a sale a quantity of mineral oil 905 which is strongly impregnated with nitro-benzol. Will Mr. Allen, or other, kindly say how this smell can be taken off?—charcoal, chloride of lime, chloride of zinc do not affect it in the least.—Oleo.

[47801.]—**Re-Olification.**—Can an oil partly saponified by caustic soda or other alkali be retransformed into transparent oil without injuring or darkening the oil? Shall be glad of suggestions or process.—Oleo.

[47802.]—**Legal.**—To Mr. Wetherfield.—A man having married within the table of affinities prohibited by the Church, desires to make his will, leaving all he possesses to his wife for life, with remainder to children of said marriage on her disease. How should he word his will to do this effectually? The said marriage was solemnised in Church of England.—C.

[47803.]—**Third Grade Art.**—I have passed the examinations in the Second Grade, and am desirous of sitting for the higher grade in May next. Circumstances will prevent me attending any classes. I shall be glad of any advice for self-instruction. I shall be able to visit South Kensington Museum occasionally. Would it be possible to do some of the drawing from casts, &c., there?—L.

[47804.]—**Model Engine Cylinders.**—Can anyone kindly tell me the best way to chuck and bore model engine cylinders ½in. and ⅞in. bore? Would a twist drill bore them truly? If not, kindly say the best way to do them.—A. G. W.

[47805.]—**To "Jack of All Trades."**—Will he kindly say what size and pitch of screw-propeller will a compound surface condensing-engine drive cylinders 2in. by 3½in. by 4in. stroke? And, what size of horizontal tubular boiler suitable for the same? and oblige—Coquet.

[47806.]—**Chemical Lung or Sanitary Punka.**—Will someone kindly give a working drawing of a sanitary punka? I think it was noticed some time ago in the *Lancet*, but am not sure. I wish to have one made for a sick friend.—Amateur Printer.

[47807.]—**Gas Water-heaters.**—Will some correspondents, unconnected with the trade, kindly give me their opinion, from practical knowledge, of the advantages and disadvantages of instantaneous (gas) water heaters for baths, especially with reference to the only forms I have heard of?—viz., Maughan's and Braby's.—M. D.

[47808.]—**Telephone.**—To Mr. Lancaster.—Having made two of Bell's telephones, I cannot get them to speak at all. I have made them with a copper reel split, and ½oz. of 36 silk-covered wire on each reel, and all the results I can get when I attached them to a battery is a ticking noise in them, and the same when I put the microphone to them—I can get no better results. Will you please to say if I have enough wire on the reel, and to say what is the best sort of a reel?—W. H., Liverpool.

[47809.]—**Legal.**—To Mr. Wetherfield.—The father A. made his will in favour of his daughter B., who was then married to C. The words of the will are the following:—"I A. give and bequeath the several houses and gardens, situated at ————, unto my daughter B., the wife of C., and her assigns for ever." The daughter B. died some years ago, leaving several children, of which two daughters are still living. The husband C. has married the second time. It is understood that he has lately sold a portion of one of the above gardens to a neighbour living close by. Now, will you kindly answer the following?—1. Is the will valid in favour of the two surviving daughters? 2. Has he a right to sell that portion of the property. 3. If not, what is to be done in order to repossess it?—Petros.

[47810.]—**Heating Soldering Iron.**—Would "Jack of All Trades," or any other brother-reader, be good enough to give me a simple method of heating soldering iron at the bench, where gas or a fireplace would be inconvenient?—T. J. O'C.

[47811.]—**Electric Pendulum.**—Would Mr. Lancaster be so kind as to instruct me how to make an electric pendulum for a clock? Also, the simplest method of transmitting the motion of the pendulum to the works?—T. J. O'C.

[47812.]—**Hydraulic Cylinders.**—There seems considerable difficulty in casting these perfectly tight when kept for 24 hours under pressure. I have a number of small ones to cast for tobacco-pressing, and would be glad to know whether any liquid put inside would close the pores through which a damp sweat exudes? Or, whether any special mixture of iron is required?—Pig-iron.

[47813.]—**Transit of Venus.**—I must tender my hearty thanks to the correspondents of "ours" who have so kindly given me information as to the suitability of Jamaica for observing the approaching transit. The local times and altitudes given by "S. G." are of the greatest value, and he has my sincere thanks for the trouble he has taken. I must also acknowledge my indebtedness to "S. B." for the full and interesting details he sends. Would he kindly give his reasons for selecting Southern Port Royal Mountains? Also, recommend some exact locality, keeping in view ease of access from Kingston, and suitability in other respects? Any information as to local travelling, living, precautions to be taken as to clothing, &c., would be most acceptable. I called at the R.W.I.M. Co.'s offices the other day, and find that in all probability there will be a numerous party of observers, as some passages are already taken by men going out for that purpose.—Jamaica.

[47814.]—**Photographic.**—Could any reader kindly put me right in the following difficulties?—1. My toning bath, after a few days, becomes of a dark indigo colour, and the gold is deposited in a black precipitate in the bottle, although kept in the dark. I wash my prints thoroughly before toning in three changes of water, but then I only float them face downwards. Should they be immersed? My bath is composed as follows:—Acetate of soda, 4½ drachms; chloride of gold, 9 grains; water, 45oz. This formula is the one recommended by Wratten and Wainwright. 2. My negatives have frequently dull-looking spots all over them, which sometimes show faintly in the print, and sometimes not at all. I should be glad to know what causes these, as my chemicals are all pure and clean. Also, my fixing and alum baths. I use dry plates. 3. My negatives have a great many "pin-holes," although I take the precaution of brushing them very gently during development with a very soft badger hair-brush. Any hints will greatly oblige—Negative.

[47815.]—**Thermopile.**—Will Mr. Lancaster, "Sigma," or some other competent authority, kindly answer the following questions?—If a thermopile were made of 100 pairs of copper and iron plates 6in. long, ¼in. wide, and, say, 1/32in. thick, and a difference of temperature of 80° Centigrade were maintained between alternate junctions, would the E.M.F. equal that of a Daniell cell? Would not the resistance of such a pile be lower than that of a Daniell cell? What would be the difference of current from a couple of bismuth and antimony, and from another of iron and copper, the other conditions being equal? Would the former give double the power of the latter?—J. N.

[47816.]—**Silicate of Magnesia.**—Will Mr. Allen or other of our kind readers inform if it is possible to form silicate of magnesia in the cold—e.g., by adding silicate of soda to carbonate of magnesia? I have no furnace, and I want to prepare a small quantity. What method could be recommended?—Magnesite.

[47817.]—**Rapid Electro-Plating.**—I have seen articles rapidly silvered by first dipping them into a copper bath and then into the silver solution. How are the solutions made up?—A Seven Years' Subscriber.

CHESS.

All Communications for this department must be addressed to the Chess Editor, at the office of the English Mechanic, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLXXV.—By J. Pierce.

2. Mates.	

PAUL MORPHY.

An Acrostic.

Paled is thy light, so bright
A Pleiad pass'd away:
Unrivall'd star, afar
Lost to our sight, for aye.
Midst wondering gaze, thy blaze
Of glory ceas'd to burn:
Resume thy sway, bright ray,
Proud conqueror, return:
Here do we wait and watch in vain.
Yet time flies on—no hopes remain.

F. F. Beechey

NOTICES TO CORRESPONDENTS.

There is a second solution to 763 beginning 1. Q to K 3.

Correct Solutions to 768 and 769 by W. A. Lee; to 771 and 772 by Schmucke.

W. A. Lee.—770 is, we believe, correct.

W. T. Bayne.—The acknowledgment appeared in last number.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Aug. 23, and unacknowledged elsewhere:—

Morris Cohen.—W. A. Thoms.—R. S. Smyth.—Selig, Sonnenthal, and Co.—W. Robertson and Co.—Whitley Partners.—Newton and Co.—Iskender.—L. J.—S. W. Burnham.—W. P. M.—A. Manock.—Vesuvius.—E. A. Brookes.—Anxious.—M. P.—G. W. Tee.—J. F.—Amateur Farmer.—Grapho.—J. H.—P. B.—J. W. Fleming.—Orderic Vital —S. P.

A NEW VOLUME.

The next number is the last of volume XXXV. Readers willing to oblige us by recommending "ours" to new subscribers should do so now, when a new volume is commencing. The index to Vol. XXXV. will be published in the number dated Sept. 22, and cases and bound volumes will be on sale shortly after. Readers desirous of making up their sets for binding the present volume are recommended to do so at once, as the back numbers soon run out of print.

A. Cowlishaw. (Yes, in the majority of cases, and nearly always if ordered through a bookseller.)—Harry Smith. (1. No, if he is in earnest. 2. As an assistant, from £1 upwards, according to ability. 3. Yes. 4. Perseverance and determination, as in most other avocations, are better than mere cleverness. 5. An army corps specially devoted to engineering. You are too old to join, we think.)—Argentum. (Price 6d., published by Cousins and Co., 3, York-street, W.C.)—T. E. D. (You must sue the sisters by their names. County Courts do not recognise "Mrs." or "Miss.")—Y. Z. (We do not understand how the local board can exist without by-laws or regulations. The probability is that the Board is acting within its authority, but if you think you have a good case, you can dispute it, and let the Board summon you before the local magistrates.)—F. Gartside Tipping. (We know nothing of him, and, of course, do not guarantee the honesty of any advertiser. Write to him that you have communicated with us, and if no satisfactory explanation is forthcoming no further advertisement of his shall appear.)—M. C. H. (We can only suggest paste. Such a mucilage as you appear to require would be a valuable commercial article. 2. Black is the correct answer, for without light there can be no colour.)—Parvus Vir. (The heat depends on the kind of plants you wish to keep. Gas, if you can get it, would be the best heating medium, all things considered; but for so small a house one of the paraffin-oil stoves might suffice.)—Barometer. (Yes, the wire "did it." To get the air out, heat the tube and tap gently on end.)—An Amateur. (He has already done so. See pp. 415, 583, Vol. XXXIII.)—Tom B. (Known as Pharaoh's serpents. See p. 485, No. 513.)—Chime. (See the back numbers, or consult an elementary manual on Sound.)—H. Walker. (It is a troublesome job. Try heating and shaking. If that is of no avail you must take it to the optician.)—J. Noon. (It is tolerably well known. You will find something about it on p. 146, this volume. We omit nothing of a practical character.)—Poor Oilman. (You must really refer to the indices, where you will find references to all kinds of telephones, &c.)—W. D. J. (See one of the cheap manuals on pyrotechny, for a full list of the recipes would occupy a column. Blue, metallic antimony 1 part, sulphur 2 parts, nitre 5 parts. Red, sulphur, sulphuret of antimony, and nitre 1 part each, dried nitrate of strontia 5 parts. Green, nitrate of baryta 60, chlorate of potash 18, sulphur 22. The eggs are abominable things. Recipe in No. 513, p. 485.)—E. S. Jones. (There is Reid's "Engineer's Handbook." Get Mr. Calvert's catalogue from Great Jackson-street, Hulme, Manchester. Most books of the kind are entered there.)—Hammer. (We scarcely understand what you mean by "sizes." They are made to numbers, and those can be learned from actual inspection of the machines or from the maker's lists.)—An Afflicted One. (See Dr. Edmunds' reply on p. 430.)—J. C. (You must look in back volumes, or procure some of the illustrated price lists of makers.)—Electric Seeker. (See p. 286, No. 811.)—Co. Limerick. (Lockwood and Co., Stationers' Hall-court, E.C., publish a little book for 6d., entitled, "The Safe Use of Steam," which probably will answer your requirements; but if you want more, the same publishers issue Mr. Reynolds' "Stationary Engine Driving" at 4s. 6d.)—M. E. (You may safely use half a dozen Léclanchés with such a coil. See p. 529. 2. The process has been frequently described. A mould of the type, &c., is taken in plaster or guttapercha, say, and carefully blackleaded. It is then put into the bath, and when the shell of copper is thick enough it is heated, and the back filled up with solder and the usual stereo metal.)—Ignor. (See reply on p. 503.)—G. B. T. (You do not answer the question—how do you get the air out again? You say the "ascending piston would have to rise against the compressure of the inner elastic air, and not against the pressure of the whole atmosphere." The pressure of the elastic air, unless removed by a pump, would therefore be greater than atmospheric pressure, which, with a reduction for friction, is all you have at the other end of the "perpetual motion" machine. If you would make a sketch and calculate the pressures, you would speedily discover the fallacy.)—John P. Davies. (We have failed to find the point of superiority in the brake, which would apparently be very costly. Does it not involve close coupling? If so, that would be an objection.)—Nonplussed. (See Mr Davies's papers on Pianoforte-making in Vol. XXVII., and those on Piano-Soundboards in Vol. XXXII. Your case seems one of those in which personal examination is necessary.)—A. P. (Described on p. 570, No. 778. It is a metallic sulphide mixed with sulphur. It might do for large type, such as is used in posters.)—W. G. (You must consult recent papers on Telescope Construction. 2. You must make a small magneto-electric machine, details of which have been frequently given.)—Electric Mad. (See recent back numbers. You should procure a description of that at the Crystal Palace; but where do you propose to lay it down, or do you want to make a "model"?)—Sufferer. (Recipes of the kind have been given many times.)—One who would Like to Know. (No doubt due to the air; but the correspondent named answered similar query a little time ago.)—A Seven Years' Subscriber. (Query inserted, but if you want a durable coat you must "take a long time.")—An O. B. (Which branch?)—Pecheur. ("The Lathe and its Uses," Trübner, 16s.)—W. J. W. (See p. 284, No. 818. The subject is scarcely suited for a "reply," and if you have no knowledge of such work you ought to get a book on the subject. Donaldson's "Platelayer's Tables," for instance, or one of the books in Calvert's catalogue.)—J. S., 13 Years' Subscriber. (Nos. 529, 696, 734, 847, 856, and 876 can be had, post free, 1s. 3d. The others are out of print.)—Jumbo. (Dr. Edmunds has already intimated that he will be abroad till the middle of September, and therefore unable to reply to queries till then. He has also several times refused to prescribe in such cases as you inquire about, and with good reason.)—T. McE. (If you order Vols XXIX., XXX., XXXI., XXXII., XXXIII., and XXXIV., and all numbers to date of Vol. XXXV., through your bookseller, you will get the series complete. Price £2 6s. 3d.)—Engineer. (You cannot do better than use Leroy's composition, but here is a good recipe when nothing better is to hand for covering steam pipes:—Four parts of coal ashes, sifted through a riddle of four meshes to the inch, one part calcined plaster, one part flour, one part fire-clay. Mix the ashes and fire-clay together to the thickness of thin mortar, in a mortar trough. Mix the calcined plaster and flour together dry, and add to it the ashes and clay as you want to use it. Put it on the pipes in two coats, according to the size of the pipes. For a 6in. pipe, put the first coat about 1¼in. thick, the second coat should be about ½in. thick. Afterwards finish with hard finish, same as applied in plastering a room. It takes the above about two hours and a half to set on a hot pipe.)—Gereb Admi, H. Stocke, P. H., C. H. Romanes, T. J. O'Connor. (In type.)

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden, London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words; afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m. on Wednesday to insure insertion in the following Friday's number.

Holloway's Ointment and Pills.—All ulcerations, sores, abscesses, bad legs, and skin diseases are best treated by these medicaments. The Ointment eradicates all noxious taints, and makes every symptom assume a milder form, and this desirable result is made doubly certain by the purifying, regulating, and alterative powers of the Pills.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Splendid pair of **Horns**, 6ft. from tip to tip, and 11in. at base. Exchange for good 52in. Bicycle; or what offers?—Address, W. T. P., Poundisford, near Taunton, Somerset.

"**English Mechanic**," 114 to 557, in parts and numbers. What exchange?—A. Harris, Wavendon, Woburn, Beds.

Wanted, powerful **Hand Punching Machine** in exchange for one small Horizontal Engine and Boiler, complete, half horse-power.—J. Bilsborough, Alderley Edge, Cheshire.

Picture Frames wanted. Exchange water colour painting or watch, &c.—S. Terril, 409, Monument-road, Birmingham.

Wanted, ¼-plate **Photo. Apparatus**, complete. I will fit up 3½in. lathe-head castings in exchange. Engineer's work warranted, genuine value, quantity, quality.—H. Chambers, 17, Charles-street, Seymour street, N.W.

Wanted, good **Microscope**. Exchange Portable Bellows, value £2, or offers.—Alcock, Sporle, Swaffham, Norfolk.

Handsome Globe-shape street **Gas Lamp**, with bold ornamental swan-neck shape iron bracket to fix to house front, suitable for hotel or business shop, handsomely painted in red and gold. Cost £7, exchange for good bicycle or lathe.—Apply J. Skinner, Sutton Bridge.

"**Cassell's Popular Educator**," complete, in 32 shilling numbers, unbound. Will exchange for a good set of Harmonium reeds.—J. W. Noble, Greetland, near Halifax.

5ft. planed gap **Lathe** bed, leading-screw, full set of change-wheels. Offers—R. D. Smith, Fazakerley-street, Chorley, Lanc.

Amateur wishes to **Exchange** remainder of his stock. 6in. slide rest, turning tools, taps, &c., &c. What offers?—Newman, 27, Raglan road, Plumstead.

Have 34 sixpenny parts of "**Wright's Illustrated** Book of Poultry." Will exchange for "Lathework," by Hasluck, latest edition.—John Holme, 467, Rivington View, Middle Hulton, near Bolton-le-Moors, Lancashire.

Amateur Small Iron **Lathe**, Printing Press, or offers for good electrical goods. List sent. No offers refused. Must be sold.—Walter Wells, Watchmaker, Malvern Link.

Warranted **Joinering Chisels**, assorted sizes, given in exchange for old books, newspapers, or periodicals. Sample chisel and prices, free, 12 stamps.—Mr. Lowe, Ironmonger, Warrington.

52in. **Bicycle**, cone bearings, in perfect condition. Exchange Gold Albert.—F. Ridge, 42 Percival street, Ardwick, Manchester.

Grindstone, about 27in., for Engineer's use. Anvil about 1½ cwt. wanted. Exchange smith's bellows, fan, or cash—Mr. S. Hewett, South Norwood, London.

Slow Combustion **Boiler Pipes** and connections for Greenhouse wanted. Exchange patent gas holders or heating coil—Mr. S. Hewitt, South Norwood, London.

What offers in exchange for Silver Plated **Snuffers** and Tray? Cost 7s.—Miss Lloyd, Leigh, Essex.

"**English Mechanic**," Vols. XXI. to XXXI., with index. Exchange for works by Darwin, Huxley, Emerson, or cash.—R. Dobson, 5, Marine terrace, Whitehaven.

Beautiful silver centre seconds, English **Detached** Lever Watch, manufactured to special order by Wheeler. Extra jewelled and crystal glass, guaranteed for 10 years, just new, worth £12 12s. Will exchange watch and guarantee for good 3½ centre self-acting and screw-cutting lathe complete, 2ft. 6in. beds.—J. Baker, 14, Cannon-terrace, Ashton-road, Preston.

52in. **Bicycle**, first-class condition. Must part. Offers.—Particulars to R. R., 11, Laverton-road, Loftus, Saltburn.

I will give 51in. **Bicycle**, light roadster (Rudge), for an armature lathe with emery wheel, or bicycle fittings.—Address, J. Steward, Conservative Club, Waterfoot, Manchester.

"**Photographic News.**" About 500 numbers of this excellent periodical, many very scarce. Exchange books on anything useful.—Mr Jewell, Westerham, Kent.

"**Old and New London**," 60 shilling parts, special edition, 30s., or exchange to 50s.—T. Gordon Bowman, 31, Compton street, Brunswick square, London, W.C.

Telegraph Instruments.—Mahogany Bodies, with batteries for commercial purposes. Exchange lantern slides, or offers. Approval with pleasure.—Thompson, 82, English-street, Hull.

Wanted, **Induction Coil**. Exchange plated Hub Lamp, cost 16s. 6d. "Keat's Bicycle Bugle," 4 turns, cost 18s. 6d. Sliding seat, 10s. 6d.—G. H. Furmedge, Gillingham, Dorset.

Extraordinary Challenge **Bicycle** 48in., equal to 51in. ordinary, in first class condition. Exchange for tricycle. Good Meteor preferred.—C. Brown, Bookseller, Dudley, Worcester.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

For Sale.

Electric Machines, Indicators, Bells, Batteries, Wires, Switches, Terminals, Carbons, &c.—King and Co., Electricians, Bristol. (List Twopence.)

Paints.—Armstrong's full instructions for making Paints is now sold by Stevens and Co., 32?, Old-street, London. Price 2s. 6d.

Saxophone's **Musical Supply Scheme**: its origin and object, post free for penny stamp.—Address, H. Wellstead, East Borough, Wimborne, Dorset.

Forty per cent. discount off Standard List of American Twist Drills. Send stamped envelope for sample free of charge. They are made of the very finest steel, by Bentall Brothers, Maldon, Essex.

Cyclists.—Challis's Stop **Bell**, with patent vibrating bracket, is best, 2s. 6d., 3s. 6d.—E. M. Challis Bros., Homerton.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, SEPTEMBER 1, 1882.

ON THE PRODUCTION OF LOOPED FIGURES BY GEARING.—II.

AS a help to those to whom the subject may be new, I will now give a sketch or two to elucidate the arrangement suggested in my last article. The ENGLISH MECHANIC has run through a great number of Vols., and gained hundreds of subscribers who have now but little chance of referring to early numbers on lathe matters, so that it must not be taken for granted that all our readers are old stagers, or that what is no novelty to one may not be so to another.

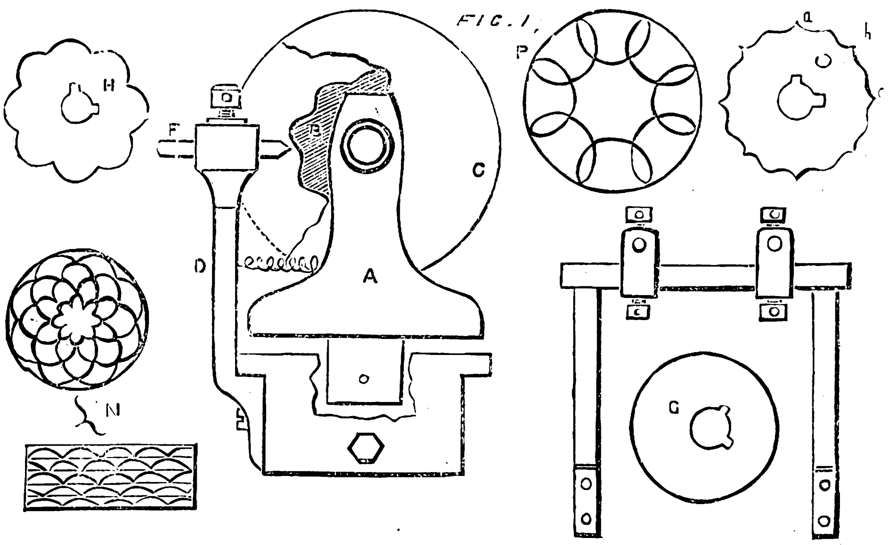

FIG. 1.

Moreover, I propose in this case to sketch out the simplest mode of making a satisfactory geared rose-engine instead of repeating the designs that have hitherto appeared. The first sketch is intended merely to explain to the novice the principle of all those machines in which an oscillating motion is given to the headstock, and consequently to the work also. A is the headstock which is now raised a little above the lathe-bed to give it room to oscillate, and it is suspended on centre-screws, one of which would ordinarily pass through the top of the standard and the other through a web cast in the bed. When not required to oscillate, packing pieces are placed below the base of the headstock, or the centres can be withdrawn and the headstock allowed to rest on the bed as usual. C is the face of the mandrel-pulley cut away to allow the rosette B to appear. This rosette is similar to H, its edge (it is about ¼in. thick) being of waved outline; the exact pattern being of no consequence for the present. It is keyed, or otherwise made fast to the mandrel, so as to revolve with it. G is an eccentric disc, which can be used instead of the rosette. D is a stiff stand, bolted to the bed carrying a rubber, F, of hard steel or other material. This is in practice like K; so that the rubber carriage, L, can be slid horizontally on the top bar, and brought opposite to any one of a row of these rosettes. But for the present, we may consider that there is but one, and that a coiled or other spring keeps the rubber in close contact with the rosette. It is plain that if the mandrel is made to revolve, the headstock will be forced to oscillate in accordance with the undulations upon the edge of the rosette. If, therefore, a disc of wood is mounted on the mandrel and made level, and a pointed tool or pencil held in the slide-rest is set against it, a copy of the rosette will be drawn or engraved upon its surface. Thus far, almost any lathe could be converted into a rose-engine; but to do satisfactory work, it is plain that a very large number of rosettes would be required, as a repetition of the same pattern would not be worth the trouble of tracing it. The next improvement suggests itself—viz., to so mount the rosette on the mandrel as to enable it to be set on either of two positions—a matter easily arranged by making it fit over a key or feather, and cutting two key-ways, as seen in the rosette H. Setting it alternately in one of these positions, we should get a pattern similar to N; but there our power ends, and with this rosette we can effect but little more.

Now, a rosette like the figure is tolerably simple yet not very easy to make, as it must be filed up; and if, instead of so simple a waved outline, the rosette has a more complicated edge, like that of O, the cutting and finishing becomes far more difficult, because each part must be exactly similar to those of the same design—the section *a b*, similar to section *b c*. Hence, the expense of the rosettes, which has hitherto kept the Rose-engine out of the hands of all but a few wealthy amateurs and workmen. In addition to this, there is a certain degree of sameness and monotony in rose-cut work, owing to the fact that there are no looped figures. The eccentric chuck, combined with the rose, will complicate figures; but something is needed of a simpler and more effective character, cheaper to make, and efficient in use. Let us now replace rosette H of eight undulations by G, a simple turned disc with an eccentric hole. We shall get one complete oscillation only of the head stock at each revolution of the mandrel, resulting in a plain, elliptic design.

If, however, we can so arrange matters as to cause the disc to revolve eight times during one revolution of the mandrel, we shall obtain a figure with eight waves, somewhat similar to that produced by the rosette. Thus our simple, cheaply-made disc, which any amateur could make, is made to replace a costly rosette. But we can also now get loops like P, or more complicated ones at pleasure, using no rosette, but the plain disc. How, then, can we manage to multiply the oscillations produced by the plain disc? There is but one way. We must mount it on a separate mandrel, and connect the two mandrels together by intermediate change-wheels. How this can best be done, will, in a great measure, depend upon the means at hand, and upon the lathe itself to which the apparatus is to be applied. Generally speaking, however, a bracket, or rather, a pair of them, would have to be bolted to the existing poppit, as A in Fig. 2. These will carry centres between which to mount the second mandrel. Then inside the poppit must be fixed the quadrant B, shown in place at H, to carry an adjustable stud in the long slot, to take the different change-wheels. If, however, a lathe is fitted with back-gear which can be spared, the back spindle can be removed, and then the arm cast upon the poppit will serve excellently, instead of having to bolt one on—or it may be possible, and probably would often be so, to use the spindle of the back gear as the mandrel, without interfering with its action, and to mount disc and wheels on that side. Of course, in any case, the rubber *must* be fixed to the *bed* outside the second spindle.

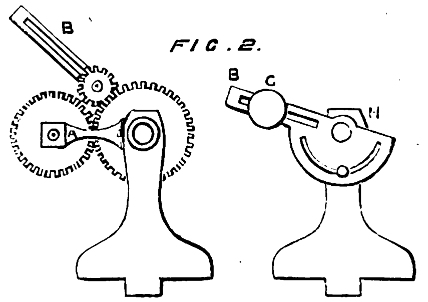

FIG. 2.

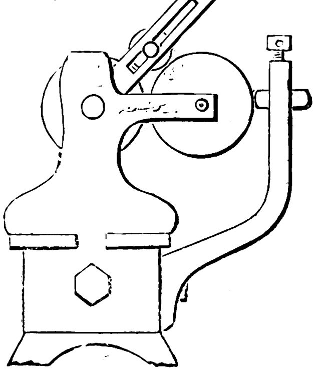

FIG. 3.

In Fig. 3 I have represented the rosette so placed on the back-action spindle.

With this simple equipment you have the means of producing innumerable complicated and beautiful designs, and, I may add, at a minimum of cost. Change-wheels are now to be had, well made, cast from cut patterns, from Lloyd's and elsewhere, and they cost but a few shillings. The radial arm, to carry the stud for these wheels, must be cast in iron or brass; but the pattern is easily made. It usually fits over the nut (circular) of the back or tail-pin, which keeps the mandrel up to its collar, and is retained in position by a short bolt passing through the curved slot into the poppit. It may be fitted, instead, however, upon the front of the poppit, embracing the mandrel, where it may be used in connection with spiral apparatus, or quite at the back, outside the end, instead of inside, where also the spiral apparatus is sometimes placed. There is nothing in all these additions to interfere with the ordinary work of the lathe, and if the rosettes can be applied to the back spindle, the whole apparatus will be quite out of the way. When fastened to the back-action spindle however, the rosettes or discs may probably require to be placed singly, or to be somewhat thinner in substance. All will depend upon the space left outside one or other of the gear-wheels; and if the spindle is made to advance by eccentric collars for the production of slow-motion instead of sliding horizontally, it may be found necessary to substitute an entirely independent spindle to carry rosettes. This is, of course, the better plan in all cases, as admitting of a more perfect and satisfactory way of attaching the rosettes; but the difficulty in most cases will be that the gear-wheels for slow-motion are so keyed that the back spindle cannot be removed from its bearings. The following plan will obviate this and make the back spindle easily available for both purposes: Knock out the keys, remove the gear-wheels, and thus clear the spindle; get a bit of gas-pipe, or stout brass tube that will fit easily, but well over the spindle, so as to form a sleeve to revolve upon it. Cut it off to such a length as just to fit between the arms of the poppit; bore out the pair of gear-wheels and key them upon this sleeve. You can now at pleasure draw off this sleeve with its wheels, and use the spindle—another almost similar one with the discs and rosettes. If you cannot get a nice bit of tube, to fit exactly, get a bit still larger, and insert a washer at each end, bored to fit the spindle. The back gear will work quite as well thus fitted, to revolve *on* the spindle, as if it revolved with it. J. L.

(*To be continued.*)

A STEERING SCREW-PROPELLER.

THE idea of placing the screw-propeller in such a position with regard to the rudder that it would aid in steering the vessel is not new, nor is the modification which places a smaller supplementary propeller on the rudder in such a manner that it swings with it; but whether or not any of the various devices have been actually tried on the scale of twelve inches to the foot, it is doubtful if they gave better results than those recently obtained with Kunstädter's screw-steering apparatus, which was illustrated and described in No. 744, p. 393. The patent was taken out in 1878, and was for an improvement on a similar invention by the same inventor, who, a native of Buda-Pesth, has now been residing in England for some years. That we should only now be in a position to give an account of a fair test experiment in actual work shows with what reluctance owners of vessels take up any new thing in screw propulsion. Kunstädter's steering screw had, we believe, been fitted to sundry small craft (see p. 8, Vol. XXIX.), and to one large vessel owned abroad, before it attracted the attention of shipbuilders on the Clyde; but a satisfactory trial has been recently made with it as fitted to the *Stratheden*, a vessel of 1,500 tons measurement, having engines of about 1,200 horse-power. The vessel is employed in the coal and iron, wine, and grain trades, between the Clyde and Bordeaux, Bilbao, &c., and is, we believe, the largest steamer engaged in the trade, which demands considerable handiness in so large a vessel in order to manœuvre readily in narrow harbours and rivers. A reference to the place cited will give a fairly accurate idea of the arrangement as actually fitted to the *Stratheden*, the principal detail being the universal joint connecting the main shaft with the shorter one running through the rudder. The propeller proper is much of the same pattern as commonly found, and is fitted in the usual way, save that the shaft carrying it passes through a boss in, or a bracket let into, the stern-post, outside which it terminates in a fork, which is connected to another fork at the inner end of the shaft passing through the rudder. A block of steel, or other suitable metal, is placed between the prongs of the forks which are held to it by means of four screw-pins. Nice and accurate work is required in connection with this joint, which is one of the special features of Kunstädter's invention, and allows of the rudder being placed at any desired angle without putting any undue strain on the joint. In Kunstädter's specification the rudder-screw is represented with two blades and about half the diameter of the propeller proper; but it is expressly stated that the rudder-screw may have two or more blades. In the *Stratheden*, the propeller proper is an ordinary cast iron one, having a diameter of 14ft. 6in., while the rudder or steering-screw is 10ft. in diameter, and is fitted with four steel blades, having a variable pitch. A number of speed trials made with the vessel light, half-loaded, and fully loaded, gave a mean speed on the measured mile of about 11$\frac{1}{2}$ knots, with the blades of the rudder-screw in position; while a mean of several runs without them showed a speed of 9·8 knots. The speed of the vessel, however, is not the point to which we wish to draw attention, for the real merit of the invention lies in the fact that it unquestionably exerts considerable power over the movements of the *Stratheden*, which is reported to answer her helm very rapidly, and to be always perfectly under control. In order to test the effect of the steering-screw, two sets of trials were made, and compared with a set made with the blades of the screw-rudder removed, the mean of two full circles to starboard shows a time of 8min. 22sec., but one trial made to port occupied 7min. 20sec. for the full circle; but in this case the engines were going a trifle faster. In the trials with Kunstädter's screw, the vessel going full speed ahead, full circles were made in 4min. 55sec.; 5min. 3sec. and 6min. 7sec. with helm to starboard; with helm to port, the full circles were made in 5min. 58sec., 6min. 2sec., and 6min. 21sec. Going astern, half-circles were made in 4min. 2sec., and 4min. 16sec. respectively to starboard and port. The average time for the half-circle going ahead was under 3min.; but the most remarkable feature in the trials was the complete circle in about two lengths and a half, the engines being started full speed astern while the vessel was without any way on her. That was accomplished in about the same time as a full speed ahead circle to port without the rudder-screw—viz., 7min. 27sec. The importance of that fact will be readily appreciated by mariners in days when collisions between steamers are so frequent, for it gives the master the power of almost immediately altering his course, with engines reversed and going astern. A jointed screw-propeller formed the subject of a patent obtained by Shorter in 1800, and it is stated that it was applied to some Government ships; but if so, it could scarcely have resembled Kunstädter's invention. Fowler's steering propeller is a submerged wheel worked by a vertical shaft, the steering being effected by "feathering" the paddles at different parts. That is accomplished by means of an eccentric cam which can be so actuated that the paddles can be made to present at one part of their revolution a pushing and drawing action on the water, while, at another, they present only their edges to the water. The steersman controls the action of the cam, and the vessel can be turned almost on her centre or backed in a straight line. This propeller, like Hunter's, patented in 1874, is useful only on small craft. The last-named consists of two wheels, one each side of the stern-post, which revolve in opposite directions, the blades being so feathered as to have only one dead point. It will be readily seen by mechanics that just as the universal joint is the chief feature of Kunstädter's arrangement, so also it is the weak point mechanically; but the inventor not only describes the joint he prefers, but gives reasons why other forms are objectionable. Link-joints, ball-and-socket joints, are rejected as being subject to great friction, and consequently to rapid wear. In the universal joint adopted by Kunstädter, there is a common centre, or intersecting lines of centre of action, so that the strain is equally divided between, and is simultaneously borne by the four screw pins; and, besides, there is an ingenious adaptation of the back part of the fork on the main shaft as a thrust collar, to take up the thrust from the steering screw when going astern. That the parts are well-proportioned and properly made, so far at least as the *Stratheden* is concerned, may be gathered from the fact that although she has made two voyages, and experienced some fairly severe weather, no signs of wear or strain can be detected in connection with the steering screw. In the experiments which he made on the Clyde some years ago, Prof. Osborne Reynolds showed that by reversing the engines of screw-steamers all command over the vessel was lost. The facts learned by the experiments were embodied in the report of a committee to the British Association, in which it was laid down that a screw-steamer at full speed could not be stopped in less than five lengths, whereas by using the rudder, without reversing, the vessel would be able to turn through a quadrant without having advanced five lengths in the original direction. From the facts above noticed, it would appear that Kunstädter's steering-screw gives complete command of the vessel, even when the engines are reversed and going astern, and, besides the advantages it confers in navigating narrow waters and sinuous harbours, it is also a useful and, perhaps, invaluable appliance in cases of threatened collision.

CHRONOLOGY OF TELEPHONIC DISCOVERIES.

IN view of the partiality with which the history of telephony is presented in different countries, the editor of *La Lumière Electrique* (M. Du Moncel) offers his readers a brief chronological *résumé*, which is as follows:—

1854.—First idea of electric transmission of speech with complete description of means to be used by M. Bourseul.

1856.—Discovery by M. Th. Du Moncel of the variation of intensity of currents over interrupters with metallic contacts *light and well cleaned*, with the pressure exerted on them. Experiments proving the truth of this principle with substances of mediocre conductivity, 1864, 1872, 1874, 1875, &c.

1857.—Representation of vibrations produced by the voice by means of a stretched membrane before which one speaks, by M. Leon Scott.

1860.—Application of M. Scott's system to the electric transmission of sounds, by M. Reiss.

1865.—Application of the principle of variations of intensity of currents with pressure to making tubes with variable resistance, by MM. Clerac and Elsasser.

1865.—Discovery by Mr. Wright of the reproduction of sounds by a condenser.

1875.—Application to the electric transmission of sound of undulatory currents, by Mr. Bell.

1876 (14th Feb.).—Discovery by Mr. Bell of the magneto-electric telephone.

1876 (10th April).—Application to the Reiss transmitter, or to Bell's liquid transmitter, of a contact with permanent action for electric transmission of sounds, by Mr. Donough.

1877 (30th July).—Application of soft carbon contacts to the Reiss transmitter, to furnish more developed undulatory currents in telephonic transmission, by Mr. Edison.

1877 (16th Oct.).—Application of hard carbons with one or two contacts to the same transmitter, for the same purpose, and at the same time to form a receiver capable of repeating speech, by M. Berliner.

1878 (Jan.)—Discovery by Mr. Hughes of a telephonic carbon transmitter, whose arrangement is such as to magnify sound; an apparatus to which was given, for this reason, the name of *microphone*.

1878.—Discovery by the same savant of the transmission of sounds by the action exerted by the voice on crushed fragments of carbon, or conductive powders applied to two metallic electrodes connected with a battery and a telephonic circuit.

1878.—First application of the microphone to the hearing at a distance, of sermons and divine service, by Mr. Crossley.

1878.—First application of the same instrument to hearing an opera, by M. Patochi.

1879.—Reproduction of speech by an iron wire used as receiver, by M. Ader.

1879.—Construction of the *motophone* of Mr. Edison.

1880.—Reproduction of speech by means of the condenser with sheets of paper, by M. Herz.

1880.—Development of this mode of reproduction of speech, by M. Dunand.

1880.—Discovery by Messrs. Bell and Sumner-Painter, of the *radiophone*.

1880.—Transmission of speech without a battery by the effect of percussions between fragments of iron wires, by M. Ader.

1881.—Speaking condenser with air-layer, of Mr. Dolbear.

1882.—Simultaneous transmission a long distance, of speech and a telegraphic message, by M. Van Rysselberghe. Same problem solved in another way, and in laboratory experiments by M. Maiche, in 1880.

[It may be remarked as strange that no mention is made in this statement of the harmonic telegraphs of Mr. Varley (1870), and of Mr. Elisha Gray (1874).]

ASTRONOMICAL NOTES FOR SEPTEMBER, 1882.

The Sun.

Day of Month.	Souths.	At Greenwich Mean Noon.

The Method of finding the Sidereal Time at Mean Noon for any other Station will be found on p. 390 of Vol. XXXIV.

At 4 a.m. on September 23rd, the Sun is said technically to enter Libra, and Autumn is supposed to commence. He will really be at this instant to the west of η Virginis.

The Zodiacal Light may now be looked for before sunrise in the East.

Spots, faculæ, and prominences continue to manifest themselves.

The Moon.

Enters her Last Quarter at 1h. 26·2m. p.m. on the 4th, and is New at 58·6 minutes after Noon on the 12th. She will enter her First Quarter at 1·27·9 p.m. on the 20th, and be full at 5h. 9·9m. in the early morning of the 27th. Pretty high tides may be looked for about the 28th.

† Near approach. ‡ Stars below the horizon.

The attention of the Student is directed to the occultation of μ Sagittarii on the night of the 20th, as, being a triple star, it will present an interesting spectacle.

The Moon will be in conjunction with Saturn at 10 a.m. on the 3rd; with Jupiter at 8 p.m. on the 5th; with Mercury at 4 p.m. on the 14th; with Mars at 1 a.m. on the 15th; with Venus at 5 p.m. on the 16th; and once again this month with Saturn at 6 p.m. on the 30th.

Mercury

Is an Evening Star during the whole of September, attaining his greatest elongation East (25° 45′) at 5 p.m. on the 28th; his rapidly increasing South Declination however places him in a very unfavourable position for the observer at this epoch. His angular diameter varies from 5·2″ to 7″ during the month.

Commencing at a point to the West of β Virginis, the path of Mercury this month will traverse nearly the whole constellation of Virgo. At 4 p.m. on the 20th, Mercury will be in conjunction with Spica Virginis and only 12′ North of that Star. He will also be in conjunction with Mars at 7 a.m. on the 21st.

Venus

Is also an Evening Star during the entire month, and attains her greatest eastern elongation (46° 31′) at 1 p.m. on the 26th. She is even worse placed than Mercury, though, for observation. Her angular diameter, which is 19·2″ on the 1st, increases to 25·8″ by the 30th.

Venus.

The path indicated by the above Ephemeris begins a little to the east of Spica Virginis, and extends through Virgo into Libra. Its neighbourhood is singularly free from conspicuous stars.

Jupiter

Is a Morning Star, in the sense of southing in daylight, but he rises a little before 11 o'clock at night at the beginning of September, and not long after 9 p.m. at the end of it. He is in quadrature with the Sun at 11 a.m. on the 23rd. His angular diameter, which is 34·6″ on the 1st of September, becomes 37·8″ by the 30th.

Ec Eclipse; Oc Occultation; Tr Transit of Satellite; Sh Transit of Shadow; D Disappearance; R Reappearance; I Ingress; E Egress. The printing of a phenomenon in *italics* indicates that its visibility is rendered doubtful, either by the brightness of the twilight or by Jupiter's proximity to the horizon.

Mars

Is practically invisible.

Saturn

Is a Morning Star in the same sense that Jupiter is, but he rises soon after 9 p.m. at the beginning of the month, and between 7 and 8 o'clock in the evening towards the end of it. His angular diameter slowly increases from 16·8″ to 17·6″ during September, and his ring continues to open almost imperceptibly, but quite steadily.

Day of Month.	Right Ascension.		Declination. North.		Souths.

From which it will be seen that Saturn will remain sensibly stationary to the naked eye in an entirely blank region in Taurus.

Uranus,

Coming as he does into conjunction with the Sun at 8 p.m. on the 11th, has left us until next year.

Neptune

Will scarcely come into view for the observer's purpose until the early mornings of next month.

Shooting Stars

Are rare in September. They may be looked for, though, about the 10th, and again between the 18th and 25th.

Greenwich Mean Time of Southing of Ten of the Principal Fixed Stars on the Night of September 1st, 1882.

The Method of ascertaining the Greenwich Mean Time of Transit of either of the Stars in the above List for any other night in September, as also that of ascertaining the Local Instant of its Southing at any other station, will be found on p. 392 of our XXXIVth. Volume.

PRACTICAL NOTES ON PLUMBING.—XLI.*

By P. J. DAVIES, H.M.A.S.P., &c.

(*Continued from page* 563.)

THE machine siphon, Fig. 229, is nothing more than a common gas siphon made for the purpose of catching the water partially given off by the steam from the acid, water, &c., within the machine. The inlet pipe A is best taken down into the bottle part B; the gas exit pipe is marked D. For my part I prefer to make C with a piece of $\frac{3}{4}$in. pipe about 5in. long. A and D are both $\frac{1}{4}$in. gaspipe soldered on to B, the rubber pipes are slipped over the ends, and of course securely fixed. F is a strap of 6lb. sheet lead bent to form a hook to hang over the rim L of the machine, Fig. 228, and as shown at Q, &c., Fig. 231.

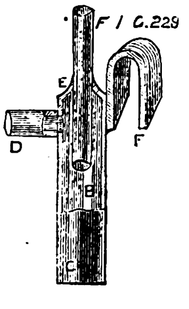

FIG. 229

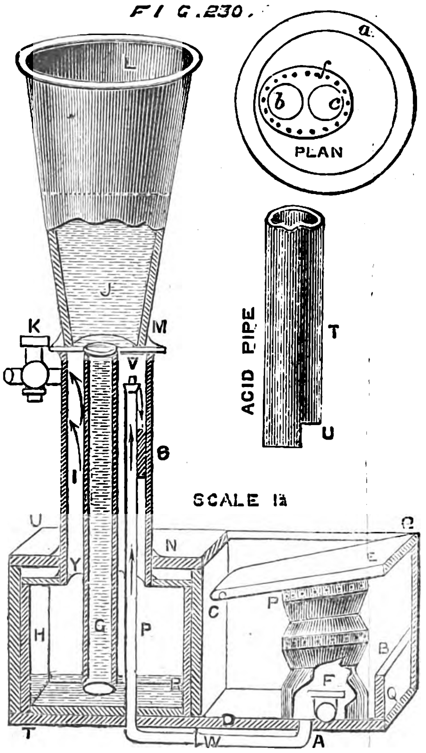
The Davies Bellows.

The bellows illustrated at Fig. 230 is of an improved form, and is made as follows, the scale being $1\frac{1}{4}$in. The frame A T U V is an oblong wooden box about 1ft. 9in. or 2 feet long, height about 9in. and width about 9in. or 10in. The half end B is fixed to answer as a stop for the treadle, which prevents the bellows spring being injured by excessive pressure from the foot, the box has also the partition C for the support of the side lead of the cistern. UN is the top board, having a 4in. hole for the wind-chamber S. The top and bottom parts, or boards, of the bellows B are made with $1\frac{1}{4}$in. mahogany; the diameter should be about 1in. less than the width of the box, that is, if the box is 9in., the top should be 8in. Round the inside of these boards should be turned the groove A, to receive the ends of a spiral spring, such as is used for sofas or easy-chairs; this spring must in size equal nearly that of the boards, and stand, when not compressed, about 15in. high. In the bottom board the aperture C is made for the inlet valve and pipe, and the aperture 6 for the outlet pipe. We now come to the inlet valve. this is simply a $\frac{3}{4}$in ground-in *short* spindle valve soldered on to a piece of $\frac{3}{4}$in. pipe properly flanged for bedding with white-lead to the board; the flange should be cut large enough to admit of both the inlet valve pipe and the outlet valve pipe being soldered to it. Then the whole can be bedded, and nailed down on the board together. Having got so far, next fix with wire or otherwise the sofa spring to the bottom board, and over the valve and outlet pipe, also fix the spring to the top board; this will have the appearance of a concertina frame without the leather. Now provide the leather casing—the best material for this purpose is sheepskin of a medium thickness: this must be properly sewn together, and perfectly windtight; the length required is about $7\frac{1}{2}$in. or 8in. Next insert a cane hoop in the middle, to keep the sides distended while drawing in the wind—then with $\frac{1}{2}$in. tin-tacks and an extra band of leather about $\frac{3}{4}$in. wide nail the leather to the bellows-boards. Now with two screws of suitable length fasten the bottom of the board to the bottom board of the box, seeing that the screws do not pass through the bottom board of the bellows; fix the outlet pipe as shown at W, ready for connecting by a blown or copper-bit joint, and bend the inlet pipe up the side of the frame as shown at F, Fig. 231. Next line the close cistern HR, Fig. 230, having a piece of $\frac{3}{4}$in. lead pipe P soldered in the bottom, and long enough to reach to the top of wind-chamber as at V, and to bend round the bottom, so as to meet the outlet pipe A from bellows as shown at W. Having the cistern made, and top and bottom soldered on, fix the $\frac{3}{4}$in. spindle valve V on the pipe P, and to a suitable height, say 10in. above box; next fix the 1in. water column or dip pipe G to the top of the box, steady it with a flange joint at Y, let the pipe go to the bottom of the box but with the end cut to the shape as shown at VU at the bottom of the ACID PIPE: this will allow a free passage for the water when the bellows is at work. Next bore two 1in. holes in the top of the cistern near the soldered pipes, to allow the free passage of the wind from the bellows to press upon the top of the water in the cistern (to be explained further on). The wind-chamber S—this is made with a piece of 5in. soilpipe of suitable length, say about 12in., by first soldering a piece 2in. long to the top of the lead cistern, then fix the top board N and taft down the end of the short piece of 4in. lead pipe over the top board, and solder the 4in. wind-chamber to this; this flange will keep up the top of the lead box. Next turn, or flange over the top of the wind-chamber as shown at M to receive the middle partition, and take the pipe VP, to the inside as shown at S; then cut a piece of sheet-lead V for the partition, and to this solder the top end of the water column pipe G, as shown in diagram. Prepare the funnel LJ, and solder it together, with the middle partition to the wind-chamber as shown; fix a $\frac{3}{8}$in. gas-cock as at K, to the top of the wind-chamber; after this fix the treadle E by putting a 10in. $\frac{3}{8}$in. or other bolt of a suitable length through the end, and through the two sides of the frame, as shown at C, then with two stout screws fasten the top of the bellows to the treadle, and in such a manner that the bellows will work nearly upright; make the joint at W and the bellows will be completed. *Turn off the wind-cock* K and fill the bellows with water to about half-way up the funnel J, then open the wind-cock and let the water run down, and the bellows is ready for use. Notice that if you get too much water it will rise above the valve V, and most likely will by degrees work its way into the bellows, thereby softening the leather, and causing it to work very flabby, and badly. For the same reason the bellows must not be left exposed to the rain, &c.

FIG. 230.



In theory the construction of the bellows is as follows:—Suppose the wind-cock K to be open, then by the water being put into the funnel L, Fig, 230, it must run down the water column pipe G and into the box R, so that by closing the wind-cock would prevent the escape for the wind or air; now suppose the box to be full of water, and an additional quantity of wind pumped in through the valve V: as the bellows is worked, so will the wind become compressed, and will press upon the surface of the water at R with sufficient force to cause it to flow back up the water column pipe G until all is forced out, when, if the bellows be kept at work the air will bubble up through the water, (exactly as the machine would when throwing up); now open the cock K, and there is the exit, and the water will flow back in proportion to the amount of wind allowed to pass through the wind-cock. The theory of the machine.—Refer to fig. 228, shut the gas-cock 2, and close up the cap and screw G, also the pipe XX; the zinc is to be placed on the strainer at ZZ (bar zinc is the kind to be used); this must be broken up to size suitable for putting through the cap CC; next pour into the machine about 5 parts of water, and 1 part of the strongest sulphuric acid (not such as is generally to be had at oil-shops, but from the makers), then open the gas-cock 2, the acid water will then run down into the bottom of the machine, and attack the zinc. The zinc takes the oxygen from the water and releases the hydrogen, which rises in small bubbles through the water; now close the cock 2, and with this action going on, the bubbles soon fill the space M with hydrogen gas. Pressure is generated, and, as in the bellows as before explained, forces the water back up the pipe RP, and into the top compartment, until the acid water is all removed from the surface of the zinc, when the action is discontinued; open the cock 2, the pressure is at once relieved, and the acid runs down again, attacks the zinc, and

---

* From the *Building News*. All rights reserved.

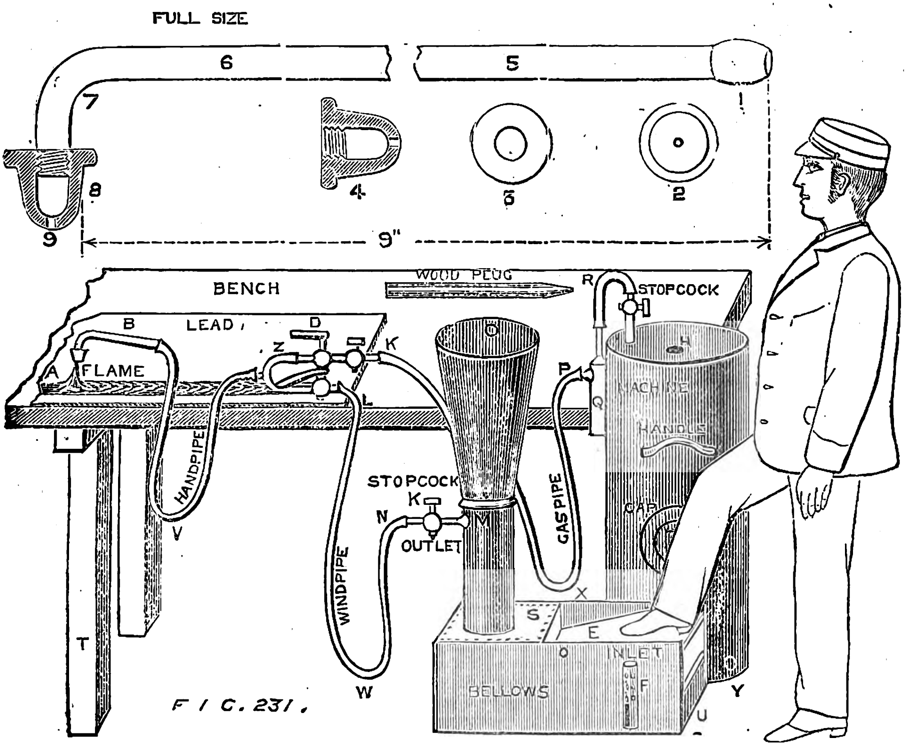


FIG. 231.

generates more gas. If the machine is a small one, it has now become heated, and should be kept at work, for if it be left to cool down, the chances are that you will require a fresh quantity of acid. The machine while working should be kept warm, and never allowed to get below 70 degrees Fahr.; otherwise, if it has been worked hard, and the exhausted liquor allowed to stand, it will soon become crystallised, when it would require a pail or two of boiling water to dissolve the crystals, and clear them away. Sometimes the machine is cased with felt &c. to keep it warm. If the machine does not make gas fast enough, it must have the acid stronger; if no gas can be obtained then look to your zinc. Probably you will not find any left; of course then you must put in more. Should you require to do this without emptying the acid from the machine, take the rubber off the gas-tap, and with your mouth, blow up all the acid water into the top chamber, but be careful not to blow too strong, for this would cause the acid to bubble up, the splashes of which would in all probability, come in contact with your face. N.B.—To prevent this it will be quite as well to place a small piece of lead over thehole H, which will also keep foreign matters from getting into the top chamber. Of course you would only apply your mouth under extreme circumstances, and when the gas cannot be got up otherwise; with a little judgment it can be blown up with the bellows. When the acid is all up, take the plug 4, 6 Fig. 228, and plug the end of acid pipe, this will prevent the return of the acid; you may then take off the large cap, throw in a pail of fresh water, next examine for zinc. Important caution: do not take fire near enough to explode the machine. The machine and bellows fitted up.—Having explained the construction of my lead-burning machine and bellows, I will now proceed to explain and illustrate the whole, exactly as I exhibited it at South Kensington before the competitors for the prizes offered for plumbing by the National Health Society, March 1882, and as used by myself and men in different parts of England, Wales, and Scotland. Fig. 231 illustrates the whole arrangement, the gas is generated in the machine, and conveyed through a *stout*, pure, rubber tube W to the regulating cock D; from there through the breeching piece Z, and through the hand-pipe V to the nipple A, at the same time wind is pumped from the bellows through the rubber tubes W, and through the breeching, where it is regulated by the spanner cock I to meet and to mix in a certain quantity or proportion (to be explained hereafter), with the gas at the meeting point of the breeching Z, and through the hand-pipe to the nipple near A.

This flame illustrates the burning of two pieces of lead together at A, known as flat-butted work. The blow-pipe, 5, 6, 7, is made of stout brass tube, ⅛in. bore, the nipples 8, 9, 4, are drawn full size; 3 is a plan looking from the back, and 2 is a plan looking from the front; these nipples are made to screw off or on to the pipe, the sized hole for the jet must vary according to the class of work done, and also the workman. The ordinary size is from 1-32 to 3 32 of an inch, or larger, if required for very heavy work, such as from 12 to 28lb lead.

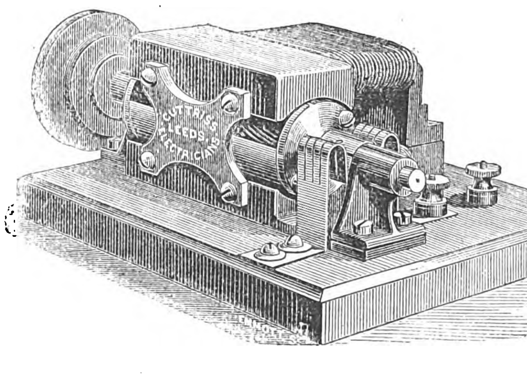
(*To be continued.*)

THE CUTTRISS ELECTRO-MOTOR.

ONE of the objects of interest to be seen at the exhibition now being held at Bradford is a small electro-motor driving a "Singer" sewing-machine, a description of which will doubtless interest many of our readers.

The accompanying engraving will almost explain itself. The total weight of motor, with base-board, is 2½lb.; the armature, "a Siemens," is 1in. diam. by 2¼in. long, which, with a current from six cells, attains a speed of about 8,000 revs. per min., when running light. The motor can be applied to any sewing-machine, the power being transmitted to the periphery of the hand-wheel by means of a rubber friction-ring on the motor-shaft, which makes a very simple and effective means of driving.

When not required, the motor may be disconnected, leaving the sewing-machine capable of being driven in the usual way. The average speed obtained by the one under notice is 450 stitches per minute, which may be varied as required by the simple pressure of the foot upon a treadle connected with a battery of six bichromate cells, each zinc being 2¼in. by 3in. It need scarcely be added that the motor is capable of being applied to various uses, such as the driving of fans, light lathes, &c.



The motors, which are of various sizes, are manufactured by Messrs. Cuttriss, electricians, Leeds.

NEW CLOCK AND CARILLONS FOR BOMBAY UNIVERSITY.

A NATIVE of Bombay having munificently provided the necessary funds for a large clock and carillons for Bombay University, the Indian Government intrusted the work to the following firms:

The bells to Messrs. John Taylor and Co., of Loughborough, Leicestershire, founders of the new ring of 12 bells for St. Paul's Cathedral, and of Great Paul; the iron bell-frame, designed by General Hyde, of the State Railway Department, to Messrs. Westwood, Bailey, and Co.; and the clock and carillon machinery to Messrs Lund and Blockley, of 42, Pall-mall, by whom the whole of the work has been erected in London, preparatory to its shipment to Bombay. The bells are 16 in number, in the key of C (12 consecutive and four half-notes.) The largest weighs about 3 tons, and the whole peal about 10 tons; they are contained in a wrought-iron bell-frame, weighing about 7 tons more.

The clock will show time on four dials, each 13ft. diameter, glazed with opal glass for illumination, either with gas or electricity; has a two-seconds pendulum about 14ft. long, iron and zinc compensation, and a bob, 600lb. weight. Inside minute and seconds dials are provided for setting the exterior hands, and the necessary apparatus is applied, by which it can telegraph its time daily to the observatory, and synchronise to correct time all the other clocks in the building, Bombay city, and on any of the railways, and in towns having wire communication with it. The escapement is that known as Denison's double three-leg gravity, and trials made here of the going qualities of the clock show that it does not vary half a second from its daily rate. The quarters (known as the Westminster) are chimed on the 2nd, 3rd, 4th, and 7th bells of the largest consecutive 8, and the hours are struck on the 8th of the same number.

The carillon machinery plays 16 tunes (two barrels of eight tunes each) one, changed automatically.

On Week Days.	On Sundays.
At 6 0 a.m.	At 6. 0 a.m.
„ 12.0 noon.	„ 1.30 p.m.
„ 5.0 p.m.	„ 5.30 p.m.
„ 9.0 p m.	„ 9. 0 p.m.

The tunes are:—

Sinfonia (Handel).
Those Evening Bells.
When the Rosy Dawn.
Luther's Hymn.
Hanover.
God Save the Queen.
The Harp that Once.
St. Bride's.
Blue Bells of Scotland.
My Lodging is on the Cold Ground.
March of the Men of Harlech.
Last Rose of Summer.
Rule, Britannia.
Home, Sweet Home.
Harmonious Blacksmith.
Auld Lang Syne.

Any number of tunes can be added hereafter.

For the Queen's birthday, and other joyous occasions, a barrel is provided by which 150 changes on twelve bells, rounds and changes on eight bells, and firing will be chimed at full proper speed, as done by ringers in this country. There are two hammers to each bell, each held by wire connections by a separate catch in the carillon machinery, ready to drop and strike its blow;

the pin in the music or change-barrel having only to withdraw the catch, like pulling the trigger of a gun, to discharge the hammer on the bell, the heavy action of relifting being done by a rapidly-revolving independent cam. The diameter of the pin-barrel is only 12in. instead of nearly 6ft., as it must have been if constructed on the old chimes plan, and the pin of brass 1-16in. diameter, instead of steel ½in. square, and being made of wood instead of iron one barrel is easily substituted for another, when it is desired to play eight other tunes, or to chime the changes.

The whole is so constructed that any one part can be removed for repair without disturbing the rest.

ASBESTOS FIREPROOF PAINT.

AN improved fireproof paint, prepared from asbestos and silicate of soda, has been recently patented by Mr. C. J. Mountford, of Birmingham. It is said not only to resist the action of fire, but also to have good covering capacity and body. In preparing the paint the patentee first reduces the asbestos to a fine state of division (usually with water to a stiff paste by means of a pug-mill or suitable grinding apparatus) and then mixes the reduced asbestos with a strong solution of silicate of soda in water: five parts by weight of the former to three parts of the latter. During mixing the mass of the material being treated is maintained at a temperature which may vary from 150° Fahr. to 240° Fahr.—a temperature of about 160° Fahr. being, however, found most suitable. The heating is advantageously effected by causing a jet of steam to rise through the mass, or the mixture may be conveniently heated in a closed vessel, say of cast iron provided with stirrers, motion being given to the vessel, the stirrers, or both. After the incorporation, the paste so formed is thinned down to the required consistency for use with a weaker solution of silicate of soda in water. Colouring matter of any desired kind may be added to the reduced asbestos and silicate solution whilst they are being incorporated together. The proportions of the materials used may be varied to suit different requirements, but the proportions and method of treatment above described are those which the patentee prefers for the standard. Silicate of potash may be used instead of silicate of soda.

UNWRITTEN HISTORY, AND HOW TO READ IT.

THE lecture to the "operative classes" during the meeting of the British Association was delivered on Saturday evening by Mr. John Evans, D.C.L., F.R.S., on "Unwritten History, and how to Read it." Commencing with a few remarks on the origin of the practice of delivering the lecture, he went on to say that it was not easy to find a suitable subject, which should, he considered, be possessed of some local interest. He thought if he spoke of those who in remote times had lived and laboured in this part of the globe, he should have a theme of general human interest. If, in addition to giving particulars of their mode of life, he pointed out the methods by which our knowledge of the manners and customs of remote antiquity was obtained, he should assist his hearers to appreciate the value or the application of scientific methods to the study of the past, and to feel that our knowledge of antiquity rested upon something more secure than vague conjecture. The neighbourhood was the home of some of the witnesses he would call. Our best evidence of what must have been the condition of occupants of the earth without the most simple appliances of modern civilisation was to be found in the relics of the past found buried in the earth. The town was formerly known as Hamtune, and Northampton had the same name; and North and South were prefixed for distinction. Ham was home, and Tune was probably derived from the name of the river in each case. Going back beyond the Roman occupation of the island, we entered the border of the domain of unwritten history. The ancient Britons had coins; particular forms had been found in particular districts: the inscriptions on some determined the names of British princes and the districts in which they reigned. In Hants and Sussex were found coins struck by two princes as to whom written history was silent. In the southern counties, and especially in Kent, coins had been found which were, no doubt, imitations of those made by Philip, the father of Alexander the Great. There was evidence of an uninterrupted succession of coins copied the one from the other. The coins justified us in saying that the Southern Britons were sufficiently civilised to make use of a coinage 150 B.C., or 100 years before Cæsar came. Besides coins of gold, silver, and brass or copper, with devices derived from Gaulish copies of a Macedonian original, there were others cast in tin with devices in imitation of some coins of Marseilles. Many of these had in relief the grain of wood in which they were cast. They had been found with iron tools and weapons near Lewes. In graves which must have belonged to the first few centuries before Christ there had been found swords of iron, with ornamental bronze sheaths. It was the custom to bury with the dead a number of ornamental or useful objects, and in graves in the Austrian Tyrol had been found swords with hilts of ivory inlaid with amber, daggers with golden sheaths, helmets, girdles, bracelets, brooches, and vessels of bronze. In other graves had been found swords, spearheads, and hatchets of bronze, of which the iron weapons appear to be imitations. It was inferred that the bronze weapons must have been in use when iron was introduced as a substitute. The terms "iron age," "bronze age," "stone age" meant certain stages of civilisation, the chronological periods of which would vary in different parts of the world. It was not known when it was discovered that an admixture of tin made copper harder and more fusible, but the discovery was made independently in the New World, for some of the weapons and tools of Peru, made before there was any contact with Europeans, were of bronze of the ordinary composition. The bronze period of Britain was well illustrated by relics (representations of which were shown on the wall). There were swords, spear-heads, daggers, shields, chisels, gouges, and hatchets or axes. In the last-named weapons the gradual development of the socket from the flat blade was traced in curious detail, and the conclusion was drawn that the art of casting hatchets with a socket was introduced into this country from abroad. The bronze-using people were skilful both in founding and in the manufacture of ornaments, and a dagger had been found in Wiltshire as delicately inlaid with gold as any ornament of our own time. But man's history in this stage might be better read on the Continent than at home. In Switzerland, Italy, and the South of France the foundations had survived of the artificial islands carried on piles above the water which the men of those days built to protect themselves against their enemies or wild animals. Those men were hunters and fishermen; to some extent too they were husbandmen, and reaped their corn with sickles of bronze. They made vessels of clay, they could spin and weave both linen and woollen cloth, they possessed domesticated animals—the dog, ox, sheep, goat, and even the horse. Besides bronze, they used flint for their weapons and other appliances, and made utensils of jet and amber. The number and varieties of instruments of that metal found in Britain seemed to carry us back to 1200 or 1400 B.C. as the beginning of the bronze period. But the flint arrow heads and scrapers and the use of stone for battleaxes carried us back to a still earlier chapter of unwritten history. It was astonishing that men in so low a stage of civilisation should have been able to furnish themselves with so many and such perfect appliances made of stone—hatchets and adzes of flint, with carefully ground edges, hollowed chisels, drills, hammers, knives, and saws. The presence of spindle-whorls—the small fly-wheels by which hand-spinning is carried on—proved that the art of spinning was known, and charred fragments of woven garments had been found in the lake dwellings of that primitive time. Wheat, barley, and millet, too, were cultivated, and the apple and pear were not only eaten, but stored up for winter consumption. It was impossible to trace the beginnings of that Neolithic period, as it had been called, although we might fix within some centuries the time at which bronze began to supersede stone as material for the most necessary utensils of life. But the circumstances under which the implements of those days were found proved that the general physical features of the country, the alternation of hill and dale, and the beds of streams, were much the same as they are in the present. In the facts which he had mentioned there was little to prove the inaccuracy of the popular chronology which fixed the creation of the world about 6,000 years ago. But within the last 20 years a marvellous vista of antiquity had been opened out to us by the researches of geologists. The drifted deposits of the Test and the Itchen, and more strikingly those of the Avon, which joined the sea at Christchurch, proved that the earth was many times older than she had formerly been supposed to be. Some of those drift-beds were as much as 90 or 100ft. above the existing river, and it must have required an enormous amount of time to scoop out channels of such a depth. The discovery also of the bones of the elephant, rhinoceros, hyæna, lion, and reindeer, of the pouched marmot, and the Greenland lemming pointed to climatic conditions as diverse as could well be imagined from those under which we now lived. At Southampton itself there were beds of old gravel capping the hill at the common 150ft. above the sea level, and yet the top of that hill must at one time have been a valley surrounded with hills. Thus the aptness of the comparison "as old as the hills" was lost, for

> "The hills are shadows, and they flow
> From form to form, and nothing stands.
> They melt like mists, the solid lands,
> Like clouds they shape themselves and go."

The Stone Age was divided into two periods. That which he had been describing was called the Surface Stone or Neolithic Period, while the earlier times had been designated the Palæolithic or Ancient Stone Period. The implements of the earlier era were of ruder construction, and never had their edges ground. Those implements had been generally found in the river drift, whence arose the term, the "River-drift Period." Yet a great gulf of time was fixed between these two periods. There was little doubt that the gravels which now capped Hengistbury Head, Barton, and Hordle, 100ft. above the sea, were originally deposited in the bed of a river which flowed in an easterly direction, and that the Needles at Alum Bay were the shattered and seaworn remains of an extension of the great chalk ridge of High Down, westward from Freshwater. There must have been a time when the chalk downs of Dorset and the Isle of Wight formed one continuous ridge, and the island was not separated from England by any arm of the sea. In those days, the rivers at Poole, Christchurch, Lymington, and Exbury, must have contributed to form one river flowing from east to west, which in the course of time had widened out until it became the Solent Sea and Spithead. Thus he had shown, though necessarily in an imperfect manner, that the history of man might be carried so far back into a dim past; and even Egyptian chronology, extending as it did over thousands of years, appeared but to cover a small link in the chain of human existence.

SIR W. THOMSON ON THE TIDES.

THE Friday evening discourse during the meeting of the British Association was delivered by Sir W. Thomson, who, after exhibiting and explaining his tide-gauge, tidal harmonic analyser, and tide-predicter, announced that the Committee of Recommendation had determined to recommend the continuance of the tidal harmonic analysis with a view to a more accurate valuation of the long period tides than has been hitherto obtained. From calculations which Mr. G. H. Darwin has already made, it seems that the earth's rigidity may be about the same as that of an ideal globe of homogeneous steel of the same dimensions. A much more accurate valuation is expected from the labours of the committee. The solar, semi-annual and annual tides, which are of high importance, will also be investigated. The learned professor described the difficulty he felt in answering the question, "What is meant by the tides? They were motions of water on the earth due to the attraction of sun and moon. There were places where lunar tides vanished altogether, and where there was only a rise and a fall once in the solar day, or twice in the solar day. There are places where the water rises and falls according to the sun, and not according to the moon; but such rises and falls may depend on other causes than those which we now know to be essential to the lunar tide. We have winds depending on the sun, and changes of temperature depending on the sun. The barometer has regular diurnal periods of change. It is a little higher in the forenoon somewhere about 10 o'clock, a little higher again about 10 o'clock at night, a little lower about 4 in the afternoon and about 4 in the morning. We must be ready, then, to expect rises and falls in the water depending on the heating power of the sun, either directly, or indirectly. It is necessary to separate these motions of the waters from others. We had to explain, and in doing this to consider variations of sea level at different times of the year, and to remember the existence of monsoons and trade winds. We have certain regular annual rises and falls of water depending on the winds, which change with the seasons of the year. These he excluded, but one very interesting point in the theory of tides proper is a solar annual tide, and again, a solar semi-annual tide. The earth being nearer to the sun in January than in July, the action of the sun will operate more powerfully on the waters of the earth in our winter than in our summer. We wish to find by observation how much this effect of the sun's attraction is. The results of observation are utterly inexplicable on the theory of gravitation. We are forced then to look to the meteorological influence—the great discrepancies between the result of observation upon the average sea-level from day to day throughout the year, and what we should expect from a purely gravitation theory of the rise and fall of the sea. But meteorological rises and falls he excluded from the denomination of tides; they were disturbing influences baffling inquiry. They did not affect the lunar influence. But did not the weather change with the moon? Careful observations with the barometer, thermometer, and anemometer at the times of new moon, full moon, and half-moon have failed to establish any relation whatever, and have proved, on the contrary, that if there is any dependence of the weather on the phases of the moon it is only to a degree quite imperceptible to ordinary observation. The discoverer of gravitation failed to reap the fruit of his discovery in explaining rises and falls of the waters of the sea; it was reserved to Newton to explain them on dynamical principles, and he left his successors to work out his theory of tide-generating force. The first rough view of the case was that the moon attracted the waters of the earth towards herself, and heaped them up on this side of the earth. That was not so; it would be so if the earth and the moon were stuck on the two ends of a strong bar and put at rest in space, but there was no such rigid bar. Why did not the moon fall towards the earth? According to Newton's theory, the moon is always doing so. Newton compared the fall of the moon with the fall of a stone at the earth's surface. Why did it not come down? Could it be always falling and never come down? That seemed impossible. It was always falling, but it had a motion perpendicular to the direction in which it was falling, and the result of the continual falling was simply a change of direction of its motion. That was simply the dynamical theory of centrifugal force. If a stone were thrown horizontally it descended in a parabola, the stone falling away from the line in which it was thrown; so it was with the moon. It was seen always to be falling from the present direction and from the further altered line, and so it might be always falling and never coming down. The parts of the moon nearest to the earth were falling most rapidly, the parts further from the earth least rapidly. Each preserved a constant distance, or very nearly a constant distance, from the common centre of gravity of the two. The earth experienced according to its mass a force depending on the average distance. The result clearly was, then, a tendency towards the moon and from the moon, and thus, in a necessarily imperfect manner, he had explained to them how it was that the waters were not heaped up on the side next the moon, but were drawn up towards the moon, and fell away from the moon, so as to tend to form an oval figure. The result of calculations founded upon those principles might be illustrated by an exceedingly delicate spring-balance, having a piece of lead, iron, or brass upon it. It would be found that when the moon was overhead the weight would be diminished by a six-millionth part. Again, when the moon was under foot at lunar midnight, there would be an apparently increased heaviness. Thus the moon's attraction made a variation in the apparent heaviness of bodies amounting to one six-millionth part above and below the mean value. The same result might be attained by a plummet, which would be found to be drawn aside by one 12-millionth part of its length, when the moon was off the vertical. Such observations gave the answer to very important questions regarding the condition of the earth. When the moon was in quarters, as it was called, its influence was greater than that of the sun. Why? Because it was 400 times as near, though enormously less massive. Calculating the moon's mass and the sun's mass, the lunar influence was 2 1-10th times that of the sun in respect of solar tides. The lunar tide-generating force was thus more than double the solar. The sun and moon acted conjointly, and when they produced opposite effects the tide-generating force was their difference. Another question arose: Would not the whole earth yield under the influence of these forces? Would not the six-millionth part of the whole force of gravity operating in different directions squeeze the earth out of shape? It would be so were it not for the enormous rigidity of the earth. That consideration sufficiently disposed of the theory that the earth was a mere crust 40 or 50 miles thick and filled with molten lava. The inference was that the earth had, on the whole, a rigidity greater than that of a globe of steel of the same dimensions. Recurring to the tides, Sir W. Thomson observed that the results of the theory which he had been setting forth, coincided with the actual observation of the tides. Tides were considerably greater when the moon was nearest the earth, and less when she was furthest from the earth. The variations in the tides due to the difference of distance of the moon from the earth were called lunar ecliptic tides, the expression "tide" being used for any of the constituents of the mean action. There was the mean solar tide in the first place, and the mean lunar tide in the second. The sum of the effects of the sun and the moon was a compound luni-solar tide. To take an illustration from the wind, there was what he might call spring and neap sounds, alternately loud and soft. When the two produced their effect together there was a spring tide, as it were, of sound; when the two were going in opposite directions there was a neap or scanty effect of sound. If the two influences—that of the sun and that of the moon—were equally loud, the alternation would be from loud sound to silence; but if one was twice the amplitude of the other we should have a phenomenon comparable with the spring and neap tides. The alternation would not be from loudest to least loud, but from loudest to silence. He might then mention the important experiments carried on by Mr. George and Mr. Horace Darwin in a pendulum so delicately hung as to be sensible of the very smallest effect. They found incessant variations, which went to prove that the palpitation of the earth was traceable to local disturbances, such as the traffic of a town. These palpitations were in effect minute and unceasing errthquake tremors, which completely masked the delicate regular periodical variation which their pendulum would have shown had the earth been worthy of its name *terra firma*.

RECENT ADVANCES IN PHOTOGRAPHY.—VI.*

By Capt. Abney, R.E., F.R.S.

I WISH to commence this evening by showing you the production of a positive picture from a positive picture; not that there is anything essentially novel in it, but it points to a moral to which I shall presently have to draw your attention. What I propose to do, is to take some sensitive iodide paper, expose it to light, and then soak it in a weak solution of potassium bromide, and next expose it behind a positive on glass. On developing, I think the probabilities are that we shall get a positive picture. It is perfectly immaterial, as I am going to expose it to light, whether the paper sees the light now or not, and the small modicum of light we have here will make very little difference to this comparatively insensitive paper. I now burn a small quantity of magnesium wire, in order to fully expose the sensitive surface. If I were to put a developer on that paper as it is now, it would at once blacken. Instead of applying the developer, I will place it in the solution of potassium bromide, then expose it under a transparency, and subsequently develop it. I will give it rather a prolonged exposure, for this paper is not very sensitive, and of course, the time in which this positive is produced depends on the sensitiveness. [A lantern image was thrown on the paper.] Half a minute with this light would be sufficient, but for safety's sake I will give 20 seconds longer. I will now develop the picture with ferrous oxalate, and a positive instead of a negative appears, as it would do in the ordinary way. In other words, the lights are reversed.

Before I draw any conclusion as to this, I will show what part of the spectrum produced this positive picture, because this is an important item in the deduction I shall have to draw. I will take another similar piece of paper, and throw the spectrum upon it. You will recollect that we applied a solution of bromide of potassium to an exposed piece of paper, and that it was then exposed to the image. I will, therefore, expose this second piece of paper to the light from the magnesium wire, as before, and immerse it in a dish in which there is a solution of potassium bromide, and place it in the spectrum. I leave it to be acted upon for about half-a-minute. This I propose to develop on the screen, so that you may see absolutely the part of the spectrum which affects the paper. If everything goes right, there ought to be a bleaching action in the blue rays, and the red rays also will exert a bleaching action if the exposure is continued for some time.

Now, if you will allow me, I will point the moral. These may seem paltry experiments to bring before an audience, but those of the audience who are interested in gelatine plates, and I believe there are a great many here who are, will now, perhaps, be able to draw an inference equally well with myself. All gelatine plates, without exception, I believe, are prepard with an excess of soluble bromide, and I will now ask you to consider what happens, supposing any bromide is left in the film. While the light is acting on the film, the bromide of silver is decomposed, and at the same time the bromide of potassium (or ammonium), is also being decomposed, and undoing the work that the light has done upon the bromide of silver; so that you see that the sensitiveness really got by gelatine plates with an excess of soluble bromide is only the difference between the effect of the light on the silver bromide, and on the bromide of potassium (or ammonium). I think those two experiments ought definitely to settle that gelatine plate-makers have not, as yet, obtained the highest sensitiveness possible, simply because they prepare their emulsions with an excess of soluble bromide. I may say with reference to this, that Dr. Eder has recently shown that on immersing gelatine plates in a weak solution of silver nitrate (in which is a little citfic acid), though strong enough to neutralise any soluble bromide which may be left behind, an increase of sensitiveness, two or three-fold, is produced. The problem to be solved by gelatine plate-makers is this—How to get rid of any possible excess of soluble bromide in their gelatine films? When they do that, no doubt they will get more more rapid plates even than they have done at present. I will now show on the screen those interested in the chemistry of the subject the formula which represents the action which takes place—

$$\text{(I.)}\ 2Ag_2I + 2KI + H_2O + O = 4AgI + 2KHO$$

$$\text{(II.)}\ 2Ag_2Br + 2KBr + H_2O + O = AgBr + 2KHO$$

In the first equation (I.) we have silver iodide, but a similar formula (II.) applies to bromide of potassium, and bromide of silver. In (I.) there is sub-iodide of silver, iodide of potassium, water and oxygen, and that forms iodide of silver, potash, and iodate of potassium. When you have more iodine or bromine liberated, we get—

$$\text{(III.)}\ 6I + 6RHO = 5KI + KIO_3 + 3H_2O$$

or the iodine and potash combine, and form fresh potassium iodide, water, and iodate of potash. When this reaction is finished, we have to go back to the equation (I.), and the same decomposition is repeated.—The oxygen of course is a crux; where does it come from? It comes from the air. It will find its way through the gelatine. Gelatine is not impervious to the air. Dr. Eder has very recently found that this reaction does not take place when there is no oxygen present. So that you see, in order for this reaction to take place, there must be oxygen obtainable from some external source. If you prepare your emulsion with hydrochloric acid, as some do, you have nitric acid left in the film, and that will supply the necessary oxygen for this formula to take effect. I need not enter into details of what takes place with the nitric acid, it is sufficient to say that the nitric acid will supply the oxygen.

This leads me next to consider what causes the destruction of the photographic image. You may destroy the image on a photographic plate, or photographic paper, by any substance which will readily part with oxygen. You can destroy it, for instance, by bichromate of potash; you can destroy it by any of the ferric salts; or you can destroy it by oxygen-yielding substances, like permanganate of potash; ozone, peroxide of hydrogen, or hydroxyl; in fact, there is hardly any substance which will part with oxygen which will not destroy the developable image; the photographic image remains behind as a rule, though not always, but these reagents prevent it becoming developable. Here is a paper prepared with bromide of silver, which has been already exposed behind a negative. After immersion in water, I propose to apply to it some of these destructive agents which I have already mentioned. First I will give it a streak of bichromate, next ferric oxalate, and next permanganate of potash. If everything goes right, on those parts to which these solutions have been applied, the image will be destroyed, or almost destroyed, and a little longer application of the solution would entirely destroy it. This demonstrates then that oxidising agents will destroy the devolopable image.

Now, I do not wish to detract from any developer, but this shows you the care you should take in seeing that your ferrous oxalate developer is tolerably fresh, for you have a large proportion of *ferric* oxalate present with it, it will be very liable to "slow" your plates, and those who are photographers will know what that means. If you take your pyrogallic acid which has been fully oxidised, you will find that it will play you the same trick as this ferric oxalate does, so that neither the ordinary alkaline developer nor the ferrous oxalate developer is certain to give you the best results unless it is fresh. Photographers take warning, and when using a ferrous oxalate developer, use it fresh! If you use the ferrous-citro-oxalate which I have introduced so often to your notice, you get the same result; it has the same bad qualities that the ferrous oxalate has.

(*To be concluded.*)

---

[*] Condensed from a series of Cantor Lectures delivered before the Society of Arts.

Ebonising.—How to make woods, such as cherry, mahogany, &c., look like ebony is often desirable, and a correspondent of the *Hub* gives the following directions:—To imitate black ebony, first wet the wood with a solution of logwood and copperas, boiled together, and laid on hot. For this purpose 2oz. of logwood chips, with 1½oz. of copperas, to a quart of water, will be required. When the work has become dry, wet the surface again with a mixture of vinegar and steel filings. This mixture may be made by dissolving 2oz. of steel filings in one-half pint of vinegar. When the work has become dry again, sandpaper down until quite smooth. Then oil and fill in with powdered drop-black mixed in the filler. Work to be ebonised should be smooth and free from holes, &c. The work may receive a light coat of quick-drying varnish, and then be rubbed with finely pulverised pumice-stone and linseed oil until very smooth.

BRITISH ASSOCIATION.

THE ADDRESS IN MATHEMATICS AND PHYSICS.

THE address in Section A was delivered by the president, the Right Hon. Lord Rayleigh, F.R.S., and was mainly occupied with a discourse upon the value and importance of measurements. Even, said the president, where we may fairly suppose that the fundamental principles are well established, careful and often troublesome work is necessary to determine with accuracy the constants which enter into the expression of natural laws. In many cases the accuracy desirable, even from a practical point of view, is hard to attain. In many others, where the interest is mainly theoretical, we cannot afford to neglect the confirmations which our views may derive from the comparison of measurements made in different fields and in face of different experimental difficulties. Examples of the interdependence of measurements apparently distinct will occur to every physicist. I may mention the absolute determinations of electrical resistance, and of the amounts of heat developed from electrical and mechanical work, any two of which involve also the third, and the relation of the velocity of sound to the mechanical and thermal properties of air. Where a measurement is isolated, and not likely to lead to the solution of any open question, it is doubtless possible to spend upon it time and attention that might with advantage be otherwise bestowed. In such a case we may be properly satisfied for a time with work of a less severe and accurate character, knowing that with the progress of knowledge the way is sure to be smoothed both by a better appreciation of the difficulties involved, and by the invention of improved experimental appliances. I hope I shall not be misunderstood as underrating the importance of great accuracy in its proper place if I express the opinion that the desire for it has sometimes had a prejudicial effect. In cases where a rough result would have sufficed for all immediate purposes, no measurement at all has been attempted, because the circumstances rendered it unlikely that a high standard of precision could be attained. Whether our aim be more or less ambitious, it is important to recognise the limitations to which our methods are necessarily subject, and as far as possible to estimate the extent to which our results are uncertain. The comparison of estimates of uncertainty made before and after the execution of a set of measurements may sometimes be humiliating, but it is always instructive. Even when our results show no greater discrepancies than we were originally prepared for, it is well to err on the side of modesty in estimating their trustworthiness. Perhaps I may be allowed to illustrate my meaning by reference to a subject which has engaged a good deal of my attention for the last two years—the absolute measurement of electrical resistance. The unit commonly employed in this country is founded upon experiments made about twenty years ago by a distinguished committee of this Association, and was intended to represent an absolute resistance of 10^9 C.G.S., *i.e.* one ohm. The method employed by the committee at the recommendation of Sir W. Thomson (it had been originally proposed by Weber) consisted in observing the deflection from the magnetic meridian of a needle suspended at the centre of a coil of insulated wire, which formed a close circuit, and was made to revolve with uniform and known speed about a vertical axis. From the speed and deflection in combination with the mean radius of the coil and the number of its turns, the absolute resistance of the coil, and thence of any other standard can be determined. About ten years later Kohlrausch attacked the problem by another method, which it would take too long to explain, and arrived at the result that the B.A. unit was equal to 1·02 ohm—about two per cent. too large. Rowland, in America, by a comparison between the steady battery current flowing in a primary coil with the transient current developed in a secondary coil when the primary current is reversed, found that the B.A. unit was ·991 ohm. Lorentz, using a different method again, found ·980, while H. Weber, from distinct experiments, arrived at the conclusion that the B.A. unit was correct. It will be seen that the results obtained by these highly competent observers range over about four per cent. Two new determinations have lately been made in the Cavendish laboratory at Cambridge, one by myself with the method of the revolving coil, and another by Mr. Glazebrook, who used a modification of the method followed by Rowland, with the result that the B.A. unit is ·986 ohm. I am now engaged upon a third determination, using a method which is a modification of that of Lorentz. Bulky records of crude and uninterrupted observations are not science, nor even in many cases the raw material out of which science will be constructed. The door of experiment stands always open; and when the question is ripe, and the man is found, he will nine times out of ten find it necessary to go through the work again. When an unexpected effect is observed, the question will arise whether or not an explanation can be found upon admitted principles. In repeating, at the beginning of the century, the well-known experiment of the inaudibility of a bell rung *in vacuo*, Leslie made the interesting observation that the presence of hydrogen was inimical to the production of sound, so that not merely was the sound less in hydrogen than in air of equal pressure, but that the actual addition of hydrogen to rarefied air caused a diminution in the intensity of sound. How is this remarkable fact to be explained? Does it prove that, as Herschel was inclined to think, a mixture of gases of widely different densities differs in its acoustical properties from a single gas? These questions could scarcely be answered satisfactorily but by a mathematical investigation of the process by which vibrations are communicated from a vibrating solid body to the surrounding gas. Such an investigation founded exclusively upon principles well established before the date of Leslie's observation was undertaken years afterwards by Stokes, who proved that what Leslie observed was exactly what ought to have been expected. The addition of hydrogen to attenuated air increases the wave-length of vibrations of given pitch, and consequently the facility with which the gas can pass round the edge of the bell from the advancing to the retreating face, and thus escape those rarefactions and condensations which are essential to the formation of a complete sound wave. Examples such as this, which might be multiplied *ad libitum*, show how difficult it often is for an experimenter rightly to interpret his results without the aid of mathematics. By direct observation one of the most experienced and successful experimenters of the last generation convinced himself that light of definite refrangibility was capable of further analysis by absorption. It has happened to myself, in the course of measurements of the absorbing power of various media for the different rays of the spectrum, to come across appearances at first sight strongly confirmatory of Brewster's views, and I can therefore understand the persistency with which he retained his opinion. But the possibility of further analysis of light of definite refrangibility (except by polarisation) is almost irreconcilable with the wave theory, which on the strongest grounds had been already accepted by most of Brewster's contemporaries; and in consequence his results, though urgently pressed, failed to convince the scientific world. Further experiment has fully justified this scepticism, and in the hands of Airy, Helmholtz, and others has shown that the phenomena by which Brewster was misled can be explained by the unrecognised intrusion of diffused light. The anomalies disappear when sufficient precaution is taken that the refrangibility of the light observed shall really be definite.

THE ADDRESS IN CHEMISTRY.

The address in Section B was delivered by the president, Prof. G. D. Liveing, F.R.S., who said that if he were asked in what direction chemical science had of late been making the most important advances, he should reply that it was in the attempt to place the dynamics of chemistry on a satisfactory basis, to render an account of the various phenomena of chemical action on the same mechanical principles as are acknowledged to be true in other branches of physics. He could not say that chemistry could yet be reckoned among what are called the exact sciences, that the result of bringing together given matters under given circumstances could yet be deduced in more than a few special cases by mere mathematical processes from mechanical principles, but that some noteworthy advances have in recent years been made, which seem to bring such a solution of chemical problems more nearly within our reach. In the first place, notwithstanding the slowness with which new ideas replace old familiar images, the molecular theories developed by Clausius, Clerk-Maxwell, and Boltzmann, and by Sir W. Thompson, have been long enough before the world to have greatly loosened the hold upon our minds of many old notions. The vortex theory, whether we think it probable or not, at least gives us a standing ground for the assertion that the supposed impenetrability of matter, and the curious compound of nucleus and atmosphere which had been invented to account for elasticity, are not necessary assumptions. The kinetic theory of gases has analysed for us the different motions of the molecules in a mass of matter, and has facilitated the conception of the part which heat plays in chemical action.

Proceeding with his remarks, Prof. Liveing referred to two hypotheses which have created a little interest lately. The notion that there is but one elementary kind of matter is at least as old as Thales, and underlies Prout's hypothesis that the atomic weights of our elements are all multiples of that of hydrogen. This famous hypothesis has gone up and down in the scale of credibility many times during the present century. Quite recently, said the speaker, a fresh revision of the combining weights has been made on the other side of the Atlantic by Professor F. W. Clarke, who, on the whole, concluded that Prout's hypothesis, as modified by Dumas, is still an open question—that is to say, his final numbers differ from whole multiples of a common unit by quantities which lie within the limits of errors of observation and experiment. Let us turn again to the evidence afforded by our most powerful instrument for inspecting the inner constitution of matter, the spectroscope. A few years ago Mr. Lockyer supposed that the coincidence of rays emitted by different chemical elements, particularly when those rays were developed in the spark of a powerful induction coil and in the high temperatures of the sun and stars, gave evidence of a common element in the composition of the metals which produced the coincident rays. Later results cannot fail to shake our belief in the existence of any common constituent of the chemical elements; but it does not touch the evidence which the spectroscope affords us that many of our elements, in the state in which we know them, must have a very complex molecular structure. Professor Liveing said he could not dismiss the subject of chemical dynamics without alluding to the ingenious theory by which the President of the Association has proposed to account for the conservation of solar energy. Commenting on this, he remarked that if it be true that the compounds are decomposed by absorbing the sun's rays, we ought to find in our atmosphere the products of decomposition; we ought to find it in free hydrogen, carbonic oxide, and acetylene or some other hydrocarbons. The hydrogen, from its small specific gravity, would not be concentrated in the lower regions of our atmosphere in the same proportions as the denser gases, but carbonic oxide and hydrocarbons could not fail to be detected in the air if they formed any sensible proportion of the gases in the planetary space. Dewar and he had recently shown that if nitrogen already in combination, as, for instance, ammonia, be brought into a hydrocarbon flame, cyanogen is produced in sufficient amount to give in a photograph (though not so as to be directly visible) the characteristic spectrum of cyanogen as it appears in the comet. It is therefore, he said, no longer necessary to make any other supposition to account for the cyanogen bands in the spectra of comets, than that ammonia, or some such compound of nitrogen, is present as well as hydrocarbons in a state of ignition.

THE ADDRESS IN GEOLOGY.

The address in Section C was delivered by the president Mr. R. Etheridge, F.R S., who referred to the geological features of the district, and gave an epitomised history of the work that had been done in the Hampshire basin, the channel, and the opposite coast. In Selsea, said the President, I draw attention to a locality of extreme interest both to the geologist and archæologist, where cause and effect are manifested in both investigations, the historical portion being based upon physical causes and changes that have long been and still are going on, to modify the form, extent, and structure of the Sussex coast, from the mouth of Chichester Harbour to Littlehampton and Bognor. The peninsula of Selsea is celebrated in English history as one of the places where Christianity was first taught in this country. It was one of the most ancient Saxon establishments. This peninsula was granted by Edilwalch, King of the South Saxons, to Wilfred, the exiled Bishop of York, about the year 680 At that time it is stated to have contained 5,220 acres of land, with 85 families and 250 slaves. The parish now contains only 2,880 acres, 2,340 having been slowly denuded away by the action and encroachment of the sea. This encroachment and destruction during the past 800 years has been very extensive. The creek called Pagham Harbour, on the south-east side of the Bill or peninsula, was due to an irruption before the year 1315, when 2,700 acres of land were destroyed. The site of the ancient cathedral and episcopal palace of Selsea, believed to have been situated to the south-east of the present church of Pagham, is no longer to be determined, but there is no reason to doubt but that it stood nearly a mile out in what is now sea. We are led to believe that when Selsea became known to the English nation is was an island, and that in Bede's time the process of silting up the estuary must have commenced, and the completion of this process would seem to have been before the Conquest. The action of the tides on this coast carries the sand and shingle from west to east, therefore the gradual wasting which has taken place on the shore of Bracklesham Bay has served to supply a large portion of the material of which these marshes are formed. The ground on which Selsea, Bognor, Littlehampton, Worthing, and other places on the Sussex coast westward of Brighton are built, is of very recent formation, being composed of gravels, sands, and loam belonging to the post-pleiocene or pleistocene series.

THE ADDRESS IN MECHANICAL SCIENCE.

The address in Section G was delivered by Mr. John Fowler, C.E., who said that in the future the present age will be remembered chiefly for the vast strides which have been made in the advancement of mechanical science. The civil engineer is essentially a product and a type of the latest development of the present century. The work which above all others would have astonished and perplexed our ancestors is the little one known to all the civilised world as "Bradshaw." The President then made some remarks on the speed and regularity of the train service, and contrasted it with the achievements at the opening of the Liverpool and Manchester Railway half a century ago. An essential condition of the attainment of high speed on the railway is that the stopping places be few and far between. On the Metropolitan Railway no sooner has a train acquired a reasonable speed than the brakes have to be sharply applied to pull it up again. Sixty per cent. of the whole power exerted by the engine is absorbed by the brakes. In other words, with a consumption of 30lb. of coal per train mile, no less than 18lb. are expended in grinding away the brake blocks, and only the remaining 12lb. in doing the useful work of overcoming frictional and atmospheric resistances. Comparatively high speed and economy of working might be attained on a railway with stations at half-mile intervals if it were possible to arrange the gradients so that each station should be on the summit of a hill. An ideal railway would have gradients of about one in 20 falling each way from the stations, with a piece of horizontal connecting them. With such gradients gravity alone would give an accelerating velocity to the departing train at the rate of one mile per hour for every second; that is to say, in half a minute the train would have acquired a velocity of 30 miles an hour, while the speed of the approaching train would be correspondingly retarded, without the grinding away of brake blocks. Could such an undulating railway be carried out, the consumption of fuel would probably not exceed one-half of that on a dead level railway, while the mean speed would be one-half greater. Although the required conditions are seldom attainable in practice, the broad principles should be kept in view by every engineer when laying out a railway with numerous stopping-places. The construction of tunnels was not one of the novelties presenting itself to railway engineers, for many miles of tunnel had been driven by canal engineers before a single mile of passenger railway had been built in this or any other country. To foreign engineers belongs the honour of having boldly conceived and ably accomplished tunnel works of a magnitude which would have appalled a canal engineer. Tunnels under broad navigable rivers and estuaries have been a subject of discussion by engineers for at least a century, but the only one at present completed is the unfortunate and costly Thames tunnel. Two important works of the class are, however, now well in hand—namely, the Severn tunnel at Portskewet, and the Mersey tunnel at Liverpool. One lesson enforced by the Thames Tunnel was the necessity of leaving a reasonable thickness of ground between the water and the tunnel. In the Severn tunnel the *minimum* thickness is 40ft., and in the Mersey tunnel 22ft. The width of the river at the point of crossing of the former tunnel is 2¼ miles, and the *maximum* depth of the rails below high water 163ft. In the case of the Mersey tunnel the width is nearly three-quarters of a mile, and the depth 144ft. The Thames tunnel, as almost every one knows, was carried on by means of a special contrivance termed by Brunel a "shield." No special appliances have been adopted in the case either of the Severn or the Mersey tunnel. Both are driven in the ordinary way, but of course enormous pumping-power is required and has been provided. Where no special appliances are used in the construction of a subaqueous tunnel, it will be clear that an unknown risk is encountered. All may go well, and the engineer will then justly receive congratulations from every one for his boldness and success But, on the other hand, something may go wrong, even at the last moment, and the engineer then would be abused by the unthinking public for his temerity and consequent failure. In many cases of tunnels under estuaries, special appliances could be used which would obviate all risk and make the successful completion of the work a mathematical certainty. A tunnel over a mile in length now in progress under the Hudson river at New York is being driven through a silty stratum by the aid of compressed air, and with a certain amount of success, as only some twenty men have been drowned up to the present time. The principle upon which the compressed air is used, however, a false one, since it is merely forced into the tunnel with a view to uphold the ground by its pressure, like so much timbering, and not to keep out the water on the principle of a diving-bell. It is clear, therefore, that the completion of the Hudson river tunnel, if the present system be persevered in, is purely a matter of conjecture, and all we can do is to hope for the best. The same remark applies, of course, to the Severn tunnel and the Mersey tunnel, although in those cases the character of the ground is such that the contingencies are small in comparison with those encountered in the construction of the Thames tunnel and the Hudson river tunnel. Nevertheless, unless special appliances of the nature of the pneumatic process be used, a subaqueous tunnel, whether it be the Channel tunnel itself or one but a few yards in length, must necessarily present an unknown risk. The prototype of all these tunnels is the one commenced at Rotherhithe in 1809, which was successfully driven a distance of 900ft. under the Thames, and failed when within little more than 100ft. of the opposite shore. A tunnel about 1½ miles in length was commenced about ten years ago under the Detroit river in America, but was abandoned in a similar manner. So far good fortune has attended both the Severn and the Mersey tunnels, and there is, I am glad to say, every chance of its continuing. Only a few months ago I became aware of the fact that a scheme, identical in all its main features with my Humber tunnel project, had been suggested for adoption in the case of the Thames tunnel, in lieu of the plan proposed by Brunel. Fifty-nine years ago a working smith named Johnson proposed to construct the Thames tunnel without coffer-dams by making it in parts, 28ft. in length, each part having the ends temporarily stopped up and being constructed on the same principle as the diving-bell. If another tunnel be constructed under the Thames, which is far from improbable, as the requirements of below-bridge traffic necessitates some such means of communication, it will be built in accordance with the plan suggested fifty-nine years ago by the working smith, and not on that of Brunel's Thames tunnel, or of any other tunnel yet carried out. A ferry still is the only means of communication across the Forth at Queensferry. Parliament by the passing of the Forth Bridge Act during the present session, has given a practical recognition of the truth that the improvement of the Forth passage is a "national object." After a careful consideration of the difficult problem, in concert with my able colleagues, Mr. T. E. Harrison, the chief engineer of the North Eastern Railway, and Mr. W. H. Barlow, chief engineer of the Midland Railway, we unanimously advised the directors of the Forth Bridge Company to abandon the project of a suspension bridge, and to construct a steel girder bridge of the uprecedented span of 1,700ft. The total length of the structure is 1½ miles, and it includes two spans, as aforesaid, of 1,700ft., and two of 675ft., over the navigable channels on each side of Inchgarvie. The execution of the work has been intrusted to me, and my intention is that the Forth Bridge shall be not only the biggest, but the strongest and stiffest bridge yet constructed. Although great navigable rivers offer the most serious impediments to lines of communication lying at right angles to the direction of the stream, and necessitate such formidable undertakings as the Forth Bridge, with a clear headway of 150ft. above high water, and the Severn tunnel, at a depth of 163ft. below the same datum, still it must be remembered that such rivers were the earliest, and are yet the cheapest highways for inland communication.

ABSTRACTS OF REPORTS, PAPERS, &c.

Report on the Ultra-Violet Spark Spectra.

The report of the committee on the photographing of the ultra-violet spark spectra emitted by metallic elements and their combinations was presented by Professor Huntington. It stated that the chief objects to be gained from a knowledge of the character of the spark spectra of metallic elements were the means of readily identifying the metals by photographs of their line spectra; a knowledge of the alterations producible in the spectra of metallic salts by the presence of various non-metallic elements; a knowledge of the alterations in spectra caused by the dilution of metallic solutions; the possible means of performing rapid quantitative determinations of metallic substances by the aid of photography and obtaining permanent records of the results. In a paper on the reversal of metallic lines as seen in over-exposed photographs of spectra presented to the Royal Society, Professor Stokes said an under-exposed plate was likewise difficult to develop, and was liable to cause the strong lines to appear reversed. Any strong lines might be reversed by over-exposure without materially altering the appearance of the rest of the spectrum. The reversal took place in the centre of the line, and was where the radiation was most active and subject to reversal by over-exposure. Professor Hartley had stated that some 14 years' practice in photography had convinced him that when a plate was properly exposed the development of the image was the simplest of all operations. In order to simplify spectroscopic work he had carefully ascertained the time of exposure required to produce the spectra under various conditions, such as intensity of spark and conductivity of the electrodes. He preferred a general period of half a minute. It was a remarkable fact that at the present time they knew little or nothing of the sensitiveness of the spectrum under certain various conditions, notwithstanding that such knowledge was absolutely necessary for the purpose of giving stability to numerous theories and arguments which were based on spectrum observations. The President said he thought the committee had a little exaggerated the difficulties regarding over-exposure.

A Small Dynamo.

Mr. W. H. Preece brought under the notice of Section A a new form of hand dynamo machine worked by two men. Mr. Preece showed a small arc light and produced a good light with three Edison lamps. The E M.F. of the machine at full speed was 70 volts. The resistance of the field magnet was 4 ohms, and the resistance of the armature was 4 ohms. One capital Swan light would be produced if only one man worked the machine. The price of the dynamo itself without the mechanical construction was only £15. He strongly recommended the machine for its usefulness in homework or in the demonstrations of the lecture-hall. Mr. Ladd explained that a hand machine of his own would produce two Swan lights with the labour of one man. Mr. Swan feared that the imposition of a heavy royalty had restricted the use of Mr. Ladd's machine, and as he understood Mr. Preece, the machine now described would be useful and cheap. Mr. Ladd having pointed out that the price quoted by Mr. Preece did not include the mechanical gearing, Mr. Preece said the cost of this new dynamo was 350 francs, and an additional £5 would complete the fitting up of the instrument. It is designed by M. De Meritens.

Secondary Batteries.

Dr. Gladstone made a communication to the same section on the secondary batteries known as the Plante or Faure accumulators, which have been proposed and used as a valuable adjunct to the means of electric lighting. The amount of force that can be obtained from one of these cells depends upon the quantity of peroxide of lead which can be reduced, and it was shown by a consideration of the chemical reaction which takes place that this peroxide is somewhat rapidly destroyed by local action, both during rest and discharge. The great object to be overcome is to minimise this destructive action. Everyone, he said, wished these secondary batteries to be successful. When they were perfected they would be extremely valuable. One important way of getting at the best secondary battery was to continue the examination of chemical reaction, with a view to getting a secondary battery which should not be subject to loss, but should be free from local action and capable of retaining the electricity put into it for any length of time that might be convenient.—An animated conversation arose, in which the main point discussed was whether the sulphate of lead formed in these batteries is reduced or not by subsequent charging. —The President (Lord Rayleigh) agreed that a minute and thorough investigation of the chemical reaction should be the key to the difficulties that remain to be overcome in the secondary battery.—Sir W. Thomson also said that a great deal of investigation into chemical theory, as compared with practical results, was urgently wanted.—Prof. S. P. Thompson pointed out that Faure, in his earlier experiments, met some of the difficulties by a process of alternately charging in different directions, and also by giving his battery periods of rest during the time of charging. When he charged his batteries in this way he obtained from them a greater electromotive force. During the period of rest local action had been going on, but the sulphate of lead deposited was by the subsequent charging itself peroxidised, and thus a stronger peroxidation was obtained. He believed the best form of secondary battery was the old Planté accumulator of 1860, pure and simple.

Report on Underground Waters.

Mr. C. E. de Rance read the report of a committee appointed to investigate the circulation of underground waters in the permeable formations of England, and the quality and quantity of the water supplied to various towns and districts from those formations, to which was added an appendix, written by Mr. Edward Wethered, on the density and porosity of rocks in relation to the water-supply, in which the author set out by averring that a knowledge of the porosity of rocks was important as regarded the water-supply, the suitability of stone for building purposes, and in accounting for some of the lithological changes often observed in the earth's strata. Though the matter had not escaped investigation, the vast volume of water stored in the rocks had not been fully realised. The density of the old red sandstone was 2·61, the volume of water absorbed by a cubic foot being 0·707 gallon, and by a square mile, 3ft. thick, 59,000,000 gallons. The conglomerate beds of the same formation were still more absorbent, being capable of taking in 0·805 per cubic foot, or 67,000,000 gallons to the square ile 3ft. thick. The millstone grit which lay at he base of the coal measures varied much in different localities, that found in the Forest of Dean being the most porous, absorbing 66,000,000 gallons to the square mile 3ft. thick. Some of the coal-measure grits also stored large volumes of water. The Pennant rock, about 900ft. thick in the Bristol coalfield, and extensively developed in Somersetshire, as also around Swansea, was capable of absorbing 12,000,000 gallons in a square mile 3ft. thick, and specimens of magnesian limestone taken from the neighbourhood of Bristol showed a porosity of 86,000,000 gallons, but the carboniferous limestone was quite the reverse, and only absorbed three and a half millions. Oolites held vast stores of water, and the rock was much used for building.

SCIENTIFIC NEWS.

◆

AFTER an animated discussion, the general committee of the British Association decided to hold the next meeting at Southport, by 64 votes to 57 given for Canada. For 1884, Montreal, Birmingham, Aberdeen, and Nottingham were proposed, and the first place was chosen by a considerable majority.

Prof. Cayley was elected president for next year, and for vice-presidents the Earls of Derby, Crawford, and Lathom, and Profs. Greenwood, Roscoe, and H. J. S. Smith. Prof. T. G. Bonney was re-elected secretary.

There has been the usual number of amusing papers read at the recent meeting—one which brought out from Sir W. Thomson a reiteration of his belief in the possibility of germs reaching the earth in meteors. The paper was by Prof. Schwedoff, on a theory of hailstones. The writer gave an account of some remarkable hailstones, one 26in. in diameter being completely eclipsed by another "as large as an elephant," which was three days melting. Prof. Schwedoff holds that hailstones come from ultra-terrestrial regions—are in short a species of meteor of cosmic origin. Prof. S. P. Thompson read a paper in support of Prof. Schwedoff's theory, which he thinks is the only one sufficiently accounting for the phenomena and variety of form of hailstones; but Sir W. Thomson thought the paper might have been put forward as a joke. A particle of Schwedoff's hail falling through the atmosphere with meteoric velocity would perform 13,000 times as much work as would raise water one degree Centigrade, and if that would not melt hailstones he did not know what would.

In a paper on electric railways, Dr. Fleeming said that Edison's electric locomotive saved about one pound of coal per horse-power per hour over the ordinary locomotive—a statement which was promptly corrected by pointing out that he had assumed the consumption of the steam locomotive to be 6lb. per horse-power per hour—about double the quantity actually consumed.

In the course of the discussion on a paper by Mr. W. S. Duncan, Professor Ball mentioned that he had seen monkeys, on an island where trees and fruit were scarce, go down to the shore and eat oysters. Mr. Duncan's paper was an endeavour to show that the scene of man's evolution might be discovered by palæontological researches. He adduced reasons for believing that the South of Europe and Asia was the probable scene, and consequently a likely field for successful explorations.

The deaths are announced of Sir Woodbine Parish, F.R.S., and of Count Lutke, the Russian Arctic explorer. The former was in his 86th year. He was made a Fellow of the Royal Society in 1824, for his contributions to science, and in consideration of his having brought to this country the fossil remains of the Megatherium, Glyptodon, and other monsters of the ancient Pampas.

Captain R. G. Morris, R.E., and Lieutenant Darwin, R.E., sailed on Saturday in the *Liguria* for Australia, to take up their stations for the transit of Venus.

Two Belgian expeditions have also left, one under M. Houzeau for Texas, and the other under M. Niesten for Chili.

Prof. H. A. Newton has been appointed director of the new Observatory at Yale College, Connecticut. The observatory possesses an 8in. refractor by Grubb, and a heliometer by Repsold.

Vice-Admiral Stephen C. Rowan has been appointed superintendent of the Naval Observatory at Washington.

The Italian Minister of Public Instruction has agreed to the proposed international expedition to the Marquesas Islands in 1883, to observe the solar eclipse in May. Prof. Tacchini has been directed to make all necessary preparations.

Mr. W. H. Neale, M.B., the medical officer of the *Eira*, expresses the opinion that if they live on the meat of the country—that is, walrus and bear—Arctic voyagers will run little risk of scurvy, even without vegetables. Preserved mutton and beef are to be preferred, but the doctor means that walrus and bear flesh will serve to keep away scurvy. At first the whole crew were attacked by diarrhœa, but recovered after about two or three weeks of the diet. He has brought some to England in sealed tins.

The courses of Gilchrist Lectures to be delivered in the autumn and winter will be by Mr. Lant Carpenter, Dr. W. B. Carpenter, Rev. W. H. Dallinger, Dr. Martin Duncan, Mr. R. A. Proctor, Prof. Balfour Stewart, Prof. W. C. Williamson, and Dr. Andrew Wilson. The English courses will be delivered in Leicester, Lincoln, Chesterfield, York, Doncaster, Reading, and Banbury; the Lancashire courses in Burnley, Bolton, Bacup, Bury, and Stockport; the Scotch courses at Forfar, Brechin, Arbroath, Dunfermline, and Kirkcaldy.

A practical trial of one of Berthon's collapsible lifeboats has been recently made. The boat in question is 28ft. long, 8ft. 6in. wide, and 3ft. 6in. deep, spreading about 460ft. of canvas in four sails. It can accommodate between 60 and 70 persons, and stores of all necessary kinds for several weeks, including 250 gallons of water. The boat, under the command of Capt. Harvey, R.A., with Capt. W. Nicholson and four seamen, was dropped from the R.M. Co.'s ss. *Essequibo*, about 400 miles W. of Land's End, and reached Scilly on the sixth day. The boat left Scilly the next day in a violent gale, and arrived off the Needles early in the morning two days afterwards. The weather throughout the voyage was very stormy, and the sun was seen once only. At times the speed of the boat is said to have exceeded 10 knots an hour.

Two series of experiments of an imitative character were described at the French Academy meeting on the 14th inst. Mr. Bergeron gets an imitation of craters in the moon by sending a current of hot air through a brass tube inserted obliquely in an alloy (Wood's *e.g.*), that has been melted and is gradually cooling. The bubbling clears away in a circular space the pellicle that is beginning to form, and the heaped-up matter forms a sort of crater. With further cooling the mass becomes pasty, and the current ceases to clear the surface, merely forming a prominence or cone in the middle, while the crater becomes hollower. The appearance is like that of a lunar crater, for which the author suggests a like action. Some modifications are described. Thus, temporary interruption of the current produced two concentric circular *enceintes*, recalling those of Copernicus and other lunar craters. The other series of experiments are by M. Decharme, in imitation of the magnetic figures obtained with electric currents or magnets. In one case, he forces a current of water through a tapered glass tube perpendicularly against a plate covered with minium in water. This gives concentric circles, like those of iron filings acted on by an electric current. Blowing air through a similar tube moved parallel to the plate gives another variety of lines of force. In another case, water is forced through one tube against the plate and drawn off by another, and so on.

We learn from *L'Ingenieur*, that M. Saur has devised a new photo-electric battery—(*i.e.*, giving a current when exposed to light.) It consists of a square glass vessel, with a solution of 15 parts of marine salt and 7 of sulphate of copper in 100 of water. This has an electrode of sulphide of silver. An inner porous vessel with mercury has an electrode of platinum. The electrodes are connected with a galvanometer, and the battery is placed in a box with light excluded. Closure of the circuit displaces the needle, the sulphide of silver being the negative. When the needle is at rest, exposure of the battery to solar light causes further deflection. The passage of a cloud causes a variation. The effect of the battery is due to attack of the mercury by the bichloride of copper formed by the mixture of marine salt and sulphate of copper. The protochloride of copper formed reduces the silver sulphide, but this reduction requires the intervention of solar light, which produces the photoelectric current.

It has been lately announced, by authority of a U.S. Government Bureau, that the white pine forests of the United States would, at the present rate of consumption, furnish less than twelve years' supply of that indispensable timber. The advance in cost of pine-timber has already begun, and the question of employing some other material for the coarser uses of building is being earnestly discussed among architects and contractors. But a decided progress will have to be made, it is thought, in the art of seasoning and working the timber of deciduous trees, before it can be used satisfactorily in place of pine.

At the Dresden Polytechnikum, Herr Ernst Müller has been making experiments as to the relation between moisture in the air and moisture in fibrous materials. The weight of such a material was determined from a series of different degrees of air moisture, and then the weight of the absolutely dry substance; hence the amount of moisture in the fibre could be inferred. The limits of temperature were 9° and 26° with a mean of of 19·67° C. In general, it was found that the fibrous substances do not take or give up water so quickly as the air, so that with increasing air moisture the values for water-content of the substances are under the mean values, while with decreasing air-moisture they are over them. The amount of these divergencies gives a measure of the velocity with which the different materials follow; expressed in percentage of the absolute dry material this is 0·12 for silk, 0·20 for flax, 0·26 for cotton, 0·21 for silver, 0·50 for washed wool, and 0·54 for unwashed. The general course of the change of water-content with increasing air-moisture from zero occurs at first very quickly with that, then proportionally to it, then, again, much more quickly. The absolute moisture-content of the air at high temperature increases very quickly, while the hygroscopic power of the fibres diminishes. (Further details will be found in Dingler's *Journal*).

Diabetes is known to be a very stubborn disease. M. Claude Bernard produced the saccharine form of it in animals by irritation of a part of the *medulla oblongata*—*i.e.*, the link between the brain and the spinal cord; and M. Félizet believes such irritation to be the cause in normal cases; therefore, instead of treating the disease by severity in diet (exclusion of bread, starchy matters, sugar, &c.), he aims at suppressing the irritation by the sedative action of bromide of potassium on the organ named. The sugar rapidly decreases. M. Félizet has cured 15 cases thus.

La Lumière Electrique has a fine illustration of the Partz system of electric lighting by reflection, for streets, squares, &c. The light produced underground is thrown up through a cylinder enamelled interiorly, and about 10ft. high, to a reflector on four slender supports, at a height of, say, 160ft., whence the rays are thrown around. The advantages claimed are the possible use of large lights (avoiding loss from division), less loss by reflection than through globes, equal diffusion, accessibility of apparatus, superiority in fogs, &c.

Among the various arrangements in connection with the American Association meeting at Montreal on the 23rd ult., the telegraph companies agreed to transmit, free of charge to all parts of the United States and Canada, members' telegrams relating to family, social or scientific, matters. Three express companies undertook to forward and deliver, free of charge, all parcels of books, drawings, instruments, or specimens of natural history for use of members at the meeting, and return them at the lowest rates. The railway companies seem also to have acted with praiseworthy liberality. The excursions during the meeting were to be to Ottawa and Quebec, to Lake Memphremagog, and to Lachine.

Operations are in progress for providing hydraulic force on a large scale from the Rhone at

Bellegarde. The property will belong to the Banque des Travaux. Permission was granted several years ago to furnish a motor force of 10,000 horse-power. A canal has been formed, capable of giving 60 cubic metres of water at low water; it is fed by about a third of the water of the Rhone, which it brings to a rock pierced with a tunnel 550 metres long, with slope corresponding to a velocity of 2 metres per second. The enormous volume of water comes into a basin, where are to be placed 6 turbines of 600 horse-power each. A second tunnel will bring the Rhone water by another basin, where, with a fall of 18 metres, five or six other turbines will be placed. The total force at once indicated will then be practicable. It is on the territory of Gex, separated from Bellegarde by the river of Valserine and according to a treaty with Switzerland, beyond the French customs line, that the various industries to utilise the force are expected to locate themselves.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

> "I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."

DOUBLE STARS.

[20434.]—I have read with much interest Mr. Perry's valuable letters relating to double stars. Whatever may be the performance of reflecting telescopes generally, there can be no doubt that he has a most excellent instrument, and one capable of doing, in his hands, the very best work in this field. The class of stars observed, and the excellence of the measures furnish satisfactory evidence on this point. Mr. Perry, however, will agree it has rarely happened that a large reflector has been so severely tested in any tangible way. We have had plenty of descriptions of how planets, nebulæ, &c., have looked, which, however satisfactory to the observer, could be no evidence to any one else. Fortunately, with the micrometer no description is needed, and the correctness of the observation can be verified at any time. In the discovery of new pairs, the imagination of the observer is entirely eliminated, provided always he does not belong to the now rather limited class of astronomers who see companion-stars where none exist. I trust Mr. Perry will continue to employ his telescope in the measurement of neglected and difficult pairs. The necessity for such work is likely to continue for a long time.

I have measured some of the pairs mentioned by Mr. Perry and others, and in that connection the following unpublished measures may be of some interest:—

η Coronæ	124·3°	0·51″	1881·32	5 nights.
μ Boötis	125·3	0·63	81·38	4 ,,
OΣ298	350·3	0·36	81·42	3 ,,
λ Ophiuchi	37·7	1·45	80·46	4 ,,
ζ Herculis	110·6	1·53	81·45	5 ,,
42 Comæ	193 0	0 64	81·37	4 ,,
,, ,,	193·1	0·68	79·37	2 ,,
25 Can. Ven.	155·9	0·41	81·43	3 ,,
ξ Ursae	269·7	1·66	81·35	4 ,,
Σ 2062	114·5	2·23	81·49	2 ,,
Σ 1555 AB	346·5	0·68	82·24	3 ,,
AC	145·1	21·17	82·24	2 ,,

Ordinarily I have not spent any time in measuring the old binaries of this class, believing a large reflector could be more profitably employed, but most of the bright pairs mentioned above were measured by daylight, and therefore did not interfere with the observation of more difficult and interesting objects. In this connection I may mention that the last of the new pairs given on page 260 is identical with β 112, for which Dembowski found, P = 292 4° : D = 1·75″ (1875·07) 3n. This is a distant companion to p. XII. 243, the distance by the same observer being 153·39″ in the direction of 347·4°.

August 8th. **S. W. Burnham.**

A BEGINNER'S METHOD OF OBSERVING.

[24035.]—In the introduction to the Rev. T. W. Webb's "Celestial Objects"—an invaluable book for the student of astronomy—the author says, "How is he to use his telescope in a really improving way? What is he to look for? For want of an answer many a good instrument is employed in a desultory and uninstructive manner, or consigned to dust and inactivity."

I feel I am attempting a very bold thing, but may I beg a little space to say how I have lately gone to work, so that, possibly, it may be helpful to others. I premise by saying that my instrument is a Wray 3in. ach. with powers of 60, 130, and 240, and my experience has taught me that a telescope by one of the best makers is by far the cheapest in the end.

Now for the method. I assume the beginner knows the constellations fairly well. This is indispensable. I would then recommend him to procure "Celestial Objects," published at 9s., and a large "Star Atlas," by Proctor, published at 15s.

Next, let him get a book, for MS. entries, of some 200 pages, size, say, 10in. by 8in., page it properly, and cutting up a Gall's shilling atlas into constellations, paste these separately, or at most by twos or threes, into the book, some pages apart. Let an alphabetical index be also made, and much trouble in reference will oftentimes be spared.

Then I would suggest to the beginner a careful study of "Celestial Objects," such doubles, &c., being selected for observation as his telescope might be expected to show well.

Let these selections be entered on the pages next the pasted constellations, taking care to leave plenty of room between the entries for remarks and memoranda—e.g.:—

Objects.	Mag.	Dist.	Pos. Ang.	Memoranda.	Remarks.
61 Androm.	7, 11	50″	355″	11 mag.: test 3in.	Obs. 240: 19/8/82.
2 Camel..	5½, 7½	1·7″	299°	Near limit of 3in.	A failure: 240: but def. bad. 15/8/82.

I may say that caustic soda liquefied, and used as ordinary ink, is the only thing that I have found to show well on the deep blue background of Gall's Atlas. The α, β, γ, &c., of the constellations can thus be inserted, and smaller stars than Gall gives put into their positions.

With a working list such as this, the beginner has in a small compass a fund of useful material, and a glance at his list shows him at once what he can hope to see, and where in the constellation it may be seen.

But perhaps the objection may arise, What cost of time and labour?

Not overmuch, I think; and when the beginner has his MS. book nicely in order, he has a compendium of useful information which will amply repay a little trouble.

I may add that such leisure as a busy life affords me for astronomical study is not unprofitably spent, I think, in following the method here given.

Discipulus.

TELESCOPIC.

[20436.]—In a letter from Mr. Purkess, published in the "E. M.," Feb. 11, 1870, reference is made to flats for reflecting telescopes. Mr. Purkess stated that "as to polishing an ordinary flat, I should, for my own part, scarcely consider it worth the trouble when excellent ones may be cut out of good selected plate-glass." I have also read somewhere that all the flats are selected in this manner, but I cannot remember where I know that a general opinion prevails that plate-glass is perfectly flat, but is a very great mistake. I have made a number of experiments on pieces of plate, and I am fast becoming convinced that an optically perfect piece of plate-glass 2in. by 1in. does not exist. The importance of perfection is obvious, since the most perfect speculum will fail in performance with an imperfect flat. I have tested some dozens of pieces by the colour-test, placing them upon one another, well cleaned, and observing the colour of the thin film of air betwixt. Some few are so far from flat that no colour appears, but the majority are channelled or fluted, and a considerable portion irregular, while in a few cases Newton's rings are tolerably circular. In one instance, however, where the rings are almost perfectly round on rotating the pieces, so as to cross the former contact, the rings become ellipses, and then vanish, showing that the pieces each have a cylindrical curve nearly approaching each other, but of which one is flatter than the other. Of course, when crossed the pieces are separated enough to destroy the colour test. By continually turning these on each other, the circles and ellipses and disappearances follow with great regularity. So far, I have only found two pieces in which rotating produces but a small alteration in the rings. In these the rings are nearly round in all positions; therefore, I suppose the pieces to be slightly convex, and tolerably regular in curve. I have, therefore, come to the conclusion that "excellent arcs" cannot be cut out of selected plate-glass, and that even decent ones would require so much selecting as to cost as much as would buy a perfect plane. I am satisfied there is nothing for it but to work the flat with as much care as the large speculum, and that any makeshifts of selected plate will always prove disappointing, and not improbably cause the condemnation of otherwise good instruments.

But supposing a flat, so-called, to be very slightly convex, and a true curve, would any perceptible evil follow, or would the result be confined practically to a small lengthening of the focus? I am aware that, theoretically, distortion would arise; but considering how very little a flat would deviate from perfection when Newton's rings were produced by contact betwixt two, I am inclined to think the result would practically be an almost imperceptible lengthening of the focus. I would test this myself, but the air with me is never steady enough to allow any comparison worth anything. In addition, I do not know that I have a perfect flat, to compare imperfect ones with. I commend this question to some abler correspondent. I have become convinced that almost everything that is said to the disadvantage of the silver on glass reflector is without foundation. They are so much more convenient for observation than refractors, as almost to settle the question; but the great drawback alleged is the rapid deterioration of the silver film. I have taken no particular care, and find very little alteration in a year in the film, and have never seen a trace of dew. But I have found that the ordinary commercial process by which looking-glasses are silvered, gives a film which is harder, much more firmly adherent, and far denser than any of the processes recommended to amateurs appear to do. I do not know what this process is; but it certainly can be done at a price which would not buy the chemicals to do it one's self. I think those who condemn reflectors cannot have tried them.

Edwin Holmes.

CASSEGRAIN MIRRORS.

[20437.]—In reference to this I omitted to consider that it is necessary (to avoid aberration) that one of the conjugate foci of the small (hyperbolic) mirror should coincide with focus of large (parabolic) mirror, and that as this requires a displacement of x, the point X will also be displaced. How far this would occur in practice I cannot tell, as in reality the mirrors are not true to the curves assumed to be employed.

Lens.

CROWN-GLASS ACHROMATISM.

[20438.]—On reading the last letter of your esteemed contributor, "W. G. P." I was tempted to exclaim, "Sorry I spoke"! But the writer puts forward the claims of his instrument in a manner so temperate and courteous, that I venture to reply again, even though my criticism is, I regret to say, not more favourable than before. For some reasons it might be better to let the matter rest, until an instrument is made on this principle; but, knowing that the mathematical treatment of chromatics in the text-books is not in a very satisfactory state, and being convinced that "W. G. P." is one to whom we may look for improvements on existing methods, I think this discussion may lead to some profitable result.

I am sorry I cannot see through the proposed instrument in the same manner that "W. G. P." does; I may be, and I hope I am, mistaken, but at present I ask for more light. Your correspondent quotes four lines from my letter, which he says has caused him the "greatest astonishment." I should have been better satisfied if he had shown how it is that I am wrong in my assumption; but after reading his letter several times, I cannot find any proof involving the values of extreme indices, that f_2 need *not* be less than f_1. I am not going to deny the correctness of equation (A) *mathematically* but unfortunately, it is one thing to be mathematically correct, and another to be practically so. All I say is that it seems to me inapplicable to the case in hand, and even in the form given it contains something which I do not thoroughly comprehend. If f_2 be negative, and the root of each member be taken, it states that

$$(f_1 - d) = \pm \sqrt{f_1 f_2} \text{ or } d = f_1 + \sqrt{f_1 f_2}.$$

Now, if the upper sign be taken, which is the only one admissible, the value of d is negative, for the root of the focal product is greater than f_1. What does this signify? How can $(f_1 - d)$ the reduced focus of the first lens be *greater* than the whole focus. Yet the equation says that $(f_1 - d)$ is equal to the root of the focal product, and this is necessarily greater than f_1.

Let us take two values for the foci, the first a convex lens 10in. focus, the second a concave lens 16·9 focus. Then evidently $(f_1 - d) = \pm 13$ or $d = -3$. Does this mean that the flint lens when place 3in. behind the convex will achromatise it? I should have thought that d would be a positive number, since f_1 and d are measured in the same direction. As to whether the shallow concave will correct the dispersion at 3in. behind the convex, we will examine by comparison with the position which a flint lens of equal focus would have to occupy.

Your able contributor says I give no proof that f_2 must be less than f_1. I did not think it necessary, as it seemed self-evident; but this is how I arrived at my conclusion. He proposes to use as the object-glass a convex lens, producing a certain amount of *refraction*, and, therefore, accompanied by a certain amount of *dispersion*. To correct this a *shallower* concave is to be employed causing *less refraction* and therefore necessarily *less dispersion* also. Hence, I say the concave is *too weak* to correct the convex when they are in contact, and if they are separated its effect will be still weaker. How does "W. G. P." purpose to get as much dispersive action out of a small-angled prism as out of a large one? Brewster succeeded in achromatising a pair of lenses of the same material when they were in contact, but I should judge this was effected by the form or relation of curves rather than by a definite proportion of foci.

I treat the general problem of achromatising two separated lenses in this way. Keeping the same notation as "W. G. P." we have for the compound focus (f_2 being negative)

$$\frac{1}{v} = \frac{1}{(f_1 - d)} - \frac{1}{f_2}$$

First, let us assume that the second is a different kind of glass from the first. Then for the chromatic variations we have—

$$d\left(\frac{1}{v}\right) = \frac{f_1}{(f_1 - d)^2}\,\frac{d\mu}{(\mu - 1)} - \frac{1}{f_2}\,\frac{d\mu_1}{(\mu_1 - 1)}$$

Now, if the extreme rays have a common focus, the variation of v will be o; also suppose the second, a flint lens, and δ the quotient of $d\mu\,/\,(\mu - 1)$ divided by $d\mu_1\,/\,(\mu_1 - 1)$: then—

$$\frac{f_1}{(f_1 - d)^2}\,\delta = \frac{1}{f_2} \text{ or } f_1 f_2 \delta = (f_1 - d)^2$$

And by taking the root of both sides we find the value of d to be thus indicated—

$$d = f_1 \mp \sqrt{f_1 f_2 \delta}.$$

Now, if δ be unity or the lenses of the same material this agrees with "W. G. P.'s" result. But is this condition allowable? I believe it is not. The entire utility of the combination depends upon the root quantity being less than f_1, or the focal product being multiplied by a factor less than unity. Suppose we had two of Chance's glasses—say f, a convex of hard crown 10in. focus and f_2 a dense flint, what must be its negative focus to achromatise f_1, when placed 3in. behind it? In this pair I believe the value of δ is 0·59 or very near it, but its exact value is not material for our present purpose. With this we find f_2 to be 8·3. If the 10in. crown requires a *flint* of this short focus for a corrector, how can we expect to achieve a like result with a much weaker *crown* concave lens. Even if our 16·9in. were of dense flint it would only be sufficiently powerful to achromatise the 10in. crown when they were in contact; the two would not bear separation.

Let us further examine the equation for d. If f_1 is the greater of the two quantities composing it, its sign is positive. Secondly, if $d = o$, we have, $f_1{}^2 = f_1 f_2 \delta$ or $f_1 = f_2\,\delta$, which, of course, is the focal condition for an ordinary double objective. Thirdly, if the root quantity is the greater, d is negative. Is this negative quantity applicable to the arrangement we have under consideration? The sign of d changes; its positive value requires the concave behind the convex; what then does the negative one signify?

Thus have I endeavoured to express my views upon the theoretical combination of your very able correspondent. I have done so in no contentious spirit, being, like "W. G. P.," wishful to arrive at a definite and useful result. The accuracy of the mathematical treatment is all that can be desired, and all I would ask "W. G. P." to throw a little more light upon is: Do the lenses—a deep convex and a shallow concave—possess the equal counteractive chromatic aberrations when the second is placed at a defined distance behind the first?

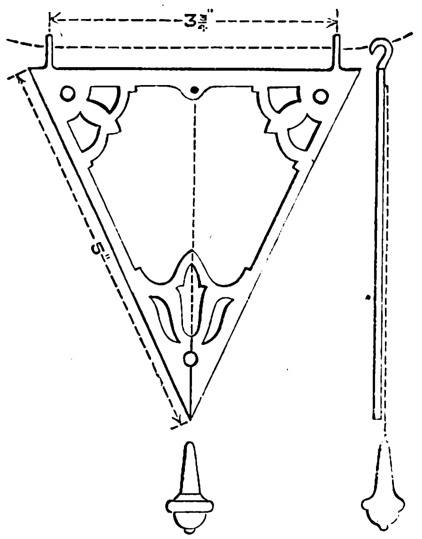
It ought not to be a very difficult matter to obtain two lenses both of the same sort of glass—convex and concave to certain foci. These would, I should think, irrespective of any particular ratio of radii, show whether chromatic error was likely to be eliminated by the method in question. But to get two ground to certain curves would most likely be an expensive job; for unless the work was executed by a firm having a very large number of tools, there would probably be four pairs of new ones to make, which is no slight consideration.

In conclusion, may I ask "Prismatique," when he has a little leisure, to favour us with his opinion on this matter, and whether he considers it possible to secure achromatism by means of a longer focus concave situated behind a short focus convex, both lenses being of the same kind of glass.

Orderic Vital.

TURKISH CARPENTERS' AND MASONS' LEVEL.

[20439.]—As I have not seen anything similar in this country, I send you a sketch of a levelling instrument commonly used by masons and house carpenters to Constantinople. It is very portable, and will be found serviceable in situations where a straight-edge cannot be applied. The principle of its arrangement is so apparent that explanation is unnecessary. It is obvious that the line on which it is suspended does not need to be quite "taut" as the sailors say, but it is indispensable that the little plummet should hang at the centre. The readiest way to find the centre, after finding the extreme distance, is to bring the two ends together—make a simple mark, with a thread or so, and then open out again and apply, when the fine line of the plummet will show the deviation from the scratch line on the face of the plate.



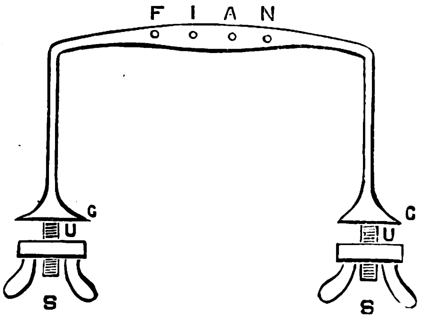
The above is a very common size, and I have never seen any double this size. It is made of brass, about 1-10th of an inch thick. Some of them are very lightly made and tastefully designed, but all embody the same principle.

Iskender.

BERLINER VIOLIN IMPROVEMENT.

[20440.]—Our good friend Mr. Berliner very justly remarks (p. 549)—"The fact is, with this new mode of stringing an endless change of experiments is before an observant experimenter," and in this observation I agree with him; but at least. until the "resonator" is in the market, it will be interesting to try this simple method of dispensing with the tailboard and relieving the pressure of the breast.

A strong brass wire is bent so as to pass through the end of the F holes behind the bridge; on either end is a flange and thumb-screw. These are represented at G V S. Those screws pass through holes in the back, and firmly clamp the wire; but so as not to allow it to press or lean against the F holes through which it passes. Then at F I A N, just behind the bridge, are holes to attach the strings to the wire. Being flattened out here, I am sure any of my readers will at once understand this application. The great trouble will be to make it stiff enough to resist the strain of the strings when the whole four are screwed up to concert-pitch.



Even if we help the string-holder by placing a stay from it back to the tail-pin, and thus taking off some of the pressure, very marked improvement is manifest, or at least, was manifest, on the one cheap violin on which I experimented.

Mr. Berliner deserves the best thanks of the readers of the "E. M." for his invention, and the kind courtesy with which he has freely placed it before the public, and yet I think the greatest modern improvement has come from the ingenious and no less generous gentleman who writes in our paper under the cognomen of "Fiddler." Drawings and descriptions of his new violin will be found in previous pages.

E. B. Fennessy.

STRING VIBRATIONS.

[20441.]—Kindly allow me space for another letter on the above subject, as I should like to ask "Fiddler" if he considers the best quality of a violin to be loudness. Most musicians prefer quality of tone. "Fid.," however, does not seem to appreciate the distinction between loudness, which depends on the amplitude of vibrations, and timbre, which depends on the sum of the fundamental and related harmonics. This last is a matter which has been proved, even to "Fid.'s" satisfaction (if he should read up the subject which he discusses), by the experiments of Helmholtz and others with Koenig's resonators, &c. I do not think even "Fid." can dispute the fact that two notes of the same pitch and timbre have the same fundamental, and, in most cases (excepting pure tones, as in the flute), the same harmonics added, resulting from secondary vibration. "Fiddler" says the s.p. diminishes the loudness of the tone. I say, no; unless it be so placed that it diminishes the amplitude of vibration of the string and soundboard. If "Fiddler" diminishes the tension of his string, and increases its diameter in corresponding ratio, he will get the same number of vibrations from it with greater amplitude, and consequent loudness, irrespective of the presence or absence of the s.p.

Just a few words more. "Fiddler's" demolition of the "old formula" is, to my mind, far more incomplete than the proof which he finds insufficient. The same incompleteness must strike everyone who has the least knowledge of acoustics. "Fiddler's" ideas about nodes are, to say the least of them, decidedly rudimentary. I do not demand the existence of a node between s.p. and bridge; if it be present, it is the result of the conjoined pressure of the s.p. on one side, the bridge on the other side, of the soundboard. I must try to explain again to "Fiddler" that a node does not represent a tone, but is the result of a certain determinate mode of vibration of a sounding body, which gives ascendency to some particular set of harmonics.

"Fiddler's" knowledge again fails him. The "intelligent schoolboy" of the educational department could tell him that a free reed does produce harmonics (½), which can be heard easily in the same reed stops of the organ, the clarionet, &c.

"Fiddler's" illustration and jargon about primary circles, the production and analysis of sound from a centre. as light, I cannot pretend to understand. "Voilà mes amis," a magnificent example of the statement that language was made for the purpose of concealing thought, for I defy any one to extract any defensible idea from "Fiddler's" sentence on the direction and formation of vibration.

The much-despised "back" of the violin is to form with the soundboard a resonance chamber which contains air vibrating in unison with the string and soundboard. I am afraid "Fiddler" doesn't understand what a resonance chamber is. His favourite instrument, the banjo, hasn't got one, which accounts for the noted feebleness and insipidity of the tone. Let me tell "Fiddler" that my argument with him is not professional blaming. I am neither a maker of violins nor a professional violinist, but a tinker of bodies, and a musical amateur who takes some degree of interest in the scientific construction of musical instruments.

Let me give "Fiddler" two pieces of advice:—Learn something about the purpose of the various parts of the violin, and with your well-known perseverance you will no doubt produce something musically of value, instead of destroying an already fairly perfect instrument. 2. Don't expose your hand by bragging of the "loveliness" of your violin.

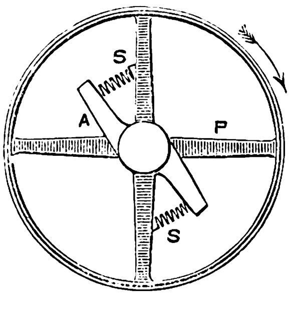
Aug. 27. **Nur ein Geiger.**

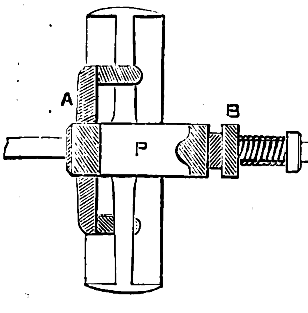
A STEAM GOVERNOR.

[20442.]—The readers of the "E.M." who use steam will readily agree with me when I say that the governors as used at present are very unsatisfactory, and also that they are likely to continue so, so long as centrifugal force is employed in working them. True, they will, if properly set, keep the speed of an engine within certain limits; but these limits are at the best far from being what a governor ought to do.

My idea of a governor is that the power being transmitted ought to be the agent employed in working the valves; the more power transmitted the more steam on, &c., and I have ventured to send a sketch, hoping that fellow-readers will give their opinion of the principle. I have supposed the power to be given off by a pulley, which is represented at P P, whose boss is live upon the crankshaft, and which is driven by the spiral springs S S, impinging upon the steadfast arms A A. The slipbox B, works upon a read, and is kept up to the boss of the pulley by spiral spring. The boss of pulley and slip-box are cam faced, so that upon the pulley being caused to transmit power, the springs S S are compressed, and the slipbox B is forced away from the pulley, and can be made to work either slide or throttle-valve, by any of the usual arrangements. Thus it becomes merely a matter of adjustment of springs and valves. Of course this cannot be employed when an engine drives off the flywheel, as it is necessary for that to be steadfast; but when pulleys or gears are employed I fancy it might be. An index hand might also be fitted so as to show the amount of power given off.

George Button.





LEGAL REPLIES.

[20443.]—Bankruptcy: Statute of Limitations (47747). The six years allowed upon ordinary contract debts begin to run from the time when the right of action first accrued. The fact that the debtor filed a petition which was abortive, and the proceedings under which were in no way continued, would have nothing to do with the Statute of Limitations. The plain result, therefore, is that six years after this petition was filed the debtor could plead the statute in answer to an action; and if the six years expired before that time, then he could do it sooner; his legal position in this respect being the same as if no petition had ever been filed.

Trustee: Married Woman (47783).—There need be no fear that a trust, once created, will ever cease; for, if necessary, the Court of Chancery would prevent this from happening. C., the lady, the acting and surviving trustee, should be asked to appoint another trustee before her marriage, to save any confusion. Formerly, if a married woman were a trustee, she could only act conjointly with her husband, being unable without him to deal with the legal estate; but, by recent legislation, a married woman who is a bare trustee can act alone. There need, thus, be no difficulty, and D. can still claim the payment of the income to her; but, should any trouble arise, any solicitor will advise how to set about appointing a new trustee.

Lending Money on Title-Deeds (47788).—Presuming the building society to have borrowing powers, the deposit of its title-deeds to secure advances would be legal and binding upon the trustees and the members. Such a deposit of deeds is really an equitable mortgage of the property they represent; and this will be so even though there be nothing in writing, so long as the deeds were delivered by way of securing the money lent upon them.

Loan (47791).—Of course, the creditor who has obtained a judgment in the County Court can proceed with it, and upon proof of means to pay can obtain an order for his debtor's committal to prison. So also the other creditor can sue for his money when he likes. But if the bill of sale be valid and registered, it would protect all such goods of the debtor as it comprises against execution by either creditor.

Bankrupt's Discharge (47794).—A bankrupt can only obtain his order of discharge upon proof to the court that he has paid 10s. in the pound, or that a special resolution has been passed by his creditors assenting to his discharge, for which purpose a meeting must be called by the trustee. The querist does not seem to have obtained such a resolution, though that he must do, presuming his bankruptcy to be closed. I really cannot tell him how to set about the requisite legal formalities. It would be quite impossible to do so with success, and he had better consult his solicitor. But as long as he remains an undischarged bankrupt, all his future earnings, and after-acquired property, remain liable to the payment of his old debts, after his new creditors are satisfied. For this reason every bankrupt or liquidating debtor should get his discharge as soon as he can, for he will be saved all risk and trouble, as the discharge becomes a conclusive plea to every action for debts barred by the bankruptcy or liquidation.

Liquidation—Dividend (47797).—It is the duty of a trustee to advertise his intention to declare a dividend at least seven days before so doing, and call upon creditors to come in and prove their claims. If this advertisement were not inserted the trustee might be liable to a creditor omitted from the debtor's statement; but it is more probable that the querist did not happen to see the advertisement. If the estate has all been paid away, the only thing the omitted creditor can do is to sue the debtor, who would be liable unless he had obtained his discharge. But if he has his order of discharge this has been held to be a good defence even to the claim of a creditor not inserted in the schedule, unless fraud be shown; and even then the discharge must first be set aside. I do not see how the bankrupt could be criminally responsible.

Will. — Illegitimate Children (47802).—I understand the marriage in this case to be illegal and void, and it would therefore be necessary that the testator should not leave his property to his "wife" and "children" without further description, as both bequests might, and the latter certainly would, fail altogether. For "wife," in law, means lawful wife; and "children" would only include legitimate children, which these are not. The will, therefore, requires to be very carefully drawn, and the so-called wife and children should be specifically mentioned by name; but I really cannot draw the will for the querist, and should advise him to consult a solicitor upon the whole matter if he wishes to leave his affairs in good order after death.

Will.—Married Woman (47809).—It is not stated in this question. 1. Whether the houses were freehold or leasehold? 2. When the wife was married, and when she died? 3. Whether she made any will?—although these points are most material to the legal aspect of the case. If the houses were leasehold and the wife died intestate they passed to her husband, and he could do as he liked with them. If freehold they would descend to her heirs, but her husband would be tenant for life by courtesy. But unless I know more of the facts above mentioned, and also how many and what children were left by the wife, &c., I cannot possibly advise further upon the many points that may be raised in this case.

Fred. Wetherfield, Solicitor.
2, Gresham-buildings, Guildhall.

RAILWAY SIGNALS.

[20444.]—Compensating levers will, of course, overcome the difficulty of expansion; but if you ask why they are not introduced, you will probably be told that "our board of directors won't pass the amount."

The set-screws might obviate the error caused by the axle wearing, as suggested by Mr. J. G. Moon; but unless they were of considerable size, with coarse thread, I am afraid the continual falling of the weight on them (or rather the weight-rod) would soon put them out of order, and restore the original error. I should insert a sliding wedge for this purpose, and secure it by means of a nut under the iron bracket which carries the weight. Of course, new signals would have to be specially made like this; it would be a big matter to alter all existing ones, and they must remain as they are. In this case there would be no screw thread subjected to strain, the rod coming down dead on the wedge, and transmitting strain to bracket. The screw for the tightening nut would have to come through a slit made for the purpose. Pivoting the arms in the centre is a capital idea, and should be adopted in the case of new signals. We should then have a good alteration of one bad point. The spars at back of arm practically carry out the suggestion of another correspondent to put a weight in that position, but in a more sightly manner.

H. Stooke.

[20445.]—I have already stated that I do not consider that the engine-driver is able to discern to a *nicety* the angle at which the arm is standing; and perhaps he would not, from a practical point of view, be able to distinguish to within 5° the true position; but in one of my letters I endeavoured to explain that my rule was to apply to "the fixing," so as to get the arms to work uniformly. And I am not aware that it was at any place stated by myself that a driver was expected to tell at what angle the signal exactly stood—which is, by the way, a moral impossibility. It must be remembered that the signal I called "doubtful" is only a provisionary one, and the engine-driver would not act on it as danger, unless he had really a doubt as to what the signal was intended to be. The rule which I laid down has, I believe, now been introduced on some lines, although to what extent I am not quite aware. I do not propose that a driver shall be able to distinguish 44° from 46°, when running in a train at any speed. I hope "F.R.A.S." now understands me, and will overlook the indefiniteness of which I must have been guilty to call forth his conciliatory and at the same time explanatory remark (20405).

Will Mr. A. Manock, before we go any further, tell me whether we are not to have a limit theoretically or otherwise, established between the two signals? He states that, "According to Mr. Stooke's arrangement, 20267, the angles from 45° to 85° are allowed as clear, but immediately the arm falls to 86° it must be treated as danger. I am inclined to think that there are very few drivers who are capable of distinguishing in this case between the clear signal and the one for danger." So far so good; but let us apply this very remark to Mr. Manock's own system (or any other) theoretically—practically we know that discernment to a degree or two cannot be clear. The gentleman in question states, "Divide the quadrant into three distinct divisions of 30° each, say, from zero to 30° danger, from 30° to 60° clear." This is quite sufficient. Now, how much difference can there be from discerning between an angle 30° danger and 31°, which is fairly within the province of clear than between an angle of 85° and 86°? "Of course, if the suggestion is barren, let it pass as such." Mr. Manock's suggestion has never been treated as barren by me. I could not agree to it, as the fall for clear did not seem to me to be sufficient; but at the same time I did not doubt the good meaning of the proposal, neither do I doubt the whole of the correspondents engaged in this discussion have been, and are still desirous of assisting me. We often condemn an opinion because it does not seem what we approve of; at the same time we do not doubt the integrity of the originator, and mean no harm to his person. If Mr. Gladstone asked Bradlaugh and Sir Stafford Northcote round to dinner during the recess, does anybody believe that they would not both be present, *despite* their diversity of political opinion?

What I intended to convey by "we do give a positive signal to come on," was when the arm shows clear. I was, however, I admit, very indefinite here, having apparently, though not actually, overlooked the running of trains past the distant signals; but as the driver has to turn steam off, if the signal is against him, and proceed cautiously to the home signal, there can be, I should say, no objection to the continuation of the arrangement. "Nun. Dor." wishes to obviate this, I believe, and thus improve the safety of the line, and no doubt practically it would do so; but trains would be kept waiting at the D. signals when they might be some distance further on—not a mean consideration with a lot of traffic—*e g.*, in the metropolis.

"Nun. Dor's." change could be practically brought into use with the present signals; but keeping the arm within the post I do not like; it does not seem distinct enough for me. In foggy weather a signal-post could not be discerned from any other; but an arm put out horizontally does materially assist discernment.

August 26. **H. Stooke.**

THE CONTINUOUS BRAKES RETURN.

[20446.]—The ninth continuous brakes return (No. C, 3339) for the half-year ending June 30th, 1882, has been published, and the following table gives the amount of stock fitted with those brakes which appear to fulfil the necessary "conditions."

On the 30th June, 1882, there were 5,395 engines used for passenger traffic, of which only 1,819 were fitted with brakes which even appear to be efficient, and this number is further reduced when 727 engines on the Midland and Great Western Railways, which have non-automatic steam-brakes, are deducted.

Statement showing the Amount of Rolling-stock fitted with Continuous Brakes which appear to comply with the Conditions of the Board of Trade, June 30th, 1882.

Name of Continuous Brake.	Name of Railway Company.	Amount of Stock fitted.		Connecting-pipes only.	Miles run by fitted trains in half-year.

	Total as above	1,819	10,763	2,511	
	Total December 31st, 1881	1,465	8,535	1,997	
	Showing an increase of	354	2,228	514	

Note.—The 40 vehicles which compose the Midland Scotch Joint Stock, also 60 Midland vehicles (including Pullman Cars) are fitted with both the Westinghouse and Sanders' Brakes; but this fact is not stated in the Return.

The total carriage stock consists of 45,546 vehicles, of which the table shows only 10,763 were fitted with efficient brakes.

One very important and satisfactory feature in the present "return" is that a very large proportion of the engines and vehicles fitted during the past six months have been provided with brakes which are "automatic," and fulfil the conditions, thus clearly showing that the companies are beginning to see the absurdity of spending money upon non-automatic, and therefore inefficient, systems.

Special attention should be directed to the progress made by the North-Eastern Company, not only in the fitting of brakes, but in the refitting of automatic in place of non-automatic brakes.

During the past half-year, Fay's brake has been removed from all the 63 vehicles, Newall's has been taken off no less than 119, and also Smith's vacuum pipes from 35 other vehicles; and the work of refitting the whole of this stock with the Westinghouse automatic brake is nearly completed.

The Dublin, Wicklow, and Wexford Company has abandoned the use of Smith's automatic vacuum brake, and changed it to the simple non-automatic system.

The Caledonian Company has taken the Steel McInnes brake off one engine, and replaced it by the Westinghouse.

With regard to the "failures," it is to be regretted that some companies have again drawn up their replies so that they shall be of no real value for purposes of comparison.

For instance, there have been several cases of trains running past stations in consequence of the Midland Company's two-minute modifications of the Sanders and Bolitho brake "leaking off," or otherwise failing to act when required, and yet *no mention whatever is made of these cases in the return;* this remark also applies to the same brake as modified by the Great Western Company, many failures having taken place, and yet *only one reported.* Col. Rich, in his report upon the Portskewet Pier accident (see page 357 of present volume) gave details of a failure which he witnessed when riding upon the engine of an express train into Taunton Station, and he considered it "a very important failure." The fact that this case is not mentioned in the "Return" proves that the information furnished by the Great Western is (like the Midland) very incorrect so far as it relates to the faults of the brake in question.

These two companies do not give any details of the numerous failures of the steam brakes fitted to their passenger engines and tenders, as they profess to consider that these do not come within the Continuous Brakes Act; but it will be seen that when a steam brake is worked in conjunction with, and is in fact a part of, a continuous brake, its faults and failures should be reported.

The Sanders and Bolitho brake is fitted to the carriages *only*, and any fault in the steam brake on the engine drawing the train is not given; therefore no comparison can be made with any other system in which the whole train, including the engine and tender, is fitted with one continuous brake throughout, as in that case failures are recorded relating to the engine and tender brakes.

Clement E. Stretton.

Saxe Coburg Street, Leicester, Aug. 26, 1882.

STONEHENGE AND SUN WORSHIP.

[24047.]—I am glad to see Mr. Stooke's letter (20386), and shall await with some interest the result of his search for the "grey wethers."

For the second time let me say I have hazarded no opinion concerning the erection of Stonehenge in the Neolithic Age. The extracts given do not exhaust "all the material likely to lead to a just conclusion." Sir John Lubbock, in *Pre-historic Times*, says:—

"No less than 270 tumuli cluster round Stonehenge, and it seems most probable that the dead were brought from a distance to lie near the great temple."

Again:—"It is evident that Stonehenge was at one time a spot of great sanctity. A glance at the ordnance map will show that tumuli cluster in great numbers round and within sight of it; within a radius of three miles there are about 300 burial mounds, while the rest of the country is comparatively free from them. If, then, we could determine the date of these tumuli we should be justified, I think, in referring the Great Temple itself to the same period. Now, of these barrows Sir R. C. Hoare examined a great number, 151 of which had not been previously opened. Of these, the great majority contained interments by cremation in the manner usual during the Bronze Age. Only two contained any iron weapons, and these were both secondary interments, that is to say, the owners of the iron weapons were not the original occupiers of the tumuli. Of the other burial mounds no less than 39 contained objects of bronze; and one of them, in which were found a spear-head and pin of bronze, was still more connected with the temple by the presence of fragments, not only of sarcen stones (grey wethers), but also of the blue stones which form the inner circle at Stonehenge; and which, according to Sir R. C. Hoare, do not naturally occur in Wiltshire. Under these circumstances, we may surely refer Stonehenge to the Bronze Age."

Elsewhere this distinguished author attributes Abury to the commencement and Stonehenge to the close of the Bronze Age.

It is the far ruder and simpler stone circles than either to be found on the Welsh border hills I judge to be of Neolithic Age.

Neo.

THE PRESSURE OF WIND.

[24048.]—I do not make the distinction "F. M. S." credits me with, and if "F. M. S." reads the first paragraph of my last letter he will see that the distinction I there draw is the same which he in the first place pointed out. What I asserted was that with a velocity of 50 miles an hour—supposing the anemometer to be accurate—the pressure on the square foot would not be 49½lb. The possibility of such a high pressure, which I afterwards consider, is another matter. "Velocity of 53lb. on the square foot" should of course be "Pressure," &c.

What does "F. M. S." consider to be "an obstinate fact?" The accuracy of the high pressures which the anemometers register? Even "if the recorded pressures were accurate," I do not think that the pressure, as calculated by a formula, would be actually "useless," though, of course, in any case it is desirable to take the registered pressure in preference to the calculated, which under the most favourable circumstances can only be approximate.

If "no one supposes that we have on the surface of the earth such a storm as Mr. Simmons experienced," then why did "F. M. S." in his letter, speaking of the gale on the 29th April, write, "and may have reached Mr. Simmons's rate on his recent balloon voyage—about 130 miles per hour!" Of course it is not necessary to build a house at the foot of Blackheath Hill so strong as one placed alongside the Observatory; but, nevertheless, there are many houses situated as high as the Observatory, and builders as a rule do not make much distinction, I think, between such comparatively small differences in elevation.

When "F. M. S." asks for "definite information as to the actual pressure," he is asking for what engineers and meteorologists have been seeking for the last century without obtaining; and it is quite a truism to remark "that the question is one which is by no means settled in the minds of engineers and architects," as if it were otherwise such disasters as that of the Tay Bridge would not be heard of.

Worthing, Augus.

NORTHCOTT'S APPARATUS FOR TURNING IRREGULAR FORMS.

[24049.]—In Mr. Northcott's classical book on "Lathes and Turning," at p. 123 he thus describes the connection of the back-shaft with surface traversing-screw of his slide-rest:—"For every revolution of the back-shaft the worm-wheel will make one-seventh of a revolution, and during one-tenth of a revolution of the screw (E) the slide (D) will traverse one-tenth of an inch." Can this be so? I do not see how it can be, and have come to the conclusion that "*one-tenth*" must be a printer's error. If the screw or the slide-rest is of a pitch of ten threads to the inch, each revolution of the screw would move the slide one-tenth of an inch, and one-tenth of a revolution would move it one hundredth of an inch only, and consequently the surface cut would be only one seven-hundredth of an inch instead of one-seventieth, as stated in the paragraph following the one above quoted.

This bothered me some ten years ago, when I first got his book, and I intended to make this inquiry, but absence in India and other occupations made me lose sight of it.

Would you kindly draw his attention to this, and at the same time ask him to give sectional drawings in your pages, corresponding with Fig. 130 of his book, which would enable persons owning a screw-cutting lathe to add his apparatus to their slide-rest. I have frequently referred to his papers in Vol. IX. of the Mechanic, but find that they are not sufficient to enable me to add his apparatus to my lathe; and several others to whom I have shown his book and the papers in the Mechanic referred to, have come to the same conclusion. I am sure that the details I ask for would be appreciated by many of your readers.

HOT AIR AND VAPOUR BATHS.

[20450.]—Since sending you my paper on the principles on which such should be constructed, I have seen and read a number of pamphlets on the use of gas for various purposes by Mr. Fletcher, of Warrington, the perusal of which has given me much pleasure. I now think that it is not worth anyone's while to make for themselves a special burner, such as I made for myself, and described in above paper. Although it was inexpensive, it involved a good deal of labour, and now that one of Fletcher's burners can be had at a cost varying from 1s. 9d. to 6s., I should be inclined to get one or more of them. His special apparatus for heating water for baths, and his coil for supplying a constant stream of hot water, are well designed and suitable to their purpose; but compared with his burners they are very dear. People, however, are not bound to adopt his apparatus in full, they may purchase his burners and use them under any boiler or coil they may choose to construct, or adapt to their purpose. If I had seen his pamphlets before I left India, I would have had a copper-boiler made for me, by a native copper-smith, to my own pattern, which I would have got at a moderate price per lb. In England, if one requires anything at all different from the usual trade pattern, one is made to pay very heavily for it; but if one enters into a trade or business so as to require a number of the new pattern, it can be procured at the same rate as the ordinary trade patterns, but only from one source, which is not known to the general public. Consequently it is in the power of the tradesman to put a fancy price on his goods, and few can resist the temptation to do so. All desire to get rich rapidly.

TRICYCLES WORKED BY GAS.

[20451.]—Had I been a mechanic instead of being a chemist I should long ago have turned my attention to the construction of a tricycle worked by gas. A mixture of light petroleum vapour and atmospheric air explodes on application of a light. Fletcher, of Warrington, burns this in table furnaces, and has devised a receptacle which furnishes it in a constant stream, why not then explode this behind a piston, or rather two pistons, which, acting alternately by means of cranks, should push forward the machine? The cylinders and other parts, if made of thin steel should, from their weight, add little impediment at least little as compared with the additional force obtained. When not needed, as when going down hill, the gas could be cut off, and turned on when the level or the up-hill was reached. The raw spirit is now generally sold, at least in all towns of any dimensions, as it is used for filling the little lamps used as substitutes for candles. I have been haunted by this idea for some time; but possess too little mechanical skill or opportunity to attempt its carrying out.

P. H.

CHEMISTRY FOR ENGINEERS.

[20452.]—I order a number of castings to be made of gunmetal, of the following composition, for instance, copper 40 parts, tin 5 parts, zinc 2·5 parts. What chemical tests could I apply to a sample bar, in order to find whether my formulæ has been adhered to? Also how can I test white and red lead for impurities? how test oils for acids and other deleterious ingredients; and how determine the quality of the acids (sulphuric, nitric, and hydrochloric) supplied for galvanising iron and soldering purposes.

A description of the qualitative and quantitative analysis of these and other engineer's stores, I shall probably be told, would involve the writing of several articles and cover much space; but what of that? If any correspondent is able and willing to contribute information of such practical value to the engineer and wholesale and retail buyers and vendors of such stores, I feel sure our Editor will not withhold the space so usefully employed.

Glatton.

DEATH NOT UNIVERSAL.

[20453.]—I expect most of us have had the following propounded to us: Suppose a knife with a lost blade, renew the blade and is it the same knife? Answer (invariably), Yes. Now lose the handle and provide a new one, is it still the same knife? Answer (hesitatingly), Well, yes. Now find the first blade and handle, which of the two sets is *the* knife? Some such muddle seems to have been in the brain of the writer of the antepenultimate paragraph of your extract, p. 542, from the *Journal of Science*. He evidently is not aware of, or cares not to acknowledge the fact, that reproduction of infusoria by fission is only a form of parthenogenesis, which takes place only so long as the conditions of existence require or are favourable to it, and that after certain not well defined intervals of time, perhaps seasons, a new order of reproduction is set up to meet the changed conditions, either that of sexual conjugation or the formation of germs in the interior of the individual analogous to that of Zoospores (the emission of which in the form of a cloud I have observed in the organisms mentioned). My only reason for writing this is to protest against the three last paragraphs of the extract, as specimens of imaginative writing, interesting perhaps to the general and uncritical reader, but not at all in accordance with facts or calculated to advance scientific knowledge—such kind of writing being easy enough for those who only care to make a sensational impression.

C. J. B. F.

STRAIGHTENING CROOKED CASTINGS.

[20454.]—I am glad to read "Pattern Maker's" reply (letter 20420) to Thomas D. West's "article." I heartily agree with "Pattern Maker." In my opinion "T. D. W." knows, properly speaking, nothing about the cast-iron "castings" in their various stages of cooling. For instance, he says, for a 5-ton ladle the basin should be not less than 18in. wide, whereas, if he had said 36in. wide, he would have been nearer the size; but any moulder knows that a basin just requires to be made to suit the ladle. A narrow ladle, requires a narrow basin, a wide ladle requires a wide basin. I send my hearty good wishes to "Pattern Maker" for his able letter.

Cast-Iron.

SCIENCE AT SOUTH KENSINGTON.

[20455.]—I am gratified to find that if I cannot make a convert of "Nun. Dor.," I have at least caused him to be more just in his criticisms, for he now admits that "Science teachers there are, I know, who work honestly and laboriously for small pay, having a love for the labour, and an earnest desire to do their duty," so that they are not all crammers. On the other hand, I willingly admit that there are so-called science teachers who are a disgrace to the profession. A case in point is given by Mr. Manock. But there are three things I should like to learn concerning this class: (1st) How the teacher passed the ordeal of the department inspector; (2nd) What was the result of the examination at the end of the session; and (3rd) How many years the teacher thought it worth his while to continue the class on the lines mentioned by Mr. Manock? I am not altogeher unacquainted with such teachers and teaching; but generally the classes came to grief before they had been in existence many years, either through the teacher finding it not worth his while to continue, or because the Department had found out the kind of teaching and stopped the grant. I may also remark that, in my opinion, it is some years since Mr. Manock gained his experience of science classes, for he speaks of twenty lessons having been given, while for a number of years twenty-five has been the minimum number, and for the past year or two twenty-eight has been fixed as a minimum, although each individual need only receive twenty.

Referring to my "friend," as "Nun. Dor." pleasantly calls the gentleman I spoke of as having been trained by the Department, cannot he understand a man having two occupations? If "Nun. Dor." knows anything of the science classes in connection with South Kensington, he must be aware that, as a rule, the lessons do not commence till seven or eight o'clock in the evening. Now, it is not so very difficult to understand how, under these circumstances, a man may be engaged at a given occupation during the day, and turn to a totally different one—viz , science teaching during the evening.

I notice that "Nun. Dor." is concerned because I have not referred more in detail to the ignorance displayed by some of the candidates. What would he have me say? Surely he does not wish me to deny that such answers were given. I have already said that, in my opinion, the teachers are not responsible for such absurd answers, and I give an instance of a student of a competent and conscientious teacher giving a most absurd answer to a question, and this instance, I contend, supports my opinion. I would also remind "Nun. Dor." that no marks would be given for such answers, and since, taking all the papers worked, the percentage of passes was large, it follows that such absurd replies were the exception, and not the rule.

"Nun. Dor." remarks that, "to really educate the masses, born teachers are required." Am I to infer from this that he blames the Department because they do not manufacture such "born teachers"? The uttermost the Department can do in this direction is to exercise care in the selection of the intended teachers, and, having selected them, impart good, sound instruction, and these things, I contend, they already do.

Edward Jackson.

Birmingham, August 26th.

CONCRETE.

[20456.]—It is not often I burthen your columns but I do better—I read them throughout, and notwithstanding that there is here and there a considerable amount of chaff, the grain is far more than sufficient to repay the reader for his time and trouble. I wish, however, some of your writers would follow the advice given in Montaigne's Essays, and only give "what they know, as much as they know, and no more"; and not what they imagine, or what they find in some old recipe book. My hobby is concrete, and if twelve years' working at it, and spending a lot of money on it gives one a right to say something on the subject, I have that right. I have seen in your columns some fearful mistakes in calculations, both as to the proportions of materials, the cost of construction, and the resulting work. The one great error that pervades most of the written articles, is the treating material measured out as producing the same volume of work in situ. Now if any one would take the trouble to weigh a cubic foot of concrete, be that concrete rammed either little or much, he would find that it took considerably more material than a foot cube to produce a foot of concrete. Now, taking a cubic foot of shingle as weighing 88lb., and a cubic foot of sharp sand as 100lb., and a cubic foot of cement at 90lb., my experience has shown me that it takes 150ft. of measured material to give 100ft. of good solid, well rammed concrete in work. My 150ft. of material are composed by measure of

Shingle	108 parts
Sand	27 ,,
Cement	15 ,,
	150

Now, I find my concrete well rammed weighs 139lb. per cubic foot. Now, were this concrete pure silex, it would weigh 160lb. per foot; thus it will be seen that, notwithstanding the ramming the 150 per measure into 100 of work, there would be still 160 − 139 = 21lb., or one-eighth air space in each cubic foot. Now, looking at volume of material and weight of each, and result in work, it will be found wonderfully near the mark:

108 c.ft. of	shingle at 88lb.	weight	9,504lb.
27 ,,	sand at 100	,,	2,700
15 ,,	cement at 90	,,	1,350
			13,554
Producing 100 × 139 of concrete weighing			13,900
The difference being			346

The difference of 346lb. I take to be the water of crystallisation retained.

Now, comparing the weight of a solid block of silex weighing 160lb. per cubic foot with the weight of concrete, there would be 160 − 139 = 21lb., representing the weight of the material required to fill the air-space, or nearly an eighth; so that concrete, as compared to silex is $\frac{1}{8}$ more porous. The result of my work actually comes very close on to these calculations, and therefore, the loose way in which calculations are given as to quantity and cost of concrete is likely to mislead.

So much for materials used and results obtained. Now for the *modus operandi. Clean and free from loam or dirt must your aggregates be.* An ounce of loam neutralises a pound of cement; cement must come into actual contact with silex or hard material, either in shape of sand or stone. The materials must be thoroughly mixed whilst dry, and then only watered out of the rose of a garden watering-can, and never made more wet than very moist sugar; in fact, no more water than is absolutely necessary for the crystallisation of the cement should be given. I have every mixing turned over five times—three times dry and twice wet, and when well rammed, it turns out good work.

In my experiments I have found out a cheap substitute for cement in using a considerable portion of finely-ground quicklime, which I get from near Bridgwater, from Boord and Co., of Dunbell. For cottage walls, garden walls, or sheds, I find half the quantity of cement and the other half lime makes very good work, and I believe in time it will be as good as concrete made with pure cement. But unless the operation is carefully conducted, and the quicklime thoroughly killed, there is a danger of blowing. I put the lime into a large tub, keeping it thoroughly stirred, and mixed with sufficient water to make a thickish cream, and let it stand for half an hour before using. The cement used is mixed dry with the shingle and sand, and then the whole is mixed and moistened by the lime cream; but the master's eyes must be about him. Now, so much for the information I can give. I now come to my turn to ask for information. I may say that I am building a tower, and my intention is to carry it up to 200ft. if I can safely do so. I do not fear the concrete crushing; but I should like to settle the vexed question of the force of the wind. I have made my calculation as to the maximum pressure; but as the force of the wind has produced a little logomachy in your columns, I should like to elicit the opinions of some of the logomachists on the data given. The following are the intended dimensions:—Outside measurement at level of ground, 20ft. square; intended height, 200ft.; measurement at top, 18ft. 6in.; from ground to 20ft. high, 20ft.; from 20ft. to 80ft., 19ft. 6in.; from 80ft. to 150ft., 19ft.; and from 150ft., 18ft. 6in. The tower is built on the square with the cardinal points of the compass, and the strongest gales are from the south-west, which would only catch the building at an angle; but I must base my calculations as if the gale caught it full on the side opposed. I have, in the calculations made by me, got a full one-third more than sufficient weight to stand a wind pressure of 52lb. to the square foot; but the Tay Bridge disaster and the logomachy in your columns have rather disturbed my equilibrium, and made me fear for that of the tower. I cannot understand how the pressure is calculated. The only safe way is to calculate on the strongest gust of wind. I am three miles from the sea, opposite the Needles in the Isle of Wight, and the wind fiend does let out sometimes with a vengeance. With the exception of a typhoon or cyclone in India, I do not think I have ever seen the gusts of wind more severe for a short time than I have seen them at my place. Here is a nice problem to be solved for my advantage. You have plenty of hard-headed contributors, some of whom are not only able, but, on the give-and-take principle, willing, to set my doubts at rest. My days are not many, but I do not want my ghost to be disturbed by seeing my tower lying its length on the ground through the efforts of the wind fiend.

Khoda Bux

INDUCTION COIL.

[20457.]—In accordance with the wish of Mr. J. Brown, of Belfast, "Quien Sabe," and other correspondents (Volume XXXI.), I send an account of a small induction-coil which I have lately constructed. Mr. Brown will notice that the effect of distributing the secondary along the core has not been so advantageous in this instance as he seemed to expect. Perhaps in his abler hands an altogether different result might have been obtained. He will also observe that one of the results has been to enormously increase the amount of condenser required. If Mr. Brown would kindly supply us with a statement of the results he achieved when using a spring contact-breaker, it would be easier to compare his admirable instrument with other coils so fitted. The core of my coil is of No. 22 B.W.G., and was carefully annealed. The length is 8¼in., the diameter about 7-10ths, and the weight 8¾oz. The primary is of No. 16 B.W.G., silk-covered, wound in two layers. Its weight is 12oz., and its resistance about 1-10th of an ohm. The secondary is of No. 16 B.W.G., silk-covered, and contains 2lb. 3oz. of new wire; 1lb. of old wire, unwound from another coil; and 1oz. of old wire of mixed gauge. Its resistance is 3,460 ohms., and its total weight is 3lb. 3oz. It is wound in 26 vertical sections upon an ebonite tube 9in. long, by 1in. internal diameter by 1-16th in. thickness, with separating discs of three-ply blotting paper, steeped in hot paraffin wax, and pressed together. Two of these discs were placed between each pair of sections, and one between the component sections of each pair. The diameter of the discs is 3½in., and the spaces were filled with wire (wound on through hot paraffin wax) to a diameter of about 3in. The average width of the spaces is 3-16ths in. The complete secondary occupies 6½in. of the centre of the ebonite tube; but as cakes of paraffin wax, each ½in. in thickness, were afterwards cast on to the ends of the secondary, to prevent sparking to the primary coil, its apparent length is 7½in. Grooves were turned in the edges of the waxen cakes, and pieces of No. 20 gutta-percha-covered wire laid in, and connected to the ends of the secondary, and brought out for attachment to the discharging points. The two grooves and the vacant intervals between the discs were then filled in with paraffin wax, and the whole turned down smooth to receive a few layers of paraffined paper, and the ornamental covering of velvet. The reel-ends are of baked mahogany, paraffined and ebonised.

At this stage I may inform Mr. Brown, who, a short while ago, was asking our justly honoured "Sigma" for his experience of spring contact-breakers; that after a great many experiments I found the best form to be that made and patented by Apps, and which breaks the battery contact directly at the back of the hammer. The secret of its success appears to lie very much in the handy arrangement of the regulating-screws, which enable the operator to increase the tension of the spring to several pounds if necessary; also the iron hammer is disproportionately small, and, being bored nearly through, is light, and possesses little or no momentum. Perhaps, however, this form would not act so well upon coils containing very large cores, like that of Mr. Brown, as its motion is extremely rapid, and slow vibrations are best where residual magnetism has to be encountered. The following is a table of results obtained with various powers:—

Pint Grove cells.	Spark.	Condenser capacity.
1	1¼ to 1½in. ..	Half a micro-farad
2	2½in.	1 micro-farad
3	3in.	Do.
4	3¼in.	Do.
5	3½in. and over	1 micro-farad and a half.

When the condenser capacity was increased to one and a half micro-farads, the spark from one cell almost disappeared, and with four micro-farads the spark from five cells was reduced to about one inch. The influence of the condenser upon the character of the spark was interesting and suggestive. These latter experiments were made before the instrument was permanently mounted, and cores of No. 24 and 26 B.W.G. were made and tried. Neither gave such good effects, the sparks from No. 26 being very markedly inferior, both in length and quality, to those from the core selected. Primaries of No. 14 and 18 silk-covered B.W.G., were also tried and abandoned in favour of the present gauge. A primary consisting of two layers of No. 18, arranged in multiple arc, had too low a resistance. From the results of some experiments with the mercury break, made before the secondary was completed, it is inferred that with an interruptor like the one devised by Mr. Brown and described by him on p. 611 of Vol. XXX., four inches, or even four and a half inches, of spark might readily be extracted from this small coil; but I fear the inconveniences of the mercury-break more than counterbalance its advantages.

Haverfordwest, Pem. Ernest.

SMALL DYNAMOS—ERROR.

[20458.]—In my letter (20417) last week, 11th line, instead of "resistance was not sufficient," it should have been "E. M. F. was not sufficient to overcome resistance." **Fred. W. Ball.**

COLOUR.

[20459.]—Having been away from home for several weeks, during which I have not seen the "E. M.," I have not replied to various remarks upon my letter (20324), p. 477. "E. H." (20339), p. 499, does not think that letter either an adequate or correct reply to Mr. Smith's. As to the correctness, that is a matter of opinion apparently, but as to the adequateness, he himself says, "It is quite impossible to give a complete or satisfactory explanation of colour vision in the compass of a short letter." The sole purpose of my letter was to show the intentions and explanation of a particular experiment of Tyndall's, which Mr. Smith had misunderstood and misrepresented. As to the general question of colour, discussion is really useless between people taking the scientific line and those dealing with it on artistic principles; it is like a conversation between people using different languages, while each has only a very slight knowledge of the other's.

It is for this reason that it would be waste of time to discuss the subject with Mr. S. Calton, who, in 20340, p. 499, expends four columns in showing that he pays no attention to anything but his own ideas, and from want of understanding them, perverts and misrepresents those views of the subject which may be called scientific, as distinguished from artistic or practical. Hence all his criticisms as to the effects of various pigments, and especially the actions of rotating coloured discs, are valueless, and, in fact, unmeaning. We all know that the effect will be nothing but a rough approximation to a white. As none of the colours employed can possibly be pure colours, and as their proportions in the disc are not likely to be exactly correct, how can a pure white be expected?

The fact is unquestionable, that blue and yellow "lights" do not produce green; but lights do not mean those resulting from passing through glass, *unless the glass cuts off perfectly all but the required light*, and this is scarcely attainable. A scientific experimenter on light-colours derives his lights from the prism, and selects definite colours. He would thus get a range of blues and a range of yellows, and could produce a variety of combinations. But it appears useless to talk of this to a person who insists upon experimenting *in* the light instead of in the dark. Why, in the light, we could never separate single colours; we should always be flooded with the whole components of white light superposed upon the experiment and should need a very intense light indeed, to obtain a visible result at all from the distributed spectrum.

Mr. Calton recognises that a coloured light is an imperfect one. Of course it is, because it furnishes only part of the compound known as white light. The evidence is: That if we pass the white light through a prism we subdivide it into a long series of such imperfect, that is partial, lights; if we receive these upon another prism, we gather them again into the perfect white with the quantity diminished by loss in reflection. If, now, we separate parts of this spectrum on the second prism by stopping off all but the selected portion, we can produce white light by a number of combinations, but obtaining, of course, a feebler light. But these several whites, though optically and artistically alike, are very different, scientifically considered. Let each of these whites be received upon a third prism, and their difference is at once manifested, because only the one will produce a full spectrum, the others showing only their special lines. Mr. E. Holmes, in his last par., p. 549, explains this fairly.

This is, of course, the same thing as happens in the case of pigments, as with the greens in the Venetian blinds mentioned by "E. H.," page 499, where two closely-resembling greens, alike to the artist, are proved by analysis to be constituted of different light or colour elements. I imagine the source of Mr. Calton's misapprehensions is the idea (which I have observed is not uncommon among artists), that black is a colour and white the absence of colour, while science teaches us that black is simply the absence of light, whether it be due to shadow or absorbed light, while white is the united effect of several colours—a harmony, in fact.

Now, let us see the difference between the vague artistic and the exact scientific definitions, p. 500. Mr. C. says, "Pure blue means a certain fixed colour, free from red and yellow, while green, being a compound colour, embraces an unlimited number of hues, &c." How does this define blue? As a mere fact, there are as many hues of blue as of green, and a green can be fixed as definitely as a blue. The scientific definition is that blue is a colour due to wave-lengths, of which the mean is 4·75 ten millionths of a millimetre, while the mean of green is 5·12, and science can prove this by taking a perfectly colourless surface and producing upon it lines of these intervals with the resulting colour. In the face of such facts, Mr. C. must really allow "mere scientists" to pass with a smile such observations as he makes about the manner in which they prepare their discs and work out "dodgey" experiments.

Mr. C.'s further five columns, 20432, p. 575, simply illustrate my previous remark that he perverts my statements of the scientific view of the subject by misunderstanding them. He does so as to my own remarks as to the experiments with the blue and yellow glass: he says "I admit an excess of green in combining blue and yellow lights." I did not: I was dealing with a special case of lights passing through glasses, both of which were stated to pass green, as well as their predominant colour, and I should not think of calling the mixed lights passing through coloured glass, blue or yellow, from a scientific standpoint, whatever I might do in dealing with their artistic effects, or in ordinary conversation. Hence, all his criticism is meaningless.

Students of light and colour should recognise the great resemblance between it and sound, in the circumstances that the colours of the spectrum of white light are to all intents an octave of sound, and the seven colours of the rainbow correspond to the seven notes of an octave of music in the relations of the number of undulations producing each. Each colour has its specific wave-length, just as each tone has its specific period, and in each the harmonies are dependent upon the numerical relations of these wave-lengths. But the perception of wave-lengths of light as colour depends not only upon the external actual light, but upon the organ of sight, as in the other case of sound. Now, the distinction of the scientific and artistic treatment in both cases is this: the sciences of optics and acoustics examine chiefly the external agency, and the artist is concerned only with the action of the living organs of perception. **Sigma.**

The following, for general use as a grease eradicator, is recommended:—Castile soap in shavings, 4oz.; carbonate of soda, 2oz.; borax, 1oz.; aqua ammonia, 7oz.; alcohol, 3oz.; sulphuric ether, 2oz, Soft water enough to make one gallon. Boil the soap in the water until it is dissolved, and then add the other ingredients.

To clean a soiled chamois-leather, make a solution of weak soda and warm water, rub plenty of soft soap into the leather, and allow it to remain in soak for two hours, then rub it well until it is quite clean. Afterwards rinse it well in a weak solution composed of warm water, soda, and yellow soap. If rinsed in water only, it becomes hard when dry, and unfit for use. The small quantity of soap left in the leather allows the finer particles of the leather to separate and become soft like silk. After rinsing, wring it well in a rough towel, and dry quickly; then pull it about and brush it well, and it will become softer and better than most new leathers.

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[47050.]—**Hot-air and Vapour Baths.**—I have received eight more letters on the subject, one of which is from Isabelle Stuart. As they all are for personal use, I think the answer contained in No, 904 will be sufficient. A London engineer seeming to entertain the idea of applying largely and publicly my system, I will send him particulars. One of the letters received is from Canada. It contains two three cents stamps, which I am sorry not to be able to give back to the inquirer, as they are quite useless to me, unless I make a trip to Montreal. The specification of my patent was sent to Madame Eugénie Baxter, Nauwoo, Illinois, U.S.A., with whom, perhaps, my Canada correspondent may communicate. I find it singular that some inquirers do not give their real name and address. Some say, Care of.... others, P.O. Box....—Ch. Rabache.

[47144.]—**Bending Wood.**—In connection with the answer to the former querist, much pressure could not be expected to be employed in a steam chest of wood; still, if the present querist has much bending to do, so as to answer his purpose to have a steam generator made for the express purpose, and is careful to select good sound wood for the chest, and makes good sound joints in putting it together, he might use sufficient pressure for all practical purposes, but the less in substance the wood to be bent, the less the pressure required. Safety-valves, such as are used with a moderate sized model engine boiler, would be about the thing.—Collodian.

[47239.]—**Deafness and Vegetarianism.**—Suppose we grant that many vegetarians are thin spare people, this is no argument against that dietary; it merely proves that they have no superfluous fat clogging their limbs, impeding the movements of their muscles, and pressing upon the array of beautiful nerves with which the human system is furnished. If a troublesome member of the House of Commons can "obstruct" longer on Zoedone than on brandy, so can the spare-ribbed vegetarian and pure-liquid-drinker work longer than his neighbour, the meat-eater and beer-swiller. I cannot fully endorse the testimony given in favour of a "vegetarian diet," so called, in the present condition of our city and town markets, in which are offered for sale cabbage, cauliflower, lettuce, and other heads, two to four days old, and which disagree with many a stomach, even when very carefully cooked. To be really wholesome and nourishing, green vegetables should be eaten the day they are cut and sent from the spot where they grew. Necessarily, they begin to spoil at the very moment of separation from the parent stem. The longer they remain uncooked the more they spoil, so that if I buy this morning three nice cauliflowers, one to use at dinner to-day will be perfectly good; a second, used to-morrow, quite passable; the third, used the following day unwholesome, and very probably a cause of severe dyspepsia, yet the illness may be attributed to a totally different cause. The often unavoidable plan of dining at eating-houses in large towns is a fruitful source of stomach complaints. The cooking may be excellent as a rule, but the late-comers get the meat and other articles of diet "all hot," because the cooled joint is used, the customer's "allowance" carved off, and then the plate and its contents goes into a hot oven, and this second warming "soddens" the meat and makes it more or less indigestible to even a healthy stomach. And cooking of the vegetables is often most objectionable. Cannot some correspondents of "ours" benefit many a family by giving us a series of articles on the subject of proper cooking? Were our vacant spaces utilised for the growth of vegetables, and the refuse of towns applied to manure the ground, it would add to both the wealth and the health of our population.—H. O'B.

[47346.]—**Boomerang.**—The description that "H." gives, from Beeton's "Encyclopædia," of the Boomerang itself is quite corect, but the directions for throwing it are not so. It should be held like a reversed scimitar, with the concave edge foremost; moreover, its flat side should be downwards. Professor McCulloch, of Trinity College, Dublin, was not the introducer of the boomerang into this country; he wrote a paper, however, on the dynamics of its flight.—Dubliniensis.

[47369.]—**Preserving Mosses (and Ferns).** These will not long retain their bright colour without being dyed. A bottle of liquid for the purpose costs 6s. or 7s. in London.—H. O'B.

[47439.]—**Cement.**—This querist can hardly expect an answer unless he says what kind of cement he means. Plaster of Paris and fireclay answer the conditions given, but probably there may be something which prevents their use.—T. P.

[47437.]—**Threads for Steam Pipes.** I copy the following from Martin's screw-cutting tables; leading-screw of lathe, two threads per inch. The wheels required for screw-cutting are as follows:—

					Pitch.
1¼in. and all above..	85	80	20	120	11 294
1in.	20	—	—	140	14
¾in.	20	—	—	140	14
⅝in.	30	65	20	85	18·412
Small brass tube	30	60	20	120	24

—A Colliery Mechanic.

[47440.]—**Converting Peat into Charcoal.**—Peat thoroughly dried can be converted into charcoal by heating it in retorts like those used at the gasworks. The gas can be utilised if desired, or the peat can be burnt into charcoal in the ordinary way.—Essar.

[47450.]—**Repairing Mirrors.**—If these have the common quicksilver backing, they can, I believe, be repaired by putting on little patches of the mercury and tinfoil amalgam. The glass must be very clean. I wish some of your clever readers would explain the method fully.—W. T. S.

[47459.] — **Silvering Looking-glasses.**—Brashear's, or any of the other processes of silvering telescope-mirrors are suitable for looking-glasses, but are more expensive than the mercury process used for the purpose. There is no difference in the process, except that you put the silvering on what is the back of the glass, and protect it with a coat of varnish.—J. T. M.

[47463.]—**Change Wheels for Screw-Cutting.**—Suppose 20 teeth in wheel on spindle of lathe required to cut 31 threads per inch; and 125 teeth in wheel on leading screw containing four threads per inch; to find the No. of teeth in stud wheels:—

$\frac{\text{The product of former}}{\text{product of latter}}$, or $\frac{20 \times 31}{125 \times 4}$, or $\frac{62}{50}$ giving the answer. Then, as the wheels from 30 upwards increase by 5, $\frac{62}{50} \times 8$ gives $\frac{496}{400}$, or $\frac{49\cdot6}{40}$ nearest to $\frac{50}{40}$. Or, reversing the calculation $\frac{4 \times 125 \times 50}{20 \times 40}$ or $\frac{25000}{800}$, or $\frac{250}{8}$ = 31¼ threads per inch. *Or, by Double Slide Rule.*—Setting 125 on slide N, B opposite 20 on line A; and 4 on slide *c* opposite 31 on slide N; then the nearest fractions $\frac{25}{20}, \frac{50}{40}, \frac{75}{60}, \frac{100}{80}, \frac{125}{100}$, are visible at one setting.—Buttershaw.

[47463.]—**Change-Wheels for Screw-cutting.**—Will T. F. Gell, who replied on p. 552, kindly explain himself on the matter of change wheels. The instance he gives does not bear out his rule. Besides, his rule only gives the number of threads that will be cut if the driving and driven wheels are known; whereas, what is generally wanted is, what the driving and driven wheels are to be when the number of required threads are known. But I cannot make head or tail of his rule as it is. The number of teeth in driven wheels are 155, of driving wheels 105. The former multiplied by 4 and divided by 105 does not give 30 10·11, yet that is his rule. It is a most useful subject. Can no one give a plain intelligible rule for finding the stud-wheels and mandrel-wheel when the only known quantities are the threads on the leading screw, and the required threads on the work?—S. P.

[47463.]—**Change-Wheels for Screw-Cutting.**—I beg to inform my brother reader, "Try Again," that the rule I gave him in my reply to his query will calculate any train that may be required. Now, a screw of 31 to the inch cannot be cut exactly with a set of wheels from 25 up to 125, each wheel increasing by 5; but, nevertheless, a train can be found that will cut one sufficiently near for all practical purposes. Now, to begin. The leading screw has 4 to the inch, and the screw to be cut is to have 31 to the inch. These give a ratio of 1 to 7·75. Let us now put a wheel of 25 on the mandrel, and one of 50 on the stud; these have a ratio of 1 to 2. Now, the ratio of the other two wheels must be such a number which, multiplied by 2, would be equal to 7·75; therefore 7·75 ÷ 2 = 3·875 the ratio required. Now, let us put on the stud along with the 50, any wheel you chose—say 30. Then multiply 30 by 3·875, and we have the number 116 25; therefore, the train 25 / 50 30 / 116 will cut very nearly 31 to the inch. Now, our stock of wheels does not contain one with 116 teeth; therefore, we must try and arrange them so that they will suit the numbers in stock. Let us take the train 20 / 40 35 / 135, and we will find they will cut very nearly 31 to the inch. Thus the ratio of 20 to 40 is as 1 to 2; that of 35 to 135 as 1 to 3·857; then 2 × 3·857 × 4 = 30·856 very nearly the required pitch.—Thos. J. O'Connor, Dundalk.

[47463.]—**Change-Wheels for Screw-Cutting.**—The rule for finding the wheels to cut a thread of any pitch is very simple; but as the wheels supplied with most screw-cutting lathes are confined to 22 in number, it is impossible in many instances to cut a thread of the exact pitch required, as is shown in your issue of August 18th by T. F. Gell and "J. K. P." in reply to query 47463. In very many instances, a mere approximation is sufficient for most purposes, and makes a working fit; but if you are constructing a mathematical instrument, where absolute exactness is necessary, it would, as no one can doubt, be a very great advantage to be able to pick out the wheels to cut the very pitch you require. I have a number of small books containing tables for screw-cutting, showing the combinations of wheels which produce a number of pitches. The best of these tables is undoubtedly by Lord Lindsay; they are calculated to a leading screw of one thread to the inch, consequently, a very simple calculation renders them available for use with any screw-cutting lathe whatever. For some time, having been confined to bed with an attack of gout, I have been unable to occupy myself in my workroom, but have, for amusement, been calculating out a set of tables for use with my own screw-cutting lathe. Seeing that the pitch depends on the ratio existing between the first and last wheel—namely, between that on the mandrel and that on the screw, which can be multiplied or divided as required by compound wheels as intermediates—I did not confine my calculations to the change-wheels in my posssssion, but have calculated the ratios of every wheel from 15 to 200 and upwards. 15 on screw, multiplied by 4, the pitch of leading-screw, and divided by each number from 15 to 200 on the mandrel, gives the ratio between the two wheels; thus 15 on mandrel and 15 on screw cuts 4, increasing by each tooth added to the screw-wheel in regular series till 30 is reached, when a whole number is again reached, and it cuts 8. After this, the calculation is easily carried out up to 200, or more, as the series of decimals are the same between each multiple of 15. The same is carried out for 16 on the mandrel, and here the series is still more simple, the rise for each tooth on the screw-wheel being ·25, or 1-16th of 4, the pitch of leading-screw, and so on up to 200, both ways. With 15 on mandrel, a change of each tooth on the wheel of screw gives a rise of ·26, till a multiple of 15 is arrived at; thus 15 on mandrel gives, with 15, 30, 45, and 60 respectively, 4, 8, 12, 16 threads; with 16, 31, 46, and 61, 4·26, 8·26, 12·26, 16·26, and so on; with 16 on mandrel, a change of each tooth on screw-wheel, gives a rise, as already stated, of ·25. With 17 on mandrel, a change of each tooth of screw-wheel gives a rise of ·2352, the whole numbers being reached at each multiple of 17; thus 17 = 4, 34 = 8, 51 = 12, &c. I have gone far enough to show the effect of a rise or fall of one tooth on the screw-wheel. I shall now make the changes on the mandrel-wheel. In the former case there is a gradual rise, in the latter there is a gradual fall. With 15 on the screw, and 15 on the mandrel, as before, you cut a thread of 4 to the inch, 15 will now remain permanently on the screw; 16 mandrel will cause a diminution in the pitch of the screw, thus:—$m / 16 = 3\cdot75$, $m / 17 = 3\cdot5294$, $m / 18 = 3\cdot3$, $m / 19 = 3\cdot15789$, $m / 20 = 3$, $m / 21 = 2\cdot857142$, $m / 22 = 2\cdot72$, $m / 23 = 2\cdot608695$, $m / 24 = 2\cdot5$, $m / 45 = 1\cdot3$, $m / 48 = 1\cdot25$. $m / 50 = 1\cdot20$, $m / 60 = 1$, $m / 61 = 0\cdot9830$, $m / 100 = 0\cdot6$, $m / 200$ 0·3, and so on. I have gone far enough to show that a table of simple ratios between wheels for every tooth from 15 to 200 would be very useful, and as you can get wheels of 14 pitch from Lloyd, of Birmingham, with almost every tooth from 15 to 200, there is no reason for any possessor of a screw-cutting lathe not being able to cut exactly any pitch whatever. It is quite true that most 5-in. lathes are fitted with wheels of 10 pitch, but for light work those of 14 pitch are sufficient; and as a complete set of 22 change wheels only costs 12s. 6d., and odd wheels of all numbers can be had at prices, ranging from 4d. to a few shillings, no one requiring to cut a screw of special pitch need be without the means of doing so. In making this table of ratios, I only thought of my own lathe, but if I had intended publication I would have calculated the series for a screw of 1in., from which, by simple multiplication or division any person could apply the same easily to his own lathe, whatever the pitch of the leading screw might be. To make such a table complete, a similar one showing the multiplying or dividing power for each tooth on stud-wheel one pinion would be useful. Thus, if you had 15 on the mandrel, and any number on the screw connecting the pair by any number of simple wheels, the latter would only serve to convey the motion and to cut a right or left-handed thread, dependent on the number of intermediate simple wheels being odd or even; but if you introduced anywhere into the series, a pair of compound wheels, say, a 20 and 100, it would have the effect of either dividing or multiplying the ratio by 5, according as the wheel or pinion was a driver or driven. If such tables were fully calculated and carried out, we would have a wonderfully minute rising and fallng series of pitches, from one requiring a microcope to see it to a pitch of several feet.—Gereb Dmi.

[47482.]—**Telephone.**—The Edison loud-speaking receiver is, I think, the best to hear all over a room, but you must be near to turn the chalk cylinder, or else work it by means of a clock train. There are not many loud-speaking receivers, but possibly some readers may know of something better than Edison's.—Essar.

[47486.]—**Euclid's Axioms**—If $A + C = B + D$, then, surely, no one need be shown the step to deduce $A - D = B - C : A + C - D = B$? This method, it may be urged, is algebraic; but, from the nature of the question, it is the only way I can suggest.—C. H. Romanes.

[47489.]—**Storage Battery.**—There is nothing more to be said than the oxygen at one plate produces peroxide, while the hydrogen at the other reduces it to to a lower state of oxidation. When the battery is at work, the oxygen of the peroxidised plate is transferred to the other plate, and when they are equally oxidised (speaking roughly) the action terminates. I don't think anyone has yet put the action into formulæ, unless, which is likely, you can find it in Gladstone and Tribe's papers.—Nun. Dor.

[47491.]—**Lantern Slides** are very difficult to colour well, and it requires practice and some experience before satisfactory results are arrived at. You can get transparent water-colours, and you will find them more manageable than oil or varnish colours; but you should buy a good slide from Mr. Lancaster, or any other of our reliable helpers, and with this before you copy the intensity and tints. No amount of written instruction will aid you so truly.—E. B. F.

[47491.]—**Magic-Lantern Slides.**—The engravings I used were about the size of the printed portion of a page of the "E.M.," they were pinned to a board, which was propped in an upright position at one end of a table near a window. A camera was placed at the other end, and was moved backwards and forwards until the image of the picture on the ground glass was the proper size to cover a quarter-plate, or about 3¼ by 4¼in. A negative was then taken on a gelatine plate, and a transparency printed from it. Almost any lens will do, if it is stopped down sufficiently. In copying oblong pictures there is this difficulty—that the transparency having to be square or circular, the ends of the picture have to be sacrificed, or else the picture taken on a smaller scale to get it into the 3¼in. square; but in that case there will be a blank space above and below. This must be left to taste. My transparencies, although so much reduced in size from the original, show every line of the engraving (seen through a glass), although the picture itself was a fine steel engraving.—M.I.C.E.

[47494.]—**Speed of Small Steam Vessels.**—There is no rule for finding the speed of steam-vessels, small or large, because so much depends on the power exerted, the manner in which it is applied, and the lines of the vessel, to say nothing of the kind of propeller used.—Launcher.

[47540.]—**Measuring Flow of Water.**—In correcting my answer to this query Mr. Bell has omitted to state that the coefficient of contraction, "c," varies under different circumstances. In the case of a uniform stream it is one, and I assumed this for the case given, as the query does not give particulars on the point.—Ditton.

[47553.]—**Problem in Dynamics.**—The answer to this problem is very simple. Whatever the monkey does as to changing his elevation, whether upwards or downwards, the counterpoise will do the very same. If the monkey ascends 1ft. the counterpoise will ascend 1ft. and so on. Of course, that the monkey may ascend 1ft. he must climb 2ft. on the rope. This will be easily seen by considering the more simple case of two stationary boats, which, including their loads, are of equal mass, on a calm sheet of water. If an occupant of one boat proceeds to draw the other one towards his by a rope, the two boats will advance equally towards each other, since their common centre of mass is stationary. The simple principle involved can be easily applied, *mutatis mutandis*, to the monkey and counterpoise. It is true that the monkey's weight varies inversely as the square of his distance from the centre of the earth; but, in the first place, the effect of this is quite imperceptible; if the monkey ascends 1ft. he will lose less than 1-10,000,000th part of his weight; and in the second place, what he loses in this way the counterpoise will lose likewise, since it will ascend as much as he.—Dubliniensis.

[47553.]—**Problem in Dynamics.**—"Tam o'Shanter" is wrong in supposing that the monkey cannot exert a downward pressure greater than his own weight. So long as his upward velocity is increasing, the tension of the rope must be greater than his weight; for if it were equal to it, the resultant force acting on him would be zero, and therefore by the first law of motion he would remain in his original state—viz., at rest. The tension of the rope, at any instant, is the same throughout its length, because the pulley is smooth, and therefore the same force always acts on the ball as on the monkey—viz., the tension of the rope minus the weight of either. Therefore, the velocity of the ball receives exactly the same increment in any period as that of the monkey, and at first they are both at rest. Hence, at any subsequent time they must be moving with the same velocity. As soon as the velocity with which the monkey is climbing the rope ceases to increase, his upward velocity also ceases to increase, and the tension of the rope must have again become equal to his weight. So that the upward velocity of the ball will also cease to increase. They will then each of them continue to move upwards with constant velocity, so long as the monkey continues to climb the rope with the same velocity. In short, no matter how the monkey climbs up the rope, he will always remain on a level with the ball, supposing, of course, that he was originally on a level with it.—Vesuvius.

[47558.]—**Water-Closet Seats.**—The hole in w. c. seats of best construction are perfectly round, not egg-shaped, as often seen in common closets. Of course, nothing is required for setting these out but a pair of compasses. Some may perhaps be seen that are slightly oval, but this is effected by bevelling away more at the sides than at the front and back; even then the hole itself is round, and the upper edge oval.—Grapho.

[47586.]—**Pure Silver.**—Dissolve in a mixture of pure nitric acid and water, equal parts, with aid of a gentle heat; dilute largely with distilled water and allow to settle three or four days, till quite clear; pour off the clear solution, and add pure hydrochloric acid till further addition ceases to precipitate; all the silver is hereby thrown down as chloride of silver; let stand till clear, decant, and wash once or twice with distilled water. Collect precipitate on a calico or paper filter, and further wash until the filtrate ceases to give any precipitate or cloudiness with nitrate of silver solution. Dry the chloride of silver carefully; when dry, mix with four times its weight of a mixture of equal parts of sodium and potassium carbonate; introduce this mixture into a crucible, and fuse at a good red heat; when cold, the silver will be found in a button at the bottom of the slag, and should be quite free from all impurities generally found in scrap silver. If required absolutely pure, I will give "Ape" further particulars.—A. E. Robinson.

[47628.]—**Private Study of French Language.**—If "Nemo" will procure Prendergast's French Manual of the "Mastery Series," published by Longmans and Co., Paternoster-row, London, price 2s. 6d., and conscientiously adhere to the instructions there given, I have reason to believe that he will be satisfied with the progress he makes. If he requires any further assistance, and will advertise his address, I shall be most happy to give him any in my power.—J. W. Fleming, Kirkwall, N.B.

[477641.]—**Rhubarb Wine.**—Cut up fruit into short pieces, 2in. long; to every gallon of such add 1 gallon of water and 3½lb. loaf sugar. Fermentation will soon commence; stir up twice daily when the pulp ceases to rise, wring out a quart at a time in a piece of thin canvas, cork down in stone bottle or cask. Ease the cork for a minute twice daily the first week, as an after fret (fermentation) may occur. Good to drink in about six months. P.S.—To please fancy you may add a little cut up dandelion root (fresh) or a handful of the leaves per gallon; but it must be all put together at commencement. Nearly all other fruits may be treated in the same way.—Meliora.

[47646.]—**Human Milk.**—Dr. Frankland's process for the manufacture of imitation human milk from cows'-milk consists in the removal of a certain portion of the casein, and the addition of a certain portion of sugar. On reference to the table:—

	Woman.		Cow.
Casein............	2·7	....	4·2
Butter............	3·5	....	3·8
Milk-sugar........	5·0	.....	3·8
Salts	·2	....	·7

It will be seen that by the addition of one-third more milk-sugar, and the removal of one-third the casein, woman's milk is closely approached, the percentage remaining then:—

Casein	2·8
Butter	3.8
Milk-Sugar	5·0
Salts	·7

The following is the method by which Dr. Frankland has accomplished this effect:—Allow one-third of a pint of new milk to stand 12 hours; remove the cream, and add it to two-thirds of a pint of new milk as fresh from the cow as possible. Into the one-third of a pint (from which the cream has been abstracted) put a piece of rennet about 1in. square, and set the vessel in warm water till the milk is curdled fully (5 to 15 minutes required, according to the activity of the rennet). As soon as the curdling commences, the rennet should be removed, and put away for subsequent use. Now break up the curd, and carefully separate the whole of the whey, and rapidly heat to boiling; separate the casein, and dissolve in the hot whey 110 grains of powdered sugar of milk, and mix it with the two-thirds of a pint of new milk, to which the cream abstracted from the one-third was added. Should be used within 12 hours after preparation. Although appearing on paper a somewhat complicated process, in practice nothing is more easy, and results in as effective a substitution of a mother's milk as could be possibly desired.—A. E. Robinson.

[47647.]—**Boiler.**—I must say that in my opinion the boiler shown on page 578, and described by "Grapho," is a very bad arrangement for generating plenty of steam. A boiler ought to be so designed as to have the greatest amount of heating, as well as the least amount of radiating surface. Having been engaged for a considerable time experimenting with a 5ft. model boat, and trying to get up steam with paraffin, colza, benzine, and spirits of wine, I have now adopted a charcoal furnace in preference to any of these. The form of boiler which I use is made thus:—Take a sheet of copper not quite 1-16 thick, and say 16in. broad; if the boiler is to be 10in. long, let this sheet be 13in. in length; bend this into a cylinder, lap over, say, ⅜, and rivet every ½in. with the little ½in. brass wire nails used to tack down stair-rod eyes, then sweat the joint with solder; make the ends out of the same sheet of copper, strike a circle of the inside diameter of the cylinder, and another, allowing ¼in., which must be beat up into a flange all round, and riveted all round at 1½in. from each end of aforesaid cylinder; make also a tube of the same stuff 1½in. inside diameter, riveted and sweated with solder; fit this through the ends, at one-third of diameter from the bottom, nicely turn over the ends and sweat. Now prepare two false ends, which may be of tinned sheet-iron, and having previously cut an aperture near one end at the bottom, and a similar one at the other end at the top, on this latter fit a flanged ring, preferably a casting, to fit the chimney on, then rivet and solder in these false ends, and the heat being applied along the bottom, travels to the end, turns up and back through the flue, then up and through the chimney. Next, for the furnace, take some sheet iron, say, 1-16in. thick, and cut two sides, allowing if possible 3in. from bottom of boiler to firebars (in mine, this is a piece of the same stuff punched full of ¼in. holes, with a bridge ¾in. from the door). Solder these sides along the sides of the barrel from one end to the other, at its greatest diameter (they will not melt off if the water supply is attended to); flange, fit, and rivet in the ends, one of which contains the door, also the part of the bottom plate from bridge to the end, which of course must be air-tight (some putty mixed with red lead will be found handy, should there be any orifices in the affair awkward to stop); let the sides extend below the bottom of grate, so as to allow of sufficient airway, and then you can use either the lamp of "Grapho," or the charcoal furnace. I have omitted to state that I found that in the open air it was necessary to fit on a tin jacket over the top of the boiler, allowing ⅜in. space, except where it is soldered to the sides of the sheet-iron at the greatest diameter, as aforesaid.—J. J. A., Liverpool.

[47654.]—**Printing.**—Although not entirely devoted to colour-work, you would do well to purchase "The Letterpress Printer," published by Joseph Gould, Middlesbro'. The following are all good books:—"Printer's Practical Every Day Book," "Printing for Amateurs" (published at the *Bazaar* Office), "Eclectic Handbook of Printing" (published by Birmingham Machinists' Company). For plenty of "dodges," "wrinkles," "tips," and "eye-openers," subscribe to *The Paper and Printing Trades' Journal.*—J. Hezmalhalch, Jun.

[47655.]—**Cotton.**—In my reply to this query, read "bast" instead of "best" in "Jute is the best of several Indian herbaceous plants, generally Corchorus capsularis and Corchorus olitorius."—W. Stuttard.

[47657.]—**Railway Signal Boxes v. Thunder and Lightning.**—Is lightning a source of danger to the signalman, and are the electrical wires and instruments a safeguard against that danger? This is a question which might be answered both affirmatively and negatively if left to mere theory: some would support one side, and some the other; but we will revert to practice and facts first, and comment upon theory and probabilities afterwards. Out of about 5,000 pieces of apparatus the following are, as near as possible, the number of casualties which took place in one year. Coils simply fused, and no other damage done, 150; lightning protectors fused, and no other harm done, 50; instruments slightly burnt only, 1; instruments entirely burnt up, although no other harm done, 2; fused leading in wires (covering burnt off in some instances, leaving wires in contact, and in others the wire also severed), 20; line wires severed by flash (probably consequent on flaw, which presented resistance to the flash, thus causing wire to be melted, gauge about No. 10, 1; signal-box struck, roof knocked off, and one side damaged, flash entered box and escaped *viâ* levers and earths, one or two coils fused, signalman luckily escaped unhurt, coils included in figures above: total casualties, 224. Thus, we see that we get about 4 12-15ths per cent. of the instruments damaged; but no serious effects ensue therefrom. About 1-26th per cent. are seriously damaged per annum, and might result more seriously for the signalman than has been the case during the year I am considering. About 1-50th per cent. of accidents occur which are liable to prove fatal to the man in the box. The flash in the instance before me did not enter *viâ* the wires, but struck the roof of the box. A part of it escaped *viâ* the levers, a part by means of the earth-wires of the instruments, and, the flash being strong, a part escaped away to "line," fusing two of the coils, thence getting to earth at the other terminal station. Here the wires proved a safeguard, as they helped to conduct away the flash. Generally speaking, the electrical earth conductors are of sufficient capacity to carry off any flash; and while any of the wires are liable to be charged by lightning, which is conducted to the box, there is an earth escape at both ends, which guards against "flying." By preventing "flying," I mean that they open up a ready path to the current, away to earth, thus stopping the flash from leaving the instrument, and entering the first earth conductor near—probably the levers—which might prove dangerous. But, still, there is the probability, but the chances are quite 99 to 100 against it. In the case where lightning protectors were provided, the instruments were saved from fusion. If wires are attached to soft metal for earth—a gas pipe, for instance—it is quite possible that it will be melted, and that the flash will "fly"; but all these probabilities are rare. In the course of five years, I have not heard of one fatal accident consequent upon the electrical apparatus; it has proved rather a safeguard than a source of danger, owing to its supplying such a ready road to earth. It may be well to remark that during thunderstorms, when working the instruments, whether block, single-needle, or otherwise, the operator should only touch the wood, or other insulating material of the handle, or he may get a fine shock, in itself not very desirable. I have noticed that it is quite a common thing to place the thumb on the metal of the handle where it joins to the barrel, in the S.N. instrument.—H. Stooke.

[47671.]—**Institute of Chemistry Exams.**—I am greatly obliged to "F. G. S." for his kind reply, on p. 556 to my query; but, as I am quite ignorant of the modus operandi of the Science and Art Department, I would thank "F. G. S." if he could tell me where, in London, the exams. are held? If I can take all the necessary subjects at the sitting? and to whom I must give notice of my intention to present myself?—Old Subscriber.

[47684.]—**Tin-plate-Working.**—You will require a hatchet stake, half-moon stake (two sizes), mallet, groove punch, bick iron, and small hammer for tapping down the joints. I quote the above names from memory. Turning up edges is done with the mallet; straight edges over the hatchet stake, and circular ones over the half-moon stake. Nothing but plenty of practice will bring proficiency in this. I forget the name of the plates I used, but I think it was XX charcoal. Size was, I think, somewhere about 15 by 22in., and price 3½d. per sheet. You would do well to procure a little work from the *Bazaar* office, entitled "Working in Sheet-Metal," price 7d., post free. For a fully illustrated price-list of tinman's tools, write to Messrs. Manoah Rhodes and Sons, Wakefield. —J. Hezmalhalch, jun.

[47694.]—**Taking Top off Violin.**—"Cremona" must carefully insert the blade of a thin table-knife, and gently and patiently prise it off all round. When replacing the head, do not rub off the old glue, but with strong and fresh glue go over it again, and having ready a number of clamps bind all together until dry. The clamps are made like the letter E, with the central stroke taken out, and are tightened in the work by a little wedge.—E. B. F.

[47699.]—**Distillation.**—The usual process for making oil of peppermint and similar oils is to use a retort with a steam-pipe attached to the under surface. The retort is half-filled with the herb in question and steam passed in; this volatilises the oil, which passes over with the steam, and condenses into the receiver. The oil being the lightest, rises to the surface, when it can easily be siphoned off when enough has collected. The oil can also be prepared by simply mixing the herb with water in an ordinary retort, and distilling by means of a fire; about 1lb. herb to 3lb. or 4lb. water. The other preparations of peppermint are made from the oil essence. Mix oil one part, rectified spirits of wine four parts. Water—mix 1½ drachm oil with 1½ gallon water, and distil till one gallon is collected, which is the peppermint-water of the British Pharmacopœia.—Junior Pharmacist.

[47703.]—**Darkening Mahogany, &c.**—If "S.W." will kindly refer to Vol. XXXIV., No. 882, page 573, he will there find a reply (penned by the writer), to his query, giving him full instructions what to do and how to do it.—A. Manock.

[47705.]—**Incandescent Lamps.**—It is a pity some readers do not read up what has been said on a subject before putting queries. It has been stated many times that unless you want to waste both time and money you must not use the Leclanché battery. Bunsen's battery is one of the best. You will find it a very messy and costly game, literally "not worth the candle." There are the Swan, Maxim, Lane-Fox, all good, and "best"—in their maker's estimation.—J. Hezmalhalch, jun.

[47709.]—**Ague.**—Your occupation may cause the disorder to hang about you. It is very detrimental to be much in the damp. Sleep in a dry room, with a more or less southern aspect, on elevated ground; wear a suit of flannel next the skin, including woollen socks; change at least once a week, put on thoroughly dry; live moderately on good, wholesome, fresh food—not too sloppy. A fire in your bedroom occasionally (daytime) will do no harm.—Meliora.

[47714.]—**Tests.**—"Pro Bono Publico" will find the following about the simplest method of estimating potash in the chrome or bichromate of that salt. Weigh off about 5grm. of the salt, dissolve in a little water, and add a little hydrochloric acid and alcohol to the solution; boil till the salt is completely reduced, and then add a slight excess of ammonia; boil till free from ammonia, filter off the precipitate of chromium trioxide, and evaporate the filtrate and washings in a platinum basin down to dryness over the water-bath; carefully ignite the residue to drive off ammoniacal salts; dissolve in a little water; add excess of platinum chloride, and again evaporate over water-bath to dryness; treat residue with strong alcohol, and transfer the precipitate to a weighed filter paper; wash well with alcohol, and dry at 100° C. till constant. The precipitate is $PtCl_4 + 2KCl$, from which the amount of potassium present can be readily found. This method is applicable to either the chromate or bichromate.—Ernest A. Brookes.

[47717.]—**Problem.**—Will "C. W. B." kindly work out the solution to $\frac{1 + x^5}{(1 + x)^5} = a$. His solution (No. 909, page 579), is too abstruse for a novice. It would be esteemed a personal favour. —Amicus.

[47720.]—**Oilstone.**—Wash your oilstone with paraffin-oil, afterwards with soda and hot water, and pour upon it equal parts of spirits of salts and water, or hydrochloric acid.—Jack of All Trades.

[47721.]—**Studying for the Medical Profession.**—You will find it exceedingly difficult to commence a medical career at the age of 30; but it will not be the first time that great things have been accomplished after such a maturity, should you be successful. In the first place you cannot prepare yourself by "private study," unless by this you mean that you can learn from *books* certain replies, which would be equivalent to certain questions of an examination. In order to qualify for the medical profession, you must have a good preliminary education, and about four years' attendance on lectures, hospital training, &c., and during this period you must pay every attention to the perfection of your education, and give special attention to *Latin*. If you were in a city something like Manchester, and could attend the medical classes at the Victoria University you would find it a great help. You say you have a "knowledge of chemistry;" but I cannot gather from the statement to what extent. Certainly it will be useful to you, and the more you know about it the better.—A. Manock.

[47731.]—**Killing-Bottle.**—As cyanide of potassium is extremely poisonous, it is a dangerous article in the hands of anyone who is not a chemist, and for that reason is not, or ought not to be, easily obtainable. The following, however, is a simple method of making a thoroughly good killing bottle with materials which are almost always at hand, and one which can be easily replenished whenever desirable. Get a large wide-mouth bottle, a French-plum bottle with a good sound top answers admirably, cut a piece of thick cardboard to fit as nearly as possible the inside of the bottle, and just so tight that it will stick firmly, and not slide up and down. Next pick a quantity of laurel leaves, young ones are best, see that they are quite dry, and chop them up into small pieces; then bruise them well, which is easily done by rolling them up in a piece of rag and hammering with a mallet; turn them at once into the bottle, and press them down; enough should be put in to be about an inch deep when pressed. Over these put the round piece of cardboard, so as to keep them in their place, and fix the lid or stopper on the bottle to keep in the fumes. Such a killing bottle will last fresh, if well stoppered, a whole season, and kill insects almost instantly; at the same time moths put in overnight will be found in a beautifully relaxed state the next morning for setting. It is well to avoid breathing the fumes, which are those of prussic acid. It is not advisable to leave chip boxes long in the laurel bottle, as they are apt to become thereby undesirably relaxed. Instead of laurel leaves, "stone ammonia" (ammonium carbonate) can be put under the card in the bottle, but it has the disadvantage of spoiling the colour of green-tinted moths.—A. Lloyd.

[47734.]—**Microscopic.**—If I may be allowed to differ with the previous replies to this question, I should advise "O. O." to purchase as follows:—A monocular stand (a binocular is simply waste money for use with the high powers he requires). I have recently had one constructed by Bulloch, of Chicago, which he calls the "Biological," and this is quite the best moderate-priced stand I have seen. As to a stage, Bulloch's is admirable, as it has concentric motion, and, by turning a small screw, the whole stage-plate lifts out, and will allow any sized slide or a plate of glass to be laid in its place. Do not get a mechanical stage; the movements of infusoria are much easier followed by hand on a glass stage. As to objectives, I should advise Zeiss' lenses; Mr. Baker, 244, High Holborn, is agent for them, and they are wonderful for the money. You will require 3-5, 1-4, and 1-9 of 24, 50, and 110 degrees aperture respectively, and probably after some time you will go in for a 1-14. The practice of using deep eyepieces, though convenient, is very bad for the eyes, and I should not advise you to try it much. You will notice I have named objectives of very low aperture; these will give you great penetration, which is quite indispensable for your work. I have a 4-10 of 100°, and a ¼ of 150° aperture, and neither is useful for bodies of appreciable thickness. You could procure a stand such as I describe for about £9, and the three objectives would cost £7 14s. I have worked on infusions myself, and shall be glad to assist you further if you will advertise your address.—P., F.R.M.S.

[47735.]—**Cataract.**—Don't eat anything at all. Notes would be superfluous, as, if you follow the advice, you won't want them. That is just as sensible and as much to the purpose as "don't eat salt." Can anyone—a chemist and physiologist preferably—say what is meant by "supersalinity" of the blood? The quantity of chloride of sodium found in human blood is about 4·6 in 1,000 parts, and somewhere about the same proportion is found in the blood of many of the domestic animals. The cat and the hen have over 5. Chloride of sodium is not the only salt found in the blood, so that it is necessary to know what is meant by supersalinity, both qualitatively and quantitatively. However, what with one thing and another being condemned as food, you will find it safest not to eat anything; but, perhaps, after all it will be more agreeable to enjoy yourself as much as possible, and throw the quack notions, as you would physic, to the dogs.—One Who Likes Salt.

[47737.]—**Black Shellac Varnish.**—If "Raj Mistry" will dissolve ¼lb. of shellac in 1 pint of methylated alcohol, and add ¾oz. camphor, and subsequently ½oz. of lampblack and ¼oz. of Prussian blue, both finely powdered, he will get a thin black varnish which dries with a high gloss. If too thin, use less spirit, but heat it to dissolve the lac, and if scent and high gloss are of no importance, omit the camphor. The recipe above given is the well-known blacking, but probably ivory black might be better, for some purposes, than lampblack. I have made the recipe above, and found it useful in many ways, notably for dressing black leather bags.—Nun. Dor.

[47738.]—**Analysis of Paint.**—Bisulphide of carbon will remove the oil from paint mixtures.—R.

[47739.]—**Tallow.**—Mineral adulterants may be detected by digesting the sample of petroleum spirit. With regard to the detection of foreign fats, Allen, in his "Commercial Organic Analysis" says they "can only be recognised by the altered physical characters of the sample."—R.

[47748.]—**Pickles.**—Take a gallon jar, put in it, without boiling, two quarts of the best brown pickling vinegar, 2oz. of ground ginger, 2oz. of flour of mustard, ½oz. of turmeric, these three to be mixed smooth with a little of the vinegar, and put into the jar; then add 2oz. of eschalots, 2oz. of mustard seed, 2oz. of salt, 1oz. of lump sugar, and as much cayenne as will lay on a shilling. Put into it a hard white cabbage, cut into slices; vegetable marrow, peeled, and cut into fanciful shapes; cucumber, peeled, and cut up; small onions, peeled; small French beans; large onions, sliced, and cut in quarters; cauliflower, broken into branches. Nothing to be washed or dried, but all put in fresh cut, and quite clean; stir it all well up together every other day for a fortnight, and keep it tied securely from the air. From No. 336. —Josiah Berry.

[47744.]—**Trigonometry.**—Tan. $\frac{a+B}{2}$ + tan.

$$\frac{a-B}{2} = \frac{\sin.\frac{a+B}{2}}{\cos.\frac{a-B}{2}} + \frac{\sin.\frac{a-B}{2}}{\cos.\frac{a-B}{2}} = \frac{\sin.\frac{a+B}{2}\cos.\frac{a-B}{2} + \cos.\frac{a+B}{2}\sin.\frac{a-B}{2}}{\cos.\frac{a+B}{2}\cos.\frac{a-B}{2}}$$

Multiply each expression in the numerator and denominator by 2.

$$= \frac{2\sin.\frac{a+B}{2}\cos.\frac{a-B}{2} + 2\cos.\frac{a+B}{2}\sin.\frac{a-B}{2}}{2\cos.\frac{a+B}{2}\cos.\frac{a-B}{2}}$$

$$= \frac{(\sin. a + \sin. B) + (\sin. a - \sin. B)}{\cos. a + \cos. B}$$

$$= \frac{2\sin. a}{\cos. a + \cos. B}.$$—C. H. Romanes.

[47744.]—**Trigonometry.**—

$$\text{Tan.}\ \frac{a+B}{2} = \tan.\left(\frac{a}{2}+\frac{B}{2}\right) = \frac{\sin.\left(\frac{a}{2}+\frac{B}{2}\right)}{\cos.\left(\frac{a}{2}+\frac{B}{2}\right)}$$

$$\tan.\ \frac{a-B}{2} = \ldots\ldots\ldots\ldots\ldots\ \frac{\sin.\left(\frac{a}{2}-\frac{B}{2}\right)}{\cos.\left(\frac{a}{2}-\frac{B}{2}\right)}$$

develop the sines and cosines of the binomials, and add the two terms together by bringing to a common denominator, and we get

$$\tan.\ \frac{a+B}{2} + \tan.\ \frac{a-B}{2} = \frac{2\sin.\frac{a}{2}\cdot\cos.\frac{a}{2}\left(\sin.^2\frac{B}{2}+\cos.^2\frac{B}{2}\right)}{\cos.^2\frac{a}{2}\cdot\cos.^2\frac{B}{2} - \sin.^2\frac{a}{2}\cdot\sin.^2\frac{B}{2}}$$

The first half of the numerator = sin. a, and the second half in brackets = 1, which therefore disappears, and the numerator becomes sin. a. In the denominator bring the second term to cosines (remembering $\sin.^2 A = 1 - \cos.^2 A$) the denominator then becomes $\cos.^2\frac{a}{2} + \cos.^2\frac{B}{2} - 1$. Now, $\cos. a = 2\cos.^2\frac{a}{2} - 1$, and $\cos. B = 2\cos.^2\frac{B}{2} - 1$, therefore, the denominator becomes $\frac{\cos. a + \cos. B}{2}$, divide the numerator by the denominator, and the expression becomes $\frac{2\sin. a}{\cos. a + \cos. B}$.

—M. I. C. E.

[47744.]—**Trigonometry.**—

$$\text{Tan.}\ \frac{a+b}{2} + \tan.\ \frac{a-b}{2} = \frac{\sin.\frac{a+b}{2}}{\cos.\frac{a+b}{2}} + \frac{\sin.\frac{a-b}{2}}{\cos.\frac{a-b}{2}}$$

$$= \frac{\sin.\frac{a+b}{2}\cos.\frac{a-b}{2} + \sin.\frac{a-b}{2}\cos.\frac{a+b}{2}}{\cos.\frac{a+b}{2}\cos.\frac{a-b}{2}}$$

$$= \frac{\sin.\left(\frac{a+b}{2}+\frac{a-b}{2}\right)}{\cos.\frac{a+b}{2}\cos.\frac{a-b}{2}}\ \text{Multiply num. and den. by 2}$$

$$= \frac{2\sin. a}{2\cos.\frac{a+b}{2}\cos.\frac{a-b}{2}} = \frac{2\sin. a}{\cos. a + \cos. b}.$$

—Square

[47745.]—**Palpitation of the Heart.**—Much has been said and written on this disease, which, unfortunately, is a common one, and one which often produces a nervous fear and unnecessary anxiety on the part of the patient. Palpitation is no proof of the existence of disease of the heart, as it may arise from many different causes. Indigestion is a common cause of palpitation of the heart. Persons of a nervous temperament are mostly subject to it, particularly if they get in the least excited. The blood being too weak or watery is another cause of palpitation. Persons possessing an irritable or passionate temper often have it when their passions are aroused. Palpitation may arise purely from constitutional weakness. These are some of the principal causes of palpitation of the heart, and the treatment entirely depends on the cause from which it proceeds. The cause must be removed before the cure can be effected. When palpitation arises from organic disease of the heart, it cannot be radically cured, only relieved. It must not be supposed from this statement, that heart disease is always accompanied with palpitation; on the contrary, many persons have heart disease who have never felt the least palpitation. It is therefore not a necessary symptom of disease of the heart. Valvular heart disease may produce, and often does, a violent palpitation, which is greatly aggravated and increased when the patient gets in the least excited, which should always be avoided in such a case, as it is dangerous. People with weak hearts should be very careful in their consideration of that weak part, and avoid everything which tends to increase or embarrass the action of their hearts. The heart is an organ liable to many forms of disease. It may be fatty degeneration, ossification, or valvular disease. There are few people, indeed, that possess hearts in a sound and healthy condition. Palpitation of the heart should be treated only by a qualified medical man. It is a disease which should not be tampered with by non-medical persons. It is not very dangerous in its nature, but still, it requires and demands skilled and careful treatment. Some people attach but little importance to this disease, while others attach too much importance. It is of some importance in every case, as, if neglected, it may lead to very serious consequences. Persons subject to palpitation need not imagine that they have heart disease, until they know for certain that they really have it; and when the unpleasant information reaches them that they have got the organic disease of the heart, they should, if possible, take the information in a quiet way, and not, even then, frighten themselves unnecessarily, as it is a well known fact that there are many persons who have organic heart disease who do not die from it. As "A Subscriber" evidently suffers from palpitation of the heart, he naturally asks, Is it heart disease or not? In answer to this question I must say that it is impossible for any reader of "ours" to give a definite reply. Personal examination by a qualified medical man is necessary in order to ascertain from what cause it proceeds, and in prescribing for palpitation many things have to be taken into consideration. It is, therefore, impossible to suggest any certain cure for this one particular case of palpitation. Consult a physician, and give every attention to the treatment he recommends.—G. Fryer.

[47745.]—**Palpitation of the Heart.**—If you have had rheumatic fever, the symptoms may indicate a diseased state of the heart; if not, they may only indicate indigestion, flatulence, or general debility. Persons of a nervous disposition and those troubled with much fat, get palpitation of the heart from the smallest excitement or exertion; but this symptom must not be deemed one of disease of the heart. —Edwin.

[47750.]—**Polishing Wardrobe.**—Never use putty; take some fine sawdust of the same wood, and whiting, and mix into a paste, either with some pale polish, gum, or glue, and well press home. When set, paper off. This is scarcely perceivable.—Jack of All Trades.

[47753.]—**Polishing Piano-Keys.**—To Mr. Davies.—The frame would not hold the keys sufficiently level or firm A better way would be to hand-screw a few at a time on a board, and scrape them in that position. They should be finished with flour-paper, care being taken that they do not get too hot during the process. Unless the keys are very hollow, or much discoloured, it would perhaps be better to dispense with the scraper altogether, using a coarser glasspaper in its stead They should be polished singly, on a board covered with several thicknesses of cloth; this should be placed on a bench, and the ivories vigorously rubbed (lengthwise and face downwards), until a good polish is obtained. Putty-powder is the best polishing material, though pumice might first be used to take out any marks left by the paper. A very brilliant polish may be got by finishing the keys with a similar board covered with wash-leather, and sprinkled with rouge. A liberal supply of water is necessary during either process.—W. H. Davies.

[47754.]—**Tin Cans.**—Down in our part of Lancashire they command a ready sale. They are used for covering small outbuildings. They are cut up into one flat sheet, one thickness of stiff brown paper tacked upon the slabs, the tin is then tacked firm. They fetch 2d. per sheet.—Tom B.

[47754.]—**Tins.**—Some time ago I had 10 tons of bad tinned meat, salmon, &c., to convert into manure, and after that process was accomplished, there was a perfect pyramid of tins, occupying space, and emitting a very unpleasant effluvium. I therefore took a piece of corrugated iron roofing, 6ft. by 6ft., placed it at an angle of 45°, bricking up round with common bricks, loose laid, with a few iron bars across, upon which I built a fire, using coal and wood for a start, but subsequently utilising the cinders from the stokehole. I placed as many tins upon the iron as would lie upon it, and made a clay mould, so that the solder and tin would fall into it. The tins were tapped with a stick occasionally, and all the solder and tin came from them in the shape of thick bars, in the mould. As the tins opened in the course of this process, they made a good bottom for a new road that was then in progress. The product from the mould was remelted in a ladle and cast in thin bars, being separated from the dross, and fetched about 7d. per pound, paying well for the operation.—Fred. Walker.

[47756.]—**Electro-plating.**—The mere intensity or E.M.F. of the current may be shown by a common current detector, price about £1; but this instrument will be of little value in estimating the proper current for electro-plating. An instrument for this purpose should have two coils, and will cost about £3. An illustrated article would be required to properly describe the instrument.—Edwin.

[47756.]—**Measuring Electric Current.**—The instrument most used for this purpose by electricians was Siemens' dynamometer, but recently Profs. Ayrton and Perry have brought out an am-meter, or galvanometer, measuring in ampères (or nearly so), and this we mostly use now, because of its great convenience. There are other measuring galvanometers similar in action, and notably a French one by Duprez. As "Galvanometer's" currents are for electro-plating, I scarcely think he requires an instrument like the above, for I have been told by a gentleman connected with Elkington's well-known electroplating establishment at Birmingham that they measure the strength of their currents by the amount of deposition obtained in a given time. Others that I have heard of could not tell me the power of their currents in the technical terms.—Tried

[47757.]—**Manganese.**—The most important manganese ores are (1) The dioxide, or pyrolusite, MnO_2 (2) Braunite Mn_2O_3: (3) Hausmannite Mn_3O_4. These higher oxides are both reduced to MnO_2 when heated to redness, and from this latter substance metallic manganese is obtained by intensely igniting it in a wind-furnace with soda-lime, glass, fluor spar, and lampblack. Other manganese ores are psilomelane (MnBa) O + MnO_2: rhodocrozite or manganese-spar, $MnCO_3$: manganite, $Mn_2O_2(OH)_2$: alabanite, MnS: and hauerite, MnS_2. "Chlorine" will see from this that (sulphur and barium excepted) there are very few real impurities in the ores of manganese. If he wishes to obtain an exact qualitative or quantitative analysis of any ore, he can do so by the methods given in the ordinary textbooks; too long to be inserted here.—C. Harris.

[47759.]—**Archæological.**—Presuming the cruciform structure to be ancient work, it seems to be comparable with the buried crosses found on the wolds of Yorkshire between 1866 and 1874. These were composed of chalk sides filled up with clay, the four arms pointing to the cardinal points. Leading antiquaries suppose them connected with Roman agrimensorial operations—division and assignment of estates among the colonists in Roman Britain. See *The Archæologia*, vol. xlii. pp. 127 and 151.—H. S.

[47760.]—**Tinning and Galvanising Iron.**—This is being done by Mr. Elmore, of Blackfriars-street, London, S.E.—Edwin.

[47766.]—**H.M.S. "Ajax."**—The engines of this vessel, made by Messrs. Penn, are twin screw engines of 6,000 indicated horse-power, and are on the steam-hammer principle, with cylinders 54in. in diameter, and 39in. stroke, and are six in number, three on each side of ship. They are compound expansion engines, the expansion slide working on the back of the main slide, and are set to cut off steam from 1-10 to 6-10 of stroke. The engines are made to work compound by an arrangement of valves fixed on side of cylinders, the forward cylinder on each side being the high pressure, so that one cylinder may be worked high pressure, and the other two low, or all three worked low pressure. The crank shafts are made in three lengths, so that either length may be disconnected in case of a breakdown. The boilers are ten in number, and work at 50lb. per square inch.—Taffy.

[47769.]—**Wire for Induction Coils.—Incandescent Lamps.**—The wire can be thus used as the secondary wire to a No. 22 primary. Platinum wire has been used, but it cannot be compared in usefulness with carbon filament. All the best lamps have carbon filaments.—Edwin.

[47769.]—**Wire for Induction-Coil—Incandescent Lamps.**—No. 36 cotton-covered wire might do for an induction-coil of a certain size if well insulated. I should not risk it, however. Use silk-covered wire, and see that you get it properly covered. Both platinum and carbon are used largely by the different makers in the manufacture of incandescent lamps. The carbon filament in my opinion is the best, platinum being liable to fuse.—W. R. HICKS.

[47769.]—**Wire for Induction Coil—Incandescent Lamps.**—Cotton-covered wire will not do for intensity coils, unless each coil is insulated with thin twine, and then well covered with hot paraffin wax. I do not advise "Amateur Electrician" to use the wire; he had better try some silk-covered, and not have any further trouble. Carbon filaments are used for lamps, the preparation of which has been explained in back numbers. —W. T. W.

[47769.]—**Wire for Induction-Coils.**—Platinum is now seldom used for the old filament in incandescent lamps. All the well-known lamps, including Edison's, Swan's, and Maxim's, are made of carbon. The Gatehouse patent, I believe, uses a carbon filament with platinum wound round it; and a new invention, the patentee I forget for the present, is one in which a platinum wire is used, round which glass is made to fit closely, so that no air intervenes. This is supposed to make the filament last a longer period, but it is open to objections.—TRIED.

[47769.]—**Wire for Induction Coils.—Incandescent Lamps.**—No. 36 wire is used for induction coils, but it is bad economy to use cotton-covered in place of silk. Much more silk-covered can be got in the same space. As you have the wire, perhaps it might pay to use it. Carbon filaments are used for incandescent lamps, platinum filaments being no good.—J. HEZMALHALCH, JUN.

[47770.]—**Preventing Rust.**—If "W. P. M." will line his show-case with waterproofed carbolised paper he will avoid the rusting of his steel goods. The theory of its action seems to be the formation of a chemical atmosphere counteracting the causes of rust and tarnish. A similarly-treated tissue-paper, "anti-tarnish paper," is made for silversmiths and jewellers' use.—E. L. S.

[47770.]—**Preventing Rust.**—Never put a case with cutlery or polished goods against an outside wall. You might prevent rust by having your case painted, or give it a coat of patent knotting and line with zinc.—JACK OF ALL TRADES.

[47770.]—**Preventing Rust.**—If "W. P.M." can place a vessel containing a small quantity of sulphuric acid in his case, I think that will prevent his articles from rusting. The action is that sulphuric acid has a great affinity for moisture, therefore, keeping the air perfectly dry. The acid should be changed now and then.—W. R. HICKS.

[47770.]—**Preventing Rust.**—Rust can be totally prevented in a close case by putting in a small cup or wide-mouthed bottle without cork an ounce or two of fused chloride of calcium. If the case is not perfectly tight this will require renewing at intervals when it becomes fluid. Common fused chloride of calcium can be obtained at the rate of about 1s. per lb.; it prevents rust by its strong affinity for water, which it rapidly removes from the air, and is constantly used for preserving steel and iron specimens, and delicate balances in cases. It is useless in the open air, becoming rapidly saturated with water. A gas-flame is worse than useless for the purpose.—THOS. FLETCHER, Museum-street, Warrington.

[47771.]—**Dead Black for Brass.**—Heat the brass till you cannot touch it; dip it, by a brass wire, into nitric acid for four or five seconds; then heat it till it turns quite black, and is covered with green blisters. When cold, brush with a hard brush. The operation should be performed in a well-ventilated room, and a Bunsen's burner will give the requisite heat, if the article is not large.—J. F. E.

[47771.]—**Dead Black for Brass.**—If the articles are small, place them near the fumes of burning straw for a little while, and they will be covered with a very adhesive pure black colour; or else tint them in silver solution AgCyKCy, and then rub them over with a hot solution of potassic sulphuret in water. Use as hot as you can, and plenty of sulphuret. You will get a fine colour this way, though it, of course, costs more than the straw method. This is what is falsely called oxidising in the trade.—GIRDLESTONE WRIGHT.

[47775.]—**Staining Sycamore.**—I generally dye my sycamore and beech veneers in logwood and a little common soda. For staining, soak red wood in wood-naphtha for imitation birch or mahogany.—J. LEWIS, Brushmaker, Swansea.

[47775.]—**Staining Sycamore.**—You will never make it look like birch for grain, but you may colour it with water and burnt sienna, or lick it over with aquafortis.—JACK OF ALL TRADES.

[47776.]—**Reading the Morse Code.**—The end of one letter is distinguished from the commencement of another by a short pause of the needle if on the machine itself; if printed by the instrument, there should be short spaces between each letter, and longer ones between each word.—W. R. HICKS.

[47776.]—**Reading the Morse Code.**—After signalling one letter a space is made before commencing the next. Thus, A N would be ·— —· and W E ·— — · A greater space is made between each word than between each letter.—TELEGRAPHS.

[47778.] — **Whitewashing.** — Very likely the walls want sizing and papering, so that the stains will not strike through.—W. T. W.

[47779.]—**Soda-Water Siphons**—Are filled from a soda-water machine, the water being under a pressure of from 130 to 160lb. The siphons are inverted and filled through the tap, the air inside being sniffed out.—B. M. S.

[47779.]—**Soda-Water Siphon.**—Soda or potash-water siphons are charged with carbon dioxide gas under pressure from a reservoir; the gas is not generated in the bottle. At the ordinary temperature, the gas is soluble in about its own bulk of water, and its solubility increases directly as the pressure, according to Henry's law; but when this is suddenly removed, the gas escapes with brisk effervescence. Advantage is taken of this circumstance in the preparation of soda-water, as it is called. For this purpose, the water, which may or may not contain soda or other salts in solution, is mechanically charged with a large quantity of carbon dioxide, by the use of a condensing-syringe attached to a reservoir filled with the gas. The excess of the gas thus forced into the liquid occasions the briskness and pungency so much prized in this beverage.—C. HARRIS.

[47780.]—**Chemical Diplomas.**—In order to become a Fellow of the Chemical Society, a candidate has to be proposed by a "Fellow," and supported by a certain number of other "Fellows" (I think four). It is a question of influence rather than knowledge. The Institute of Chemistry requires a candidate to pass two examinations, the first in general and theoretical chemistry, physics and elementary mathematics, and the second a practical examination in all the details of analytical chemistry—this examination extending over five days. Write for a prospectus to the secretary, Somerset House-terrace, W.C.—W. CORDUKES STABLES.

[47781.]—**Gold-Dust Varnish.** — Take some pale copal varnish (oil), and add about six times the quantity of turpentine (oil of turpentine if you like, but there is no difference between oil, spirit, and essence); then get some slaked quicklime, and put about a thirtieth of the whole bulk of your varnish into the bottle; shake violently a good many times and put aside to settle. Decant the clear, and there you have the liquid for painting with gold-dust, or any of the bronze powders. —T.P.

[47784.]—**Cistern.**—10 × 24 = 240, difference in quantity run by C and A + B. Then, 1200 / 2 − 120 = 480 gals. run by C. And as 480 : 1200 : : 24 : 60 minutes, time which C will take to fill cistern ∴ 60 + 30 = 90 minutes, time taken by A. Hence. $24/60 + 24/90 = \frac{2}{3}$ part of cistern filled by C and A. And $1 - \frac{2}{3} = \frac{1}{3}$ part filled by B ∴ 24 × 3 = 72 minutes time B takes; so answer is, A 90 minutes, B 72 minutes, and C 60 minutes.—SCOTCH WORKING MECHANIC.

[47784.]—**Cistern.**—A + B + C pour in cistern 50 gallons per minute. Manifestly A + B pour 30 gallons per minute, and C 20 galls. per minute. Then C would fill cistern in 60 minutes; A in 90 minutes. A + C fill 1-60 + 1-90 per minute = 1-36 of cistern. But A + B + C fill per minute 1-24 of cistern. Then B fills 1-24 − 1-36 = 1-72 per minute of cistern. Therefore B would take 72 minutes to fill cistern. Ans.: A, 90; B, 72; C, 60.—MACHEN.

[47787.]—**Black Shellac Varnish.**—Gas-black is best; mix with about 1 in 10 of finely powdered rosin, and rub well up with spirits of turpentine to a stiff paste, and put in the shellac in pellets; shake up well, and it is done. But naphtha is better than methylated spirit.—JACK OF ALL TRADES.

[47789.]—**Tank.**—Make a solution of curd soap with boiling water; to this mix a little linseed oil, in which a little camphor has been dissolved. Pour over inside, and go over outside with a solution of sugar of lead, sulphate of zinc, or alum.—JACK OF ALL TRADES.

[47793.]—**Electro-plating.**—The cyanide used by you must have been utter rubbish. One ounce of good cyanide would have been more than enough. Get some really good cyanide at 7s. per lb. Add nitrate of silver to your present solution until no more precipitate is thrown down. Pour away supernatant liquid. Wash p.p. in distilled water, then dissolve in solution of good cyanide, add one-fifth more cyanide than it took to dissolve p.p., and the plating solution will be formed.—EDWIN.

[47793.]—**Electro-Plating.**—When you had your cyanide of silver, you should have made a saturated solution of potassium cyanide, and added it to the white precipitate until it was all dissolved, and then added a little more for free cyanide; and then added water according to the class of work you intend to do. For electrotyping, about a pint; for general plating, half a gallon. You had better now evaporate a good deal of the water, then add a little solution of potass cyanide, and try with battery. If it does not act, add some more, and try again. Try this; and if it does not answer, write again, and I will tell you how to cover silver. Never despair.—GIRDLESTONE WRIGHT.

[47793.]—**Electro-Plating.**—"A Beginner" probably owes his failure to the use of the commercial cyanide of potassium. Cyanide of silver (like the chloride) is easily soluble in a solution of potassium cyanide, with which it forms a soluble double salt (KAg) $(CN)_2$. Had the cyanide been pure all would have gone well; but commercial cyanide of potassium (by Liebig's process) always contains about 1-5th of potassium cyanate, since it is prepared by heating a mixture of potassium carbonate and potassium ferrocyanide according to the following equation:—$K_2CO_3 + K_4Fe(CN)_6 = 5KCN + KCNO + Fe + CO_2$. The iron is easily separated by means of its superior specific gravity, but the cyanate is allowed to remain, as for most purposes its presence is immaterial. The undissolved precipitate, therefore, probably consists chiefly of cyanate of silver, which, though soluble in ammonia, is insoluble in potassium cyanide, therein differing from silver chloride. A cyanate can be reduced to a cyanide by heating it with charcoal in a covered crucible. "A Beginner" might try this: If he wishes to purify the commercial cyanide, it can be done by dissolving it in cold dilute alcohol in which the cyanide is soluble—the cyanate only very slightly so; filter off from cyanate, and evaporate the solution down. —C. HARRIS.

[47795.]—**Riveting China.**—By tempering, I mean hardening too soft, and softening too hard metal. There are two kinds of wire sold, hard-drawn and soft-drawn. If you use the hard it must be heated a little, or, in the act of bending an angle, it would be almost sure to crack or break. The very soft needs only a little hammering to make it more firm or springy. The wire should be flattened and faced off with a file on both sides, and the length of the rivet should be accurately adjusted to the length required—i.e., the distance between the holes. If the metal is not left too thick, you will find, on pressing the rivet to its place, that there will be just sufficient "give" or "spring" to admit of the ends passing the edges of the holes and closing in afterwards. This can, of course, only be attained by accurate fitting. You may not succeed at first.—ALFOJOE.

[47804.]—**Model Engine Cylinders.**—Presuming that the cylinders are cored, I think that the best way to do the above would be to obtain a piece of hard wood about 1in. thick, fasten it firmly into the face-plate of the lathe, then turn a hole large enough for the cylinder-flange to fit tight, then fasten the tool in the rest, and take a light cut right through; finish off with a smoothing-bar. I should not advise you to use a twist-drill if you are not a good hand, for they are likely to run out of centre, and it is next to impossible to get them right again. I have made a good many cams, rollers, &c., in my time, and have always bored out the small things in the above way. Shall be happy to give any further information, if required. —W. T. W.

[47810.]—**Heating Soldering Irons.**—Would not a small, tinman's charcoal stove answer your purpose? or, if only wanted for a short time, why not use a spirit-lamp.—W. T. W.

[47816.]—**Silicate of Magnesia.**—"Magnesite" may not, perhaps, be aware that talc, meerschaum, asbestos, and French chalk are all of them silicates of magnesia, possessing the following empirical formulæ:—French chalk, $Mg_3Si_4O_{11}$; meerschaum, $Mg_2Si_3O_8$; talc, $Mg_3Si_4H_2O_{12}$; asbestos, $MgCaSiO_3$; meerschaum and French chalk are, perhaps, the purest. Would not one of these answer the purpose?—C. HARRIS.

[47817.]—**Rapid Electro-Plating.**—Solution of cyanide of copper and potash, and cyanide of silver and potash. (See answer to "A Beginner," 47793.) The copper cyanide is precipitated from a solution of the sulphate with a solution of potassium cyanide. The green precipitate is washed with water, and dissolved in a solution of potassium cyanide in the same manner as the silver solution. In use to be kept warm; however, it is not always necessary. It is only wanted for pewter, zinc, iron, or steel, or articles pewter-soldered. The articles must be thoroughly clean and free from grease of any kind. If you know nothing of the subject, you had better get a book of chemistry or electro-metallurgy, and understand what you are doing.—GIRDLESTONE WRIGHT.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[47818.]—**Horizontal Windmill.** — Will some reader give a design for a horizontal windmill, and best way to fix it at gable end of house to work a force-pump? Please give size and shape of sails, what material, and length of arm, and supposed power of mill represented in design.—CONSTANT READER.

[47819.]—**Electrical.**—I have a Griscom motor, the armature of which, when the current is applied, only turns a short distance—about $\frac{1}{3}$ of the circumference of the magnet. Will some kind reader tell me the cause, and how to remedy it? I use a 6-cell Bichromate, supplied by the makers. Also, the cause of my battery running down after about three minutes' working? How can it be rectified, and what are the best proportions of materials? Also, what number and size of bichromate cells are required to work a 10-candle power Swan lamp? Any hints will be gratefully received.—RHEOSTAT.

[47820.]—**Legal.**—Can I compel the property owners in a private street to put grates and a channel down to take the top water beyond my property, as it is a great nuisance to me, or what course can I take to remedy it? I have a grate, and it has to take the water from the whole street?—Q.

[47821.]—**Rainwater.**—I should be glad to know how small tadpole-like creatures can be kept out of a waterbutt? Although the butt was well rinsed and scrubbed before the last spell of wet weather, the water is already swarming with these creatures.—W. P. M.

[47822.]—**Tempering.** — I am turning up some bicycle hubs, and my tools will not keep any edge for more than about two minutes. Having heard that tools are sometimes hardened in lead, I should like to try it, but do not know how to do it. Can any reader assist me? I make my tools red-hot, and plunge them into water, but still they will not keep a good edge, and after a few minutes' use they cease to cut altogether.—ANXIOUS.

[47823.]—**Drink.**—Will some of ours tell me what I can take when I feel a craving for alcoholic drink coming on me?—M. P.

[47824.] — **Fuller's Mercury Bichromate Battery.**—To H. STOOKE.—Thanks for your proffered recipe to make the above, but I wish to know what proportion of sulphuric acid to water is used in both the inner cell and outer jar, and what quantity of mercury is used? Also, how often the battery should be replenished, and how? I made one according to your formula which worked exceedingly well at first, but soon deteriorated in intensity, and apparently seemed worn out. I shall be pleased if you will kindly answer the above queries. I have used a Leclanché cell for over two years to ring a night bell, and also in connection with a door contact, but now it has ceased to work, although I have thoroughly washed both the carbon and porous cell in vain. The connections are good, and the muriate of ammonia is sufficiently pure. Can you please inform me what may be wrong, and how to remedy it?—GEO. W. TEA, Pittsburg, Pa., U.S.A.

[47825.]—**Legal.**—Will Mr. Wetherfield kindly give me his advice on the following?—A. leases a farm of B.; lease stands three years when A. complains that it is too dear, whereupon B. reduces his rent. Shortly after B. dies. B.'s son, C., now comes in as landlord. Now the lease mentions nothing as regards the game. C.'s son, D., who has shot over the ground, now hears that A. has leased the game to a person who advertises the ground, and says all former leave withdrawn. Now, has D. (through his father, the landlord) any power to shoot on the ground, and would not the alteration in the lease (reduction of rent) bring it under the Ground Game Act? That is, could D. be prohibited from shooting hares and rabbits?—J. F.

[47826.]—**Dandelion Beer.**—Will any correspondent be kind enough to inform me how to make dandelion beer so as to drink "sharp"? The following is the manner in which it has hitherto been made, but each time it has been a failure:—1. Boiled dandelion, and then added a little ginger, sieved, and allowed to cool down, and then 1oz. German yeast, or 1 gill of brewer's yeast instead, to every 5 quarts, and sugar to sweeten has been put in and allowed to work for 12 hours, after which it has been sieved again, and put into a large stone bottle; but at the end of about three days it invariably turns sour. Will any one say where the mistake comes in, and oblige?—ONE IN LODGINGS.

[47827.]—**Grist Mills.**—Will some practical readers of the "E. M." kindly give me a little information as to the best kind of grist mill for a farmer's use who has a 4-h.p. steam-engine? Whether one would be profitable to a farmer grinding for neighbours, &c.? I have heard a great deal of Barford and Perkins' machines, Nicholson and Sons, and lots of others, but every maker claims to be the best, and to be able to beat mill-stones. I shall be very glad indeed if I can get some really useful information as to the above, as I cannot afford to waste money on experiments.—AMATEUR FARMER.

[47828.]—**Microphone.**—What is the best one to use for transmission of speech, &c., to a telephone receiver? How should same be arranged at the transmitting end of wire, with telephone and battery there?—J. H.

[47829.]—**Lantern Slides**—Wishing now to prepare some magic-lantern slides for coming winter, wanted best method of developing gelatine plates for same. Also, particulars of chromos for transferring to glass?—J. H.

[47830.]—**Plating Solution.**—Would some correspondent kindly give a method of determining the percentage of free acid in solution of $CuSO_4$ used for plating, or say if there is an instrument for the purpose?—P. B.

[47831.]—**Milk Analysis.**—Will Mr. Allen kindly give the process usually adopted for analysis of milk, and calculation necessary to adduce the probable amount of added water? Also, if any process will detect milk which is the product of a diseased animal?—R.

[47832.]—**Nickel Analysis.** — Will Mr. Allen kindly say what is the usual process now adopted for analysis of nickel and cobalt ores, and nickel regulus, &c.?—R.

[47833.]—**Coil.** — To MR. F. WALKER. — Having referred to back numbers for a form of medical coil, and seeing yours, I wish to ask if you would explain to me the way the small powers or wires are soldered to helix's, as, of course, there would be several rows one above the other?—ONE IN A FIX.

[47834.]—**Married Woman's Property Act.**—Can a married woman hold real and personal property over £200 falling to her from an intestate, for her separate estate, and can she legally will the same without the consent of her husband? Is it necessary to do anything to prevent the husband claiming it? The woman was married in 1880. The intestate died in June last. Will the Act passed during the present Session affect the above?—MAUGHOLD HEAD.

[47835.]—**CheapTent or Workshop.**—Will any of ours assist me? I am about to erect a rough shed for a smoothing-room of about 14ft. by 14ft. by 9ft. high. Whether would wood, bricks, or stone be the cheaper, or is there any such thing as all metal tents? A friend told me he had seen some such thing advertised. The place would be unusually warm, as there would be a stove inside. I have plenty of room to build on, and I want to know which of all these would be the cheaper. I would require a great many windows, as the shed would have to be well lighted.—J. M. L.

[47836.]—**Pott's Patent Irons.**—Will any fellow-correspondent kindly oblige me by saying what purpose these irons were specially designed to fill? The handle is of polished hard wood, and is separate from the iron, and the latter is packed inside with something like tow, to retain the heat, I suppose. Are they superior to the old 12 or 14lb. irons cast all solid? They are made up in "sets" of three different-sized irons and one handle. Can three or four all large ones be had? Why are they in "sets"?—J. M. L.

[47837.]—**Legal.**—I am a candidate for a situation under a town council, two or three of whose members are bankrupt, but have compounded, and have retained their seats in the corporation, notwithstanding their being bankrupt. I want to know, as those members will vote against me, a son of one of them being a candidate, could I challenge the votes of those members who are or have been bankrupts, and who never resigned, but kept their places in the town council? Have they a right to vote? The situation is as head of a large department, and my principal opponent (the son of the councillor) is only 23 years of age. It is in Ireland.—CANDIDATE.

[47838.]—**To Mr. Wetherfield.**—A friend in the west of Ireland has proposed to assign me some lands there which he holds by lease. I fear, however, this lease cannot be valid, for I find included in the area or acreage are the public highways which partly border the farm. Surely the landlord who gave the lease had no more right to the public roads of the country than he has to the space of Trafalgar-square. It is as though I let our Editor the house, 31, Tavistock-street, and put in the agreement the space of half the street in front. Now, if he were foolish enough to accept a lease from me of what does not belong to me, and in the same document accepts of something which I have an honest power to dispose of, can the document and the agreement be valid, and is not part of it fradulent? You may think, perhaps, that I ought not to accept of such foolish bargains, nor do I think I would if I had the power of refusing; yet I find in Ireland such transactions are quite common between landlord and tenant, and my friend has actually been paying rent for the public roads for 20 years and county-cess also.—A PUZZLED SAXON.

[47839.]—**View Lens.**—I have an opportunity of getting my choice of three view lenses, each of 6in. focus: the first measures 1in., the next 1¼in., and the third 1½in. diam. I want the glass for a pocket camera, and desire faultless definition. What is the advantage of the larger lens? Shall I be able with it to use a larger stop, and so shorten exposure? Does it help the definition—or what?—FOCUS.

[47840.]—**Microscopic.**—I have been examining that most curious object, the Volvox globator, with a ½in. and ¼in. objective, yet I cannot see the reticulations on the globe, or the vibratory filaments which move it. Will some friend say what power is necessary, and if I must have a wide-angle objective? My Volvoces seem small, and are rolling about in company with another variety of 16 little balls which are attached together like a raft, and go lurching through the water. I do not see their cilia either.—VOLVOX.

[47841.]—**Sifting Machine.**—Will any reader inform me what kind of sifting-machine is the best for sifting washing-powder?—DRY SOAP.

[47842.]—**Electric Light for Workshop.**—Will any reader of ours give his opinion as to the advisability of adopting the electric light under the following circumstances?—Our ironfoundry is about 90ft. by 40ft. and about 24ft. high to underside of the beams. A traveling crane running the full length of the shop prevents us fitting up with gas except side brackets, and these are of little use for floor-work in the middle of the shop. We have ample engine-power, and I thought with, say, two lights, we should be able to illuminate the place well. Respecting the dynamo, would it be possible for us to construct our own? We have a capital engineers' shop. Any suggestions as to the best system to employ under the circumstances, and the probable cost, will be thankfully received by—IRONFOUNDER.

[47843.]—**Acoustics.** — Can any reader kindly answer the following?—Has the material of which a case containing air is formed any influence on the intonation of the mass of air? For instance, I make a hollow case, put into vibration the air contained in it, and find that I get a certain note. I now make a second case, similar in all respects, but of an entirely different material. Will the note rendered by the vibration of the air in this second case be the same as in the former instance? Or, to give the special example to which I wish to apply the principle. I find the intonation of the mass of air contained in the body of a violin, and then replace the ordinary sides by steel or brass ones of the same dimensions. Will the intonation of the mass of air be affected?—A. E. TEBB.

[47844.]—**Tricycle-Riding.**—Mr. W. G. Cresswell, L.R.C.P. Ed., replying in the *Lancet* of Aug. 25 to a querist, seems to think the bicycle not at all likely to cause hernia; but at the end of his reply, he says:—"I should like to point out that I do not wish my opinions to be taken as extending to the tricycle, since the conditions which attend the rider of that machine are widely different in some important points, as I soon found out on the only occasion I have ridden one." Will Dr. Edmunds when he returns, or some other medical reader, say if tricycle-riding causes more strain on the abdominal muscles, &c., or those portions likely to be ruptured, than bicycle-riding?—Q.

[47845.]—**Canaries.**—I have been unsuccessful in rearing my last two broods of canaries, owing to the old birds killing their young ones from over-feeding them and pecking the top off their beaks when they are a few days old. Will some one tell me the cause of this? I give my birds clean sand, fresh water, and baths every day, and a clean nest the day before the young are hatched.—JULIA.

[47846.]—**Electro-Plating.**—In a work on electro-metallurgy I find it recommends using a solution of nitrate of mercury to dip articles in, previous to plating in the silver bath. Is this plan injurious to health—e.g. in the case of electro-plating tablespoons which are used frequently in dishes at a high temperature? Is there not great danger of the mercury volatilising or becoming incorporated with the food in which the spoon is placed?—A BEGINNER.

[47847.]—**Electro-Plating.**—I have been trying to plate silver direct on some "Nevada" silver spoons with a bath made of cyanide of silver dissolved in cyanide of potassium, but without success. The deposit of silver on the spoons has a white frosted appearance, and contains a number of blisters, so that when I try to scratch-brush, the silver at once strips from the spoons. Will "Os," or some other kind reader, say what is the cause, and how to remedy the evil?—A BEGINNER.

[47848.]—**Replating Worn Steel Pickle Fork.**—I wish to replate a pickle-fork from which the silver has been worn, exposing the steel. Will some one give me a receipt? I succeed in replating old forks and spoons, but fail here.—G. T. J.

[47849.]—**Strength of Pipes.**—I find a curious rule in Rankine's "Rules and Tables" (p. 268, fifth edition) which I should like to have explained. The rule is one for determining the least proper thickness for a cast-iron pipe of a given bore to bear a given pressure from within. "First, divide the greatest pressure, in feet of water, by 12,000, and multiply the bore or internal diam. of the pipe by the quotient. Secondly, take a mean proportional between the internal diam., and $\frac{1}{48}$in.: the greater of those two quantities will be the required thickness." It seems to me that the latter quantity must always, or nearly always, be far in excess of the other, and, further, far in excess of what is reasonable. Fancy a 24in. tube with a thickness =

$$\left(\frac{24 + \frac{1}{48}}{2}\right) = 12^1/_{96}\text{in.}$$

!—GLATTON.

[47850.]—**Sensitised Paper.**—Would a brother-amateur or Mr. Lancaster tell me why the ready-made sensitised paper that I use for photographic prints, after being kept for a little time, becomes covered with black spots or specks, and please state how I can prevent these spots from appearing?—A. L. V.

[47851.]—**Sewing-Machine.**—I have a chain-stitch sewing-machine, manufactured by James G. Weir, London, which does not feed well. Can anyone kindly tell me how it can be remedied?—J. J. V.

[47852.]—**Misconduct of Apprentice.**—To MR. F. WETHERFIELD.—I have an apprentice who absents himself from work just when he chooses. I have stopped him heavily for it—as much as 5s. 6d. per day. Would it not be best to take him before a magistrate? If so, which Court should it be? The indenture states that all lost time is to be stopped for, but I take it that staying away altogether is a different thing from losing a little time through being late and so forth.—W. A. R.

[47853.]—**Erector for Microscope.**—Will Mr. Lancaster, or some other reader acquainted with the subject, explain how this very useful addition can be cheaply made to an ordinary microscope for botanical work? The pancratic power which an erector gives, as well as the erection, is most convenient in dissecting minute objects; yet I am told that erectors are very seldom made, and are, perhaps, for that reason, expensive. On an emergency, lately, I used the first two joints of a pocket telescope with a 2in. micro. objective at the end; but the contrivance, though better than nothing, was naturally not very satisfactory.—Nomad, Carlsbad, Bohemia.

[47854.]—**Reaping-Machine.**—In working an ordinary reaping-machine, how much of the energy expended is utilised in the cutting? I suspect a large percentage must be lost in friction.—A. J. F.

[47855.]—**Gas-Engine for Dynamo.**—I have a 1½-h.p. gas-engine of Crossley's make, vertical pattern. Have I sufficient power to drive a dynamo, large enough to work six or eight incandescent lamps of 20-candle power each? If so, what would be the probable cost of the dynamo? The current would have to be conveyed about 35 yards. Will "Anglo-Dane" or "Tried" inform me?—B. M. S.

[47856.]—**Preserving Meat.**—Would any reader of the "E. M." kindly inform me of the best process for packing cooked meat in hermetically sealed tins (giving the modus operandi)? Also, if meat can be preserved in above manner in whole joints and larger quantities?—P. M.

[47857.]—**Defective Sewing-Machine.**—Would Mr. E. Martin kindly answer the following?—I have a boot machine, the stitches of which are very irregular in length. If the feed-wheel is kept free from oil, it works better for a short time.—F. E. T.

[47858.]—**The Berliner Violin.**—I have read with great interest the previous letters on this subject. In one of them "Fiddler" states that the Berliner resonator improves only the tone of common violins. From this arises the question: For what reason should it not even improve the tone of the best violin? I fail to understand why it should not improve the tone of the better class as well as those of the inferior class. Logically speaking, the improvement should be greater in the higher class violins.—G. Fryer, Swansea.

[47859.]—**Dirty Oil.**—I have about 80 gallons of oil which I have obtained by cleaning dirty and greasy cotton-waste and sponge-cloths, as used in engine-cleaning, &c. Will any of your very numerous and generous readers kindly inform me by what means or process I can clean the above, so as to make it useful and saleable, or to what purpose it can be applied? I have heard it can be used in making printers' ink.—Stamford.

[47860.]—**Mounting Diagonal for 6½in. Glass Reflector.**—Would "Orderic Vital," or some other of your correspondents, describe the best and newest method of mounting the diagonal for a 6½in. silvered glass reflector, with its adjusting screws or means of adjustment?—R. E. C.

[47861.]—**Photography.**—What is the reason that the ordinary 15-grain iron developer used with wet plates will not do for dry plates? Also, why will not cyanide of potash do to fix dry plates, instead of hyposulphite of soda? What is absolutely the best developer for studio use for dry plates, and the easiest and most under control?—Ouvrier.

[47862.] — **Painting and Gilding Wooden Letters.**—Would some one inform me how to gild the above sort of letters? Also, what colour the sides should be painted to suit a black ground on which the letters are to be put? Size of letters, 7in. from top to bottom, and 1in. broad.—Church-Hill.

[47863.]—**Aniline Dyes.**—Can any of our readers inform me which of the following dyes is the least fugitive—magenta, fuchsine, or violet? Which would be the better dye (magenta or fuchsine) to use with ultramarine for bringing up a lively white colour in paper pulp?—W. O. T.

[47864.]—**Chemistry Examination.**—Will any reader kindly recommend me one or two books to use for the South Kensington examination in organic chemistry, advanced grade?—W. O. T.

[47865.]—**Utilisation of By-Products.**—Can any fellow-reader help me in the following difficulty?—On an extensive farm some small gasworks have been erected. The tar is most useful in a variety of ways, also the "gas-lime" as a manure; but the ammoniacal liquor merely collects in a pool near the works, and is said to be useless. The supply of it is not great, there being only two retorts; but as it is beginning to run down the field, something must be done. Is there any cheap practical way of utilising it as a manure? How would it answer to mix it with the offal of a neighbouring slaughterhouse?—Puzzled.

[47866.]—**Landlord and Tenant.**—I let furnished apartments, and, unfortunately, got bad lodgers, who run a bill of nearly £20: gave them notice to quit, they took no heed of notice. I took first opportunity of locking them out of apartments after notice to quit had expired, and retain their boxes, papers, &c. Can I dispose of these and sue for balance? I may say they (the lodgers) are working a patent through an agent: the agent manufacturing and securing orders, and paying patentees, after deducting commission, &c. Any information gratefully received.—Landlord.

[47867.]—**Magnetic Sands.**—I should be much obliged if anyone could give me any information respecting magnetic sands. These are found largely in Canada and New Zealand. I am not aware that they have ever been worked in the Dominion, but some time ago a company was formed for making steel therefrom in New Zealand. Can you tell me if such a company is still in existence, and what it is called?—Philip Taylor.

[47868.]—**Deep-Sea Cables.**—Will somebody kindly answer the following question, which is one asked in the last examination by the City and Guilds of London Institute?—The conductor of an Atlantic cable broke inside its insulating sheath without making any earth whatever. How was the locality of the rupture determined?—Telegraphis.

[47869.]—**Induction Coils.**—Will Mr. Lancaster, or any of ours, kindly give me, if possible, the best size and amount of wire to use for a miniature shocking coil about 2¼in. long? Also, the plates used with sulphate of mercury for battery? Can he also give me the best sizes for a 1in. spark coil, with thickness and length of coil?—Phenyl.

[47870.]—**Desmids.**—Wanted recipe for a medium that will preserve desmids and delicate algæ in their natural colours?—H. A.

[47871.]—**Power for Churning.**—As a rule, my wife wants to churn an hour or two after my men and I have gone from the homestead, and it is often inconvenient to spare a man just at the time. Would some mechanical reader of your journal be good enough to tell me of any simple arrangement for storing energy that the wife could turn on when wanted?—some arrangement the carpenter and I could rig up would suit me best; and I suppose a big weight which a couple of men could wind up, like winding a clock, would be the handiest way of making a start, as we could do the winding up before leaving home. The power required is about ½-m.p. for, say, two hours at the outside. The churn is a barrel of the old-fashioned style.—Yokel.

[47872.]—**Boiler.**—I have a locomotive boiler which I have had much trouble with, on account of the tubes leaking at the smoke-box end. They are soldered in with soft solder. In the firebox they remain perfectly tight; at the other end, although I have done them over and over again, after using a few times, they become as bad as ever. I thought of brazing them, and should be very glad if some kind reader would tell me how, and what I should require? Any hints on brazing would oblige.—M. C.

[47373.]—**Revolving Shutters.**—Can any correspondent living near the sea-coast inform me if they find revolving shutters for shop-fronts expensive to keep in repair, as I am informed by a neighbour that his has to be sent to London nearly every year for repairs, costing from £5 to £7 per annum in repairs? Also, how are they fixed, and what space do they require for a window about 7ft. square? Would it be any advantage to have them in two widths?—W. L. P. P.

[47374.]—**Plastering Rooms.**—Can any one inform me of an expeditious way of plastering rooms three coats so as to be dry in a week or ten days, and would it be safe to occupy the rooms in two or three weeks after being finished? Will any of the patent cements answer for the purpose?—if so, which will be the best, and in what proportions should it be mixed, and what will be about the cost per yard on wall and laths? Will the cement answer mixed with ordinary lime? Shall be pleased if anyone can inform me the best and quickest way to get the plastering to dry off.—W. L. P. P.

[47875.]—**Concrete Floor.**—I was pleased to see our old friend, "Khoda Bhux's" kind offer to give further information on concreting on p. 17 of last volume. I will thank him to assist me with his advice: I am about to put a galvanised tank over w.c., 10ft. long 6ft wide, supported on the two sides, one end and middle with 9in. ashlar wall, and one end recessed in the main building 4in. I am told this is not sufficient support, so should like to put a concrete floor over all to support the tank. Will "K. B." kindly inform me what thickness I should put it, and in what proportion the concrete should be mixed, broken stone, coarse sharp gravel, and will it be necessary to arch it under?—W. L. P. P.

[47876.]—**Irish J.P.'s.**—I should feel obliged if a correspondent would please say what are the necessary qualifications for a Justice of the Peace in Ireland?—Nemo

[47877.]—**Photographic Dusting-on Process.**—Can any reader oblige me with the details of this process? I have looked through the back numbers, but can only find one in which the powder adheres to the parts of picture not acted on by light. Now it happens I require just the reverse. I wish the powder to adhere to those parts of the print which have been exposed under the clear parts of the negative. From hints gathered here and there, I think there is such a process, but I have been unable to find it. It seems to be so little thought of, that in photographic manuals it is only mentioned to be at once dismissed. I do not know whether the powder adheres firmly or not. For my purpose it would do best if it adhered very lightly, in fact, just what would keep it from falling off when shaken face downwards.—Try Again.

[47878.]—**Electro-Gilding.**—I want to electro-gild parts of a silver cup—viz., the name-plate and lines down the handle. How should I proceed?—An Amateur.

[47879.]—**Silversmiths' Work.**—What is the shape of hammer-head that silversmiths use to finish their work—that left with the facets on it?—George Eversley.

[47880.]—**Liquid for Binnacle.**—To Mr. Lancaster.—Querist being desirous of putting fresh liquid to float the compass in the binnacle of a small yacht which has recently come into his possession, would feel much obliged for information as to the composition of same, and whether it should completely cover the compass card. On unscrewing the glass top, it would appear that it had been cemented on, but that the cement (red putty) had given given way in places, admitting dust, and thus discolouring the contents, so as to make it difficult to read the points of the compass.—Jim.

[47881.]—**Tricycle-Making.**—Does the tricycle with two front steerers and the large driver behind connected by rods to the treadles work well? I have a 50in. and an 18in. wheel, and I wish to utilise them in constructing a tricycle. Would it be better to get another 18in. or another 50in., and what would be best design, so as to get it through door 27in. wide? Any hints as to making will oblige—Henry Ward.

[47882.]—**Amateur Engraving.**—Would some reader kindly give the names and how to work the different tools used in engraving monograms, initials of names and scroll-work only? Having put a pair of polished oak covers on a large photo album, I want to put a German silver monogram in the centre and corners with some scroll-work on them, wishing to do the engraving myself. I have plenty of time for practice, and as tools and materials are cheap, I can put up with a lot of failures. I inserted a query in the "E. M." about six or eight months ago on this subject, and got no reply. I am sure there are a number of readers who can give a few simple directions which will suffice for a beginner, and will, I am certain, be as acceptable to others as well as—Young Amateur.

[47883.—**The "Vicar of Bray."**—Can any literary reader kindly inform me what was the name of the "Vicar of Bray," celebrated in song, and at what date and for how long he held his benefice?—M. R. C. S.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Aug. 30, and unacknowledged elsewhere:—

W. Stanley.—Adams and Francis.—R. E. Quinn.—A Driver.—An Amateur.—A Templar.—A. S. L.—H. A. Wassell.—H. B. T. S.—J. W. J.—Steeple Jack.—S. B.—S. H. Salt.—E. S. Beaven.—Countryman.—Jack of All Trades.—Wm. Harris.—G. E. Bonney.—A Fellow of the Royal Astronomical Society.

A NEW VOLUME.

This number is the last of volume XXXV. Readers willing to oblige us by recommending "ours" to new subscribers should do so now, when a new volume is commencing. The index to Vol. XXXV. will be published in the number dated Sept. 22, and cases and bound volumes will be on sale shortly after. Readers desirous of making up their sets for binding the present volume are recommended to do so at once, as the back numbers soon run out of print.

Oatmeal. (Certainly. See p. 360 for method of using them.)—Double Dragon. (You can try the effect of a solution of chloride of lime; but you must wash carefully with two or three waters afterwards; or expose to the fumes of burning sulphur. A little bichromate of potash has been recommended for fixing the ink. The light so acts upon it that it renders the vehicle in which the carbon is mixed, insoluble.)—Bodge. (See p. 381, No. 874. They are mostly thin brass, and are held by rubbing the edge into a saw kerf on the outside.)—Au Desespoir. (For "Photography on Porcelain," see p. 85, No. 680, or any of the recognised textbooks of the art.)—Electrician. (The E.M.F. is the same whatever the size of the plates. 2. Not that we know of. 3. The E.M.F. is about the same; probably the mixture of acid and bichromate giving a decimal or so more volt than the plain acid. Why do you not learn the rudiments?)—Tam O'Shanter. (See the lessons on blowpipe analysis in Vols. XXX. and XXXI., and the subsequent discussion on the merits of various handbooks. Landauer's book, published by Macmillans, is one of the most recent.)—Eureka. (We did not misunderstand. You can drink gallons of such a distillate without putting a fraction of a grain of phosphorus into your body. Hypophosphite of quinine is, like other preparations containing phosphorus, useful in nerve diseases; but it should be taken only under the direction of a physician. You can easily learn the price by consulting a list to be obtained at any of the dealers in chemicals. We cannot possibly say how much two inches is worth, but we have no doubt it is quite "pure" enough.)—Collodian. (The process is almost exactly the same as that described in the book mentioned. A mould is taken in plaster, guttapercha, or wax; that is coated with fine plumbago and metallically connected with one of the conducting wires. It is then immersed in a tank, and the current put on. When the deposit is sufficiently thick the shell is removed, heated on an iron plate, tinned at the back and filled up with the usual metal, lead and antimony alloy. 2. You want what is known as a copper-plate press, two rollers through which the plate is passed. The ink is cleaned off by means of whiting and a leather—in fact, the surface is so polished that it takes very little, while the ink in the lines takes a fresh supply at each application. By looking through the indices you will find that both subjects have been fully treated many times.)—T. Wye. (For hæmorrhoids, see pp. 329, 338, 361, this volume.)—W. E. K. (Answered on p. 407. The directors could not prevent you taking photographs outside of their grounds, but they certainly could object to your taking them inside.)—A. M. (See p. 96, No. 810; p. 539, No. 776; p. 610, No. 700. Illustration and directions for cutting the gores, &c., on p. 566, No. 594, and p. 613, No. 596.)—M.R.C.S. (It is usually ascribed to the protosalt of iron contained in the shell becoming a persalt through absorbing oxygen in the process of boiling, but nothing very definite is known.)—A. M., Peterborough. ("Lead" is the width of the steam port when the piston has arrived at the end of the stroke; that is, the amount of opening for the admission of steam for the piston to cushion against. "Lap" is the extent to which the face of the valve overlaps the port, and produces a fixed amount of expansive working. You should read up the subject in one of the treatises on the steam-engine, or in many places in back volumes.)—George Eversley. (See several replies in recent volumes for the solution. As to the second question, a sand-bath is used for placing vessels in which cannot be treated by direct application of flame. It is simply a pan of sand heated by a fire beneath.)—A. J. F. (One has been worked by a trick rider. He used a machine that resembled the front half of a bicycle, the backbone being cut just behind the saddle.)—Tom B. (Not that we know of.)—Simple Simon. (Look through the indices.)—A Beginner. (Suppose you look through the back volumes. Answers to your questions would occupy a page or two, and be of interest to only a few of our readers, especially as they are on such elementary matters.)—Caloric. (We do not think the suggested course would have produced the desired result. It would be anything but "simple information.")—W. J. G. (We do not see what definite answer could be given to so vague a question; but suppose you adapt one of the ordinary stoves.)—Ignoramus. (Get the catalogue of the Tonic Sol-Fa Agency, Warwick-lane, E.C.)—Vulcan. (You will find articles on the subject in back numbers. There is no good book on the art, but you could find useful information in the specifications of the patents.)—Irishwoman. (The only way is to put it up in air-tight tins, or mince very fine and press down close in jars, covering with a layer of melted fat, not forgetting the pepper.)—E. O. Simmonds. (You do not say in what respect you failed. If you mean the glass fails to indicate storms, that is not news. The usual recipe is as follows:—2½ drachms of camphor, and 11 drachms of spirits of wine. Dissolve, and add a solution made of 9 drachms water, 38 grains of saltpetre, 38 grains of sal-ammoniac. Shake well, cork the top of the tube, and wax it, then make a pin-hole through it. Then hang it up, and by diligently studying you *may* be able to foretell storms.)—City of Rome. (We have given all particulars many times. See p. 100, No. 836. The situations can be obtained only on application to the owners of steam vessels, and in the navy only by going through a course of training at one of the dockyards. Get Ainsley's "Engineer's Manual of the Local Marine Board Examinations," of the author, South Shields, or apply for particulars to the superintendents of the Marine Board at any of the large shipping ports.)—Locomotora. (You can see them at the Patent Office Library or the British Museum. Perhaps Mudie's keep them. 2. Second query incomprehensible.)—A. B. C. (Porcelain, fireclay, plaster of Paris.)—R. S. S. (We gave the authority for the statement. We have not tested it, but should use a saturated solution. Hyposulphite of soda can be had of any seller of photographic chemicals.)—Subscriber. (See recent numbers, and almost any back volume.)—Y. Z. (We cannot spare space for repeating recipes for making blacking and vinegar. You must consult the indices.)—Romeo. (Look through recent back numbers, and you will find that Dr. Edmunds has fully treated the subject of indigestion.)—J. F. (Wright's book on Fowls, published by Cassell's; or "Management of the Poultry Yard," L. Upcott Gill.)—Machinist. (Maxton's "Manual of Engineering Drawing" (Lockwood and Co., Stationer's Hall-court, E.C., 3s. 6d.), or one of the series of books on drawing published by Cassells.)—L. J. (Longmans, Lockwood, Macmillan, and Collins all publish books of the kind; but you will find some recommended if you look through back volumes.)—Electrician. (You want just the same arrangement as is adopted between two telephones, which has been several times described. The arrangement depicted would do.)—J. N. Unwala, Bhannagar. (Paid to Sept. 28, 1883, inclusive.) Dejon. (No examination is necessary. The British Government allows anything to be sold under cover of a three-halfpenny stamp.)—F. W. B. (Nobody doubts that there are many able and conscientious teachers doing splendid work in spite of the discouragements offered by the Department. We have attacked the *system*, which is calculated only to produce bad teachers, while highly-paid officials at head-quarters absorb the money that ought to provide good teachers and good teaching.)—J. T. E. (Hardly, we fear, unless you have plenty of money to spend, and can afford to commission one of the large art furniture makers to pay an artist to design a case for your pianoforte. We agree entirely with you that pianos are generally hideous things to look at; the old "squares" that our grandmothers thrummed were far more comfortable-looking pieces of furniture, though, of course, not to be compared musically with modern instruments. The "grand," especially, is an awkward customer to make presentable. anyhow. A good attempt may be seen in a piano designed for Mr. Alma Tadema, the celebrated painter, illustrated in to-day's *Building News*.)—Inquirer, Newcastle. (Dr. Edmunds will not—and, really, *could* not without personal examination—advise in such cases. Skin diseases are among the most difficult and tiresome to cure.)—Constant Reader. (Inquiries as to individual crests are inadmissible.)—One Doubt. We cannot spare space to reprint leases, &c., for our legal querists. If you wish further information, you had better send the copy direct to Mr. Wetherfield.)—Amateur. (Any builder will supply such a chimney top. Boyle's is one of the best.)—Thos. Lees (Ihlee and Horne, Aldermanbury, London, E.C.)—Electron. (It is not a fact.)—G. S. H. (Very likely; hair-dressing is out of our line.)—J. F. Wm. Baucke, Chatham Island, South Pacific. (We cannot undertake to obtain protection for inventions or to negotiate the sale of patents. Possibly one of the patent agents who advertise in these pages might take the matter up. We will preserve your specification and drawings and hand them to any one on your behalf, or return them, as you may direct.)—J. H. Huxley, Ch. Rabache. (In type.)

A new Government graving dock, to be made at Cockatoo Island, Sydney, at a cost of £150,000, will be excavated almost entirely out of sandstone rock.

CHESS.

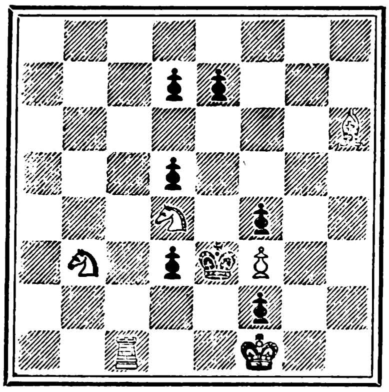
PROBLEM DCCLXXVII.—By C. Callander.

Black.



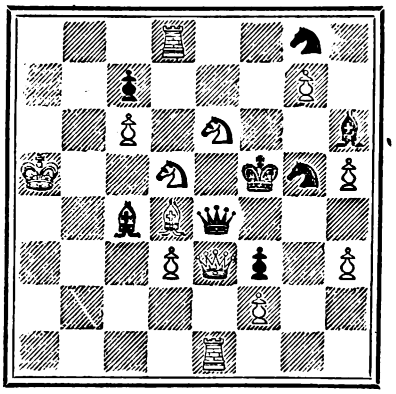
White.

White to play and mate in four moves.

PROBLEM DCCLXXVIII.—By Fidèle Jusqu' à la Mort."

From the *Leed's Mercury*

Black.



White.

White to play and mate in two moves.

Solution to 773.

White.	*Black.*
1. Q to Q R 3.	1. K to K 2 (a).
2. Kt to Q B 6 (ch).	2. K to B 2.
3. Kt mates.	
	(a) 1. K to K 4 or (b) B 4
2. Kt takes B (ch.).	2. K moves.
3. Q mates.	
	(b) 1. K to Q B 2, or anything else.
2. Kt to R 6 (ch.).	2. K moves.
3. Q mates.	

Solution to 774.

White.	*Black.*
1. K to Q B 4.	1. Anything.
2. Mates.	

NOTICES TO CORRESPONDENTS.

Correct Solutions to 773 and 774 by Celsus and Schmucke; to 771 and 772 by Celsus.

T. P. T.—Thanks for the problem.

W. T. P.—We have entered your name on tourney-list.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

Holloway's Ointment and Pills exercise priceless power over lumbago, all pains of the muscles, nerves, and joints, and quickly reduce all swellings caused by accidental injuries, weakness, or hereditary taints. The intelligible instructions enveloping Holloway's medicine give full counsel for using it most advantageously for regaining health, strength, and mobility.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 2d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 1d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each. [Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. I., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions, and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

OUR EXCHANGE COLUMN.

◆◆◆
